---

## Foreword

### Extinct Birds

The subject of recent extinctions is one that seems, increasingly, to be a part of popular culture. Today the words Great Auk (*Pinguinus impennis*), moa (Dinornithidae), Thylacine or Tasmanian Wolf (*Thylacinus cynocephalus*), Quagga (*Equus quagga*) and, of course, Dodo (*Raphus cucullatus*) are names with which many people are familiar. Yet, while the subject has always held an intrinsic fascination, it is one that comparatively few have cared to pursue – until recently. Now, the increasing vigour of the conservation movement, combined with the new vogue for popular science, has brought with it a fresh awareness of, and enthusiasm for, the subject.

It is not difficult to see why. First, there is the mystery – and mystery exerts a great influence over the human psyche. Yet, paradoxically, recently extinct creatures are accessible in a way that animals known only from the fossil record are not. They sometimes seem almost touchable but, of course, this is only an illusion. In reality, they remain as elusive as those species that passed away aeons ago.

Recent extinctions have a major advantage over those from the deep past: they offer the possibility that we may learn something significant from their example. Perhaps if we listen to these woeful stories we may be able to find a way to prevent similar tragedies from occurring in the future. Or, perhaps not!

Then, also, there is the tantalizing possibility of rediscovery. While there may be no chance of finding a *Tyrannosaurus* lurking in some jungle fastness, who can say with certainty that Pink-headed Ducks (*Rhodonessa caryophyllacea*) do not still survive in an Indian wilderness? There have been numerous examples of rediscovery and, doubtless, there will be others.

It has become traditional to regard 1600 as an approximate cut-off date from which to determine recently extinct bird species. Lionel Walter Rothschild's pioneering work of 1907 began this trend, since which time the date of 1600 has been adopted by several other writers, including the present one. The date is not quite as arbitrarily chosen as it may seem. The year 1600 represents a date heralding a period at which relatively reliable records began to accumulate; before this time it is generally impossible to make realistic sense of the few records that exist. The date also largely eliminates fossil birds or most birds known only from skeletal material. Such a subject is a vast and complex one and totally beyond the scope of a work such as this. For various technical and practical reasons it is impossible to put an exact figure on the number of bird species that have become extinct during the last 400 years. Obviously, any number may have passed away without leaving any trace at all. Concerning those of which we have certain knowledge, most authors would agree that there are something between 80 and 100, depending on how one interprets evidence. Sadly, this number is likely to increase dramatically during the next few years.

At many practical levels the subject of recent extinctions is a difficult one, for how can these be accurately and consistently defined? First comes the very complex question, "How do you know it is extinct?" In many cases – the Dodo, for instance – it is obvious: a very large, conspicuous bird restricted to a relatively small island could certainly not survive unnoticed. In others the issue is rather more difficult to resolve. From the ranks of the world's bird species it is possible to select a considerable number that might be extinct. But on the other hand, they might not be!

Figure 1. Egg of *Aepyornis maximus*, life-size; some eggs were even larger.

---

In order to help the reader in comparing this foreword with the main body of the HBW texts, normal HBW usage has been adopted in the taxonomy and in the choice of vernacular names. Also, the criteria followed throughout HBW have likewise been applied here in the decisions as to which forms are included and which omitted. The editors are extremely grateful to Errol Fuller for very kindly agreeing to adapt his own preferred usage in all three aspects. See also editors' Introduction to Volume 7, page 69.

One well-known definition states that any creature not seen for a period of 50 years may be regarded as extinct. Unfortunately, however, such a definition – understandable and persuasive though it may be – is unworkable from any realistic point of view. Patterns of decline, remoteness of terrain occupied, recent changes to the environment and a whole variety of other elements may be relevant in this or that particular instance. There are a number of bird species that went missing for upwards of 50 years and then returned from seeming oblivion, notably the Forest Owlet (*Athene blewitti*) and the New Caledonian Owlet-nightjar (*Aegotheles savesi*) “absent” for 113 years and 118 years respectively, and even more recently Bruijn’s Brush-turkey (*Aepyptodius bruijnii*), rediscovered on the remote and almost inaccessible New Guinean island of Waigeo. Yet there are others that have been seen in the last decade or two that could now categorically be considered extinct.

Rarity is a peculiar thing. Some species can stay rare for decades, or even centuries, without actually dropping into the doleful condition of extinction. Others become extinct in much more dramatic style.

The celebrated case of the Takahe (*Porphyrio mantelli*) of New Zealand provides a perfect example. Known from just four specimens taken during the nineteenth century, the species “vanished” for a period of 50 years before being rediscovered during 1948. Since this time the species has limped on in extreme rarity and managed to survive into the twenty-first century. This might be compared with the famous downfall of the Passenger Pigeon (*Ectopistes migratorius*), which at the start of the nineteenth century was possibly amongst the most numerous birds on Earth. In the space of two or three decades numbers plummeted from many, many millions to just a handful of individuals, and during 1914 the last individual of all died in her cage at the Cincinnati Zoo.

What does all this mean? Simply that, while there may be guidelines to govern the nature of extinction, there are no hard and fast universal rules. Each case must be judged on its own merits.

This introduction to the subject features only those birds that can claim without doubt the title of extinct. Other, more controversial, cases are reviewed in brief.

Another great difficulty that surrounds extinct birds concerns the definition of a species. As so many of these creatures are poorly known it is by no means certain that some of them had actually passed the boundary at which they could be regarded as full species. This might particularly be the case where a form is known only from skeletal remains, but even with more substantial evidence there may still be controversy over definitions, as indeed is apparent with the differing taxonomic views regarding even common and well-known taxa. One authority might define an extinct form as simply a subspecies, while others may see it as a full and legitimate species. The Norfolk Kaka (*Nestor (meridionalis) productus*) and the Guadalupe Caracara (*Polyborus (plancus) lutosus*) are good examples. Both hover rather uneasily at the junction where full species meet subspecies, and either can be fairly defined in either way.

Then there is the matter of mystery species and others that might be termed “hypothetical”. A surprisingly large number of species have been described from just a single specimen with no other similar bird ever turning up. Sharpe’s Rail (*Gallirallus sharpei*), for instance, was described from a single specimen that was purchased by the Leiden Museum during 1865 and came from an unknown source. Since that time no comparable specimen has come to light. Is the bird a freak or is it an otherwise unknown – but legitimate and presumably extinct – species? Probably it is the latter, but no-one knows for sure.

“Hypothetical” birds come into a related but slightly different category. These are forms that have been described from early travellers’ tales or descriptions. The desire to name new species seems so great that many ornithologists (who should have known better) have succumbed to temptation and named birds on evidence that is totally unsatisfactory and against the rules of scientific nomenclature. Perhaps the most famous case of this kind is that of the White Dodo (*Raphus solitarius*) of Reunion. There is a very, very small amount of evidence that such a bird may once have existed but absolutely no hard proof of any kind. Many other “hypothetical” bird species have been proposed but, while their stories may be fascinating, none of these have any real place in a serious list of extinct birds.

It may be worth briefly remarking on another category of disappearing species, namely those classified by BirdLife International as “Extinct in the Wild”, at present numbering just three species, the Alagoas Curassow (*Mitu mitu*), the Guam Rail (*Gallirallus owstoni*) and the Socorro Dove (*Zenaida graysoni*). Sadly, it is very likely that within just a few years quite a number of other species may join this group. The prime candidate must be Spix’s Macaw (*Cyanopsitta spixii*), with a wild population of only a single bird from 1990 until it disappeared in 2001, but with at least 60 birds (probably all closely related) currently held by aviculturalists. By definition, all such

species survive in captivity, and the chances of their eventual reintroduction to their natural range should not be discounted, so they remain outwith the strict scope of this foreword.

All these considerations mean that no-one can come up with a definitive extinct list that is totally satisfactory to everyone else. Even the birds featured here are at some variance with the list given in the present author's recent (2001) book *Extinct Birds*. In order to ensure continuity and conformity with HBW, certain eliminations and additions have been made. Most notably, several species covered in *Extinct Birds* have been excluded from this foreword because they have already received full treatment in the main body of HBW, with individual species account, illustration and map; most of these were, perhaps optimistically, listed as "Almost certainly Extinct". These variations should be regarded in the spirit in which such determinations must necessarily be made. No decisions on what is extinct or what is not, what represents a subspecies and what does not, should be regarded as graven in stone. All such things change according to current knowledge and attitude. The information given here represents a good and honest guess at the truth – but it should never be considered as an absolute truth.

Reasons for recent extinctions are, of course, many and various but most are due to human intervention. Hunting and shooting, though the most obvious kind of destructive processes, are not – at the species level – necessarily the most devastating. Destroying habitats and/or altering them have caused immense damage. The problems caused by complete destruction of habitat are obvious, but alteration, in the form of altering land use or introducing alien species, is similarly critical and both of these are among the main factors that destroy bird populations and ultimately lead to extinctions.

The geography of recently extinct birds is a particularly revealing one. By and large such extinctions come from islands rather than from the major land masses. Although there are a number of spectacular exceptions – and this number is likely to increase in the coming decades – it is on oceanic islands and island groups that the major casualties have occurred. Thus, the Hawaiian Islands, the Mascarenes, New Zealand and the islands south of Japan are all among the great theatres of extinction.

Clearly, if a species' habitat is demolished or radically altered, sooner or later that species will inevitably vanish along with the environment. With many island birds being endemics, it must follow that a species lost from its island home is a species lost entirely. Many, many island forms are already gone and many more are today under threat; there is little doubt that true island insularity hugely increases any species' vulnerability.

At a less dramatic level, local populations of otherwise flourishing species are often wiped out when a marsh is drained or a forest chopped down. If the species is plentiful elsewhere, its loss in one particular place may well pass unnoticed. Even subtle interference can sometimes have the same result and such subtle interventions can take many forms. The results of the random (or sometimes highly organized) introduction of predators to predator-free places are obvious but the introduction of animals with no predatory intent can cause equal chaos. Competition for limited territory or an ecological niche is one obvious area of concern. Equally insidious are the possibility of introduced disease, the spread of alien plants pushing out the natural flora, or the introduction of poisons.

There is a tendency to think that the creation of reserves might provide a convenient solution. Unfortunately this setting aside of portions of land does not necessarily work. When environments become fragmented, it is often not possible to foresee the ultimate consequences of such fragmentation.

The birds featured here are listed in an order conforming to the general arrangement of HBW. A short preface for each major bird group that is currently affected by extinction is included to facilitate some discussion of controversial or problematical forms.

Concerning many extinct species virtually nothing is known; about others there is a considerable body of information. If basic ornithological information is not given in any particular case, it may be assumed that this is because such information remains unknown.

A computation has recently been made (for BirdLife International's book *Threatened Birds of the World*, 2000) that one in eight of the world's bird species (around 1200 species) are at risk of extinction during the next 100 years. No-one should assume, therefore, that extinct species are irrelevant. They are not things that are gone and best forgotten. Rather, they should be seen as something to illuminate the future. And that future will be much drabber, should we not look at these pictures from history and learn from them.

## RATITES

The celebrated nineteenth century ornithologist Alfred Newton defined the ratites as:

That division of the Class Aves whose sternum developing no "keel" resembles a raft or flat-bottomed boat.

This is, then, a rather loose assemblage of creatures but from it can be selected a number of the largest birds known to us. Among living ratites are the Ostrich (*Struthionidae*), the rheas (*Rheidae*), the cassowaries (*Casuariidae*) and the Emu (*Dromaiidae*), and the much smaller and different-looking kiwis (*Apterygidae*). Among extinct groups are the elephantbirds (*Aepyornithidae*) and the moas (*Dinornithidae*).

The origins of these rather un-birdlike birds are unclear and how each of the distinct groups relate to one another – if at all – is a matter of some controversy.

The major areas of mystery concerning the ratites can be summed up in two questions. Did the various ratite orders evolve separately or are they all derived from a common ancestral stock? Was this ancestral stock – or these stocks – made up from true flying birds, or were these prehistoric creatures that never actually acquired the power of flight?

As far as the second question is concerned, it can be said that the extinct moas show no vestige of a wing. In simplistic terms they are the most perfect of bipeds, their forelimbs having vanished without trace. Notwithstanding this curious fact, it seems most likely that the ancestors of the birds now called ratites could all fly perfectly well and that they gradually lost the power in much the same way, and for much the same reasons, as other flightless birds.

*Figure 2. Richard Owen photographed alongside the skeleton of a moa, in about 1865. In his right hand, he holds Rule's Bone.*

The question of common ancestry is, perhaps, rather more contentious. Although most of the ratites show some overall similarity in general appearance, this may be entirely due to the factor known as convergent evolution. In other words, these creatures may have grown to look alike simply because they share similarities in their lifestyles.

Traditionally, the five extant ratite families have been awarded four or five separate orders, but in recent years there has been an increasing tendency to lump them all in a single order, Struthioniformes, with the different groupings being reduced to four suborders, the families Casuariidae and Dromaiidae being placed in the same suborder. How this affects the extinct Aepyornithidae and Dinornithidae, each traditionally placed in its own separate order too, is not always discussed, but the general consensus of opinion is that they too are probably most usefully placed in this all-enveloping Struthioniformes.

Ratites have certainly been very successful in many parts of the world and Africa, Asia, South America and Australia have all been occupied. So too have smaller land masses: New Zealand, Madagascar, New Guinea and many of the islands that make up Indonesia. Yet despite this evident success, the ratites have been in general decline during the age of man. There is, for instance, no doubt that until comparatively recently Ostriches occurred in many places where they can no longer be found. They have vanished from many parts of Africa, from Asia, and from Arabia, where the last individuals may have died during the 1940's or, perhaps, during the 1960's. There is evidence that Ostriches once lived in parts of southern Russia. Whether the birds that inhabited all these places belonged to just a single species or whether there were, in fact, several different kinds, is difficult to determine.

Similarly, it is difficult to determine exactly which ratite species have become extinct since 1600. For the purposes of this work four species have been selected, an elephantbird and three moas, although in each of these cases there is doubt over the actual date of extinction, and some might consider that these birds were gone before 1600. Each of the four is known only from skeletal remains, skin or egg fragments, and in some cases complete eggs. Curiously, the eggs of moas are excessively rare whereas their bones are relatively common; the reverse is the case with the elephantbirds and their eggs turn up far more frequently than their bones.

Two other forms are sometimes listed as recently extinct species. These are dwarf emus from Kangaroo and King Islands, off the south coast of Australia, known from skeletal remains and a single stuffed specimen now in Paris. Although there is no doubt that these two island forms are now extinct, both having vanished during the early years of the nineteenth century, there is uncertainty over whether either had passed the point at which it could be considered specifically distinct from their extant relative on the mainland, the Emu (*Dromaius novaehollandiae*).

There has been a certain amount of sloppiness over the way in which scientific names for these forms have been changed. The Kangaroo Island birds are now usually listed as *Dromaius novaehollandiae baudinianus* (formerly *D. n. diemenianus*) and those from King Island as *D. n. ater* (previously *minor*). There is, in fact, no certainty over which specimens came from which island, and, as a result, the switch to these names from older ones may not be justified. The controversy over this is still raging (see Greenway, 1958, Jouanin, 1959, Fuller, 2000a) so no hard and fast determination can be made.

Another rather distinct form was the Tasmanian Emu (*Dromaius novaehollandiae diemenensis*) but, like *D. n. baudinianus* and *D. n. ater*, it had probably not evolved into a species that could be regarded as separate from the Emu of the Australian mainland. This Tasmanian population became extinct during the middle years of the nineteenth century.

## AEPYORNITHIDAE

### Great Elephantbird

### *Aepyornis maximus*

#### *Aepyornis maximus*

I. Geoffroy Saint-Hilaire, 1851  
*Ann. Sci. Nat. Zool. Ser. 3, no. 14:* 209.

The Great Elephantbird of Madagascar holds the distinction of having laid the largest egg known to man, in fact the largest of single-celled objects. This extraordinary egg is far bigger than that laid by any known dinosaur or any other giant reptile and is thought to have given rise to Arab tales of the "roc".

Nothing is known of the bird's habits and even its exact appearance in life is unknown; it is assumed that it looked something like an enormous Emu. Standing some 3 m high, this was an incredibly ponderous and heavy bird and in terms of sheer weight it is the largest bird ever known to have lived.

There appear to have been several related species occupying the island of Madagascar and this particular one – the largest – seems to have been the last to become

extinct. The testimony of the first French Governor of Madagascar, Étienne de Flacourt, seems to indicate that individuals still survived in the 1650's. He mentioned a large bird that laid an egg similar to that of an Ostrich. Sadly for Monsieur de Flacourt, he was killed by Algerian pirates on his way back to France without further elaborating on his story.

The gigantic eggs of the bird, as big as an American football or a rugby ball, are still found from time to time in Madagascar and fragments of them are common at certain localities. Although virtually complete skeletons exist, bones seem to be much, much rarer than eggs.

## DINORNITHIDAE

### Slender Moa

### *Dinornis torosus*

Because the original fauna of New Zealand contained no mammals, these islands were often called "The Land of Birds". Such a title has long been inappropriate, as introduced mammals now rule the land in much the same way as they do elsewhere – but for aeons birds represented the dominant lifeform. Quite why mammals were originally excluded from this corner of the planet is one of the mysteries of prehistory, but excluded they certainly were. In the land now known as New Zealand, birds adapted to fill many of the niches more familiarly occupied by mammals.

The most spectacular of these creatures were the birds now known as moas. There were a number of species and argument rages today over just how many. Some authorities put the figure as low as 10, others identify 30 or 40; such controversy is typical of the kind of difficulty experienced when ornithologists try to make sense of osteological material and have little else to go on. In the case of the moas there are some skin and feather fragments as well as a very few eggs and egg pieces, but these remains are tantalizing and reveal little of significance.

The largest of the moas, *Dinornis giganteus*, was the tallest known bird ever and it raised its head, upon a long serpentine neck, to the extraordinary height of around 4 m. Although not as hugely ponderous as the Madagascan Great Elephantbird, this was a considerably taller creature and presumably it must have been an awe-inspiring sight.

The evidence suggests that this particular species was probably gone by 1600 but it seems probable that a smaller – but still gigantic – relative, *Dinornis torosus*, survived after this date.

There is, in fact, much controversy over the date at which the last of the moas became extinct. Some argue that this was at a comparatively antique time, others suggest the extinction was much more recent.

*Dinornis torosus* Hutton, 1891  
*New Zealand J. Sci.* 1(6): 2476.

Figure 3. Rule's Bone.  
This fragment, brought and shown to Richard Owen by John Rule, is the article which led to Owen's sensational deduction that large ostrich-like birds had once inhabited New Zealand, and indeed might still do so.  
Lithograph by G. Scharf, 1842.

A fragment of bone from *Dinornis torosus* seems to have been the first moa relic to come to the attention of ornithologists. This was in 1839 when the celebrated comparative anatomist Richard Owen stuck his neck out and made his famous announcement that there had lived in New Zealand – or even perhaps at that time still lived – a gigantic bird similar to an Ostrich. Owen based this deduction on a very small fragment of bone that had been brought to him for identification by a Dr John Rule. Despite the unpleasant things that are often said of him, Owen was certainly not lacking in courage: had he been proved wrong, his reputation, and indeed his whole career, would have been in tatters. However, only a short time after his sensational announcement, solid proof, in the form of skeletons, came to light and proved his deductions to have been accurate.

Bones of *D. torosus* have been found at widely scattered localities on New Zealand's South Island. Their comparative rareness in swamp deposits suggests that the species may have preferred hill country. Some of the tops of the skulls of this species show deep pits in the surface and this may indicate that birds carried crests.

### Greater Broad-billed Moa

*Euryapteryx gravis*

*Dinornis gravis* Owen, 1870  
*Trans. Zool. Soc. London* 7: 123.

There were several moas belonging to the genus *Euryapteryx* and these are distinguished from other moas by their broad, round-tipped beaks. Species have been described from both the South Island of New Zealand and the North. *Euryapteryx gravis* seems to have been the most widespread of these, and it has left its remains scattered throughout New Zealand. Although it was rather smaller than birds belonging to the genus *Dinornis*, it was nonetheless a very large and bulky creature. Its bones are said to be those that are most commonly found in Polynesian kitchen middens, so there is little doubt that this bird was often eaten by man.

At what date this supply of meat ran out is not known and it is possible that the species was extinct before 1600. On the other hand, birds of this species may have been the creatures referred to by ancient Maoris when they recalled moa hunts that took place during the last half of the eighteenth century. These intriguing stories have long fascinated researchers and they centre around the reminiscences of aged warriors who told their tales of long ago during the middle years of the nineteenth century. Whether these old men were simply enjoying being the centre of attention or whether there was some substance in their stories is a matter of speculation.

### Lesser Megalapteryx

*Megalapteryx didinus*

*Dinornis didinus* Owen, 1883  
*Trans. Zool. Soc. London* 11: 257.

Although gigantic by bird standards, this creature was diminutive in comparison to other moas, standing little more than a metre tall. It may have been restricted only to the South Island.

It seems quite likely that the species survived to a later date than any other, and it may have been extant during the early nineteenth century; there are even those who hope that it survives still in some remote mountain fastness of New Zealand's fiordland. Its small size and the wild terrain it occupied may have combined to enable it to survive when the lines of its larger relatives failed.

There are several relics of this species that have survived in a remarkably good state of preservation. Dried heads and necks with ligaments and flesh attached have been found and so too have feathers and mummified feet. Such finds come from the province of Otago and they make it clear that the species was feathered right down to the toes. The feathers show an open structure, lacking barbicles and presenting a rather hair-like appearance. They are greyish-brown in colour, some with a rufous tinge and some tipped with white.

Sir George Grey, at one stage Prime Minister of New Zealand, was once told at Preservation Inlet, South Island, of the recent capture and killing of a small moa out of a drove of six or seven. This incident is supposed to have happened around 1868. Did it really occur, or is it just a story?

## PODICIPEDIFORMES

This group of birds may or may not contain extinct species but it certainly contains several that are under grave threat of extinction. The most seriously threatened is the Aitlan Grebe (*Podilymbus gigas*), and it now seems highly likely that this form is actually extinct. In Volume 1 of HBW, the species was listed as Almost Certainly Extinct; several years later the "almost" can probably be removed. However, since the

genes of this creature may still exist, there may be an argument for retaining it on the list of living creatures for a while longer.

Affected by habitat degradation, the introduction of an alien, predatory fish and the arrival of a closely related species with which it hybridized, the species – in its purest sense – seems no longer to be extant.

The Atitlan Grebe was always restricted to a single lake in Guatemala, where it adapted to the prevailing conditions by becoming flightless and isolating itself from its close relative, the widespread Pied-billed Grebe (*Podilymbus podiceps*). In essence this was simply an outsize version of the Pied-billed, and it was probably always vulnerable to the threat of hybridization with that species. This seems to be the factor that finally led to the loss of Lake Atitlan's grebe, an event that probably took place around 1990. The possibility that a few pure-bred examples of the species still exist cannot be completely excluded, of course, although it seems very doubtful. For more on this species and the cases of the probably extinct Rusty Grebe (*Tachybaptus rufolavatus*) and Colombian Grebe (*Podiceps andinus*), see HBW 1, pages 185-194.

## PROCELLARIIFORMES

This group, containing the albatrosses, shearwaters and petrels, includes many threatened species but only one seems to be extinct.

### HYDROBATIDAE

#### Guadalupe Storm-petrel

*Oceanodroma macrodactyla*

The island of Guadalupe lies off the coast of Baja California, some 320 km south-west of San Diego. It should not be confused with Guadeloupe in the West Indies. Guadalupe of the Pacific was once a home to several forms that are now extinct; these were mainly subspecies of more widespread birds.

A distinct species of storm-petrel once lived here, a species that nested in burrows carved out of the soft soil beneath trees on the steep north-eastern ridges of this small island. The population was probably never large but there is no reason to suppose that it was anything but thriving until cats and goats were introduced to the island. Cats are known to have infested the nesting areas and, presumably, it was this agency that brought about the destruction of the petrels. Apart from the fact that breeding began in March and continued until May, with a single white egg being laid, nothing of significance is known of the species. It seems to have become extinct during the years immediately preceding World War I.

*Oceanodroma macrodactyla* W. E. Bryant, 1887  
*Bull. Calif. Acad. Sci.* 2: 450.

Guadalupe Storm-petrel  
*Oceanodroma macrodactyla*

Plate F1

## PELECANIFORMES

One member of this order can confidently be listed as extinct, but there is one other rather mysterious form that may be. This is a bird known as Kenyon's Shag (*Phalacrocorax kenyonii*). It is identified from just three specimens from Amchitka Island, in the Aleutian Archipelago of the north Pacific, collected during the late 1950's and preserved as skeletons. The external appearance of this bird is unknown. So too is its relationship to other cormorants, and it has even been suggested that these may merely have been outsize individuals of the extant Red-faced Cormorant (*Phalacrocorax urile*), a species that is still common in this same area. It is not even known if the form *kenyonii* still survives, so this is truly a mystery bird.

## PHALACROCORACIDAE

### Spectacled Cormorant

*Phalacrocorax perspicillatus*

*Phalacrocorax perspicillatus* Pallas, 1811  
*Zoographia Russo-Asiat.* 2: 305.

The spectacular Spectacled Cormorant is a particularly striking member of the list of extinct birds. Discovered on Bering Island during 1741 by the celebrated naturalist George Wilhelm Steller, the species was exterminated in little more than a century. At the time of its discovery this large cormorant was common, although its range was very

Spectacled Cormorant  
*Phalacrocorax perspicillatus*

limited. In addition to Bering Island, it was also found on the nearby Commander Islands, and it probably lived on other islands of the Aleutian Archipelago in the north Pacific. Its general unwariness, its suitability for the pot and its small wings that rendered it almost flightless, combined to make this bird an obvious target for man.

There are very few specimens in existence and nothing of significance is known of the bird in life.

## CICONIIFORMES

There are several seriously threatened birds in this order but only one full species is known to have become extinct during the last 400 years.

## ARDEIDAE

### Rodrigues Night-heron

*Nycticorax megacephalus*

*Ardea megacephala* Milne-Edwards, 1874  
*Ann. Sci. Nat. Zool.* Ser. 5, no. 19: 10.

During 1691 a small band of Huguenots, fleeing from religious persecution in France, ended up marooned for around two years on the Mascarene island of Rodrigues, far out in the Indian Ocean. Their leader was one François Leguat, and this gentleman made notes on the things he saw during his stay on the island, notes that included

detailed observations of the birds he encountered. Years later, after his return to Europe, Leguat's notes were published in book form (simultaneously, in both English and French) and his book was called *A New Voyage to the East Indies* (1708). This splendid little volume provides primary source material for a number of extinct species, including the present one.

Leguat describes a powerfully built and pugnacious heron that had almost lost the power of flight but had developed strong legs that enabled it to move very quickly.

In their loneliness (there were no women with the small band!), Leguat and his followers found some small solace in the companionship of some endemic geckos, which they shook down from the trees. These little creatures, which were themselves to become extinct around the time of World War I, were surprisingly tame and the Huguenots often allowed them to feed from their own table. So bold and aggressive were the herons, however, that Leguat and his friends had great difficulty in protecting their little pets from the marauding birds.

Despite their bullying manner, the night-herons died out at an unknown date during the eighteenth century. There is a fleeting mention of them in a document that dates from around 1725 but nothing more recent is recorded of the living bird.

During the 1870's bones were found on Rodrigues that confirm the earlier written reports and suggest that this species was derived from a night-heron, but nothing more is known of it.

## ANSERIFORMES

The waterfowl – the swans, geese and ducks – have always been enormously attractive to man. Like parrots, they are comparatively easy to domesticate and they have been bred in captivity, or semi-captivity, for many centuries. Ducks, geese and swans have been used for food, sport and also simply for decorative purposes.

Many kinds have been seriously affected by changing patterns of land use, habitat alteration and wetland drainage. Many species have declined drastically and four are now regarded as extinct and discussed below, although there is still some hope that two of them might conceivably still hang on in remote parts of their ranges.

One other species, the Chatham Swan (*Cygnus sumnerensis*), sometimes occurs on lists of recently extinct birds but there is no real evidence to show when this creature died out. Known only from bones, it may well have become extinct long before 1600. Another species that is sometimes listed as recently extinct is *Sarkidiornis mauritiana* from Mauritius but, like the Chatham Swan, there is little to suggest that this creature lived on into recent historical times, and again it is known only from bones.

Were it not for the fact that many kinds of waterfowl can be successfully bred in captivity, there would have been several additional extinctions, and some very notable conservation success stories concern waterfowl. Perhaps the most famous is that of the Néné or Hawaiian Goose (*Branta sandvicensis*). The population of this striking goose was long in decline and by the early 1950's it had plummeted to around 30 individuals. With numbers at this low level the prospects of the species' survival looked bleak. At various times during the nineteenth century and early years of the twentieth (and also in several places) it had proved possible to breed Nénés under captive conditions and so one last effort was made to save the species at the famous waterfowl reserve at Slimbridge, England. The operation was an enormous success and numbers steadily increased. There are now hundreds of Nénés in existence and captive colonies can be seen in many parts of the world. The species has also been reintroduced to its native Hawaiian Islands where around a thousand individuals probably survive. There is no reason to suppose that its future is anything but secure.

Another Hawaiian species or subspecies that survives thanks largely to captive breeding is the Laysan Duck (*Anas (platyrhynchos) laysanensis*). It is recorded that numbers once dropped as low as seven individuals and during the 1930's the tiny surviving population was alleged to contain just a single female. Somehow this form survived, and a captive breeding programme was started in 1958. Many birds have been successfully bred in captivity and populations of Laysan Ducks now exist in a number of waterfowl collections. Unfortunately, some of these populations may no longer be pure.

A form that has caused considerable confusion is the one known as the Marianas Duck ("*Anas oustaleti*") and there is no general agreement about the true nature of this creature. It comes from the Pacific islands of Guam, Tinian and Saipan and there are two distinct colour morphs, one of which resembles a Mallard (*Anas platyrhynchos*), the other looking rather like a Pacific Black Duck (*Anas superciliosa*). Because of

this resemblance and also because of the extreme isolation of the islands on which it occurs, it seems likely that the population is the result of hybridization. Probably, individuals of the two commoner species arrived on the islands, naturally or with human assistance, and, because of the unusual circumstances, interbred. A viable hybrid population was established and some authorities consider that the colony represents the evolution of a species through the mechanism of hybridization. Unfortunately, this evolutionary experiment – assuming that this is what it is – seems to be coming to an end. The isolated colony is now very close to extinction; indeed, perhaps it is already gone.

## ANATIDAE

### Crested Shelduck

*Tadorna cristata*

*Pseudotadorna cristata* Kuroda, 1917.  
Tori 1: 1.

Only a very few specimens of this striking duck are in existence, and virtually nothing is known of it in life. Even the limits of its original range are a matter of speculation; there is an assumption that it bred in eastern Siberia and migrated to Korea and Japan, but this may be incorrect. It is not even certain that it is extinct, although hopes for its continuing survival are probably forlorn.

The most recently obtained specimen was taken in 1916 but a number of much later sightings are claimed, including a reported observation in southern China as late as 1990. Such unsubstantiated sightings should be taken with caution, but as long as tracts of potentially suitable habitat remain in unsurveyed areas, hope lives on.

Although the earliest known specimen was taken near Vladivostok during 1877, the Crested Shelduck was not recognized as a species until 1917 when the Japanese ornithologist Nagamichi Kuroda formally described it. Prior to this the form had been regarded as a hybrid between the Ruddy Shelduck (*Tadorna ferruginea*) and the Falcated Duck (*Anas falcata*).

Despite the fact that this is now such a mysterious bird, it seems that it was well known historically to both the Japanese and the Chinese and it is said to be depicted on a number of antique artefacts.

### Pink-headed Duck

*Rhodonessa caryophyllacea*

*Anas caryophyllacea* Latham, 1790  
Index Orn. 2: 866.

There is a certain amount of controversy over whether or not the Pink-headed Duck of north-eastern India still survives. Probably it does not, but there are those who believe it might and every few years or so an expedition goes in search of it. Thus far none of these expeditions has proved successful.

This was a shy and wary bird that sometimes emitted a wheezy whistle and was always difficult to flush. Its rather secretive nature is one of the factors that encourages the optimists. Against this it might be said that individuals were found without too much difficulty during the nineteenth century and early years of the twentieth, yet none has been seen in the wild since the 1930's.

On the water – where the birds spent most of the hot day – individuals showed a rather peculiar, stiff-necked posture and a strange triangular patch was evident on the top of the head. Despite some reports to the contrary, they seem to have been capable divers and were probably omnivorous feeders. Small groups sometimes gathered, particularly during the cooler months, and typically these groups consisted of six to eight birds, although sometimes the groups were considerably larger. The birds were rarely seen in the air and descriptions of their mode of flight are mildly contradictory: one report suggests that it was rapid and powerful, while another maintains it was light and easy.

Pink-headed Ducks bred in April and May and they built circular nests from dry grass and feathers. The eggs – white or faintly yellowish in colour – were almost spherical in shape and the clutch numbered between five and ten. The species was recorded from Assam, Manipur, Bengal, Bihar, Myanmar and Orissa.

Curiously, the last Pink-headed Duck of all may have died in England, thousands of miles from its native home. A number of captive individuals were kept in a private collection at Foxwarren Park, Surrey, and a rumour suggests that a male bird may have survived until 1945.

### Labrador Duck

*Camptorhynchus labradorius*

*Anas labradoria* J. F. Gmelin, 1789  
Syst. Nat. 1(2): 537.

The Labrador Duck is one of the most mysterious of North American birds. It was always uncommon, shy and wary and for these reasons seems to have been little affected by shooting.

Reasons for its extinction are unknown but one school of thought suggests that it was a very specialized feeder unable to cope with the vast changes to the environment that came about as a result of European settlement. This idea is, perhaps, supported by the slightly aberrant development of the bill which shows a curious softness around the edges.

The species occupied the eastern seaboard of North America where it seems to have ranged from Labrador, in which area it may have spent the summer months, down to Chesapeake Bay. Nesting grounds were never reliably located; they may have been in Labrador or on islands in the Gulf of St Lawrence. Several eggs exist that are attributed to the species, but all are of doubtful provenance.

Labrador Ducks seem to have declined rapidly after 1840 and the last sighting of the species dates from the 1870's. A specimen was apparently taken from Long Island waters during 1875 and another individual was allegedly shot near Elmira, New York, during 1878.

### Auckland Merganser

### *Mergus australis*

The Auckland Islands lie some 320 km south of New Zealand and this rather forlorn group was once home to a species of merganser that, while not entirely flightless, showed a marked reduction in wing size compared with its relatives. As often happens when birds develop in evolutionary backwaters (i.e. areas without mammalian predators), the adults begin to resemble the immature stages of their relatives and this is just what was happening in the case of this merganser. Similarly, and typically, its chicks were showing none of the distinctive patterning shown in related species.

*Mergus australis* Hombron and Jacquinot, 1841  
*Ann. Sci. Nat. Zool.* **16**: 320.

The Auckland Merganser was first discovered in 1840 during a French exploratory visit to New Zealand waters. Two French corvettes, *L'Astrolabe* and *La Zelée*, arrived at the rarely visited and remote Auckland Islands, and some of the crew collected specimens. A Lieutenant Charles Jacquinot obtained a merganser and published a description of it, jointly, with ship's surgeon, Jacques Hombron. No further examples were spotted for 30 years or so, but then the species was seen on a number of occasions until the year 1902, after which time it vanished.

The most extraordinary aspect relating to this species lies, perhaps, in its range. Five kinds of merganser exist north of the equator, a sixth inhabits parts of Brazil but none – other than this one – occurs anywhere near the Auckland Islands. Bones found in Polynesian kitchen middens indicate that the species once occurred on the main islands of New Zealand.

The reasons for its extinction are unknown, although some reports suggest that individuals were prone to hide among rocks when pressed, rather than take to the water and dive like their European counterparts. Such a defensive strategy obviously did not work well against man and the predatory mammals he introduced.

## FALCONIFORMES

The birds of prey are, of course, well known as being among the most persecuted of the world's birds, yet, despite the fact that many are seriously threatened, none can be categorically listed as recently extinct.

One form that might qualify as an extinct species is the Guadalupe Caracara (*Polyborus plancus lutosus*). There is no doubt that the form is extinct, as no individual has been seen since the year 1900, but what is in doubt is the bird's taxonomic status. This is one of those creatures that hovers close to the border of what defines a full species and what defines a subspecies. Some authorities (including the present writer, 2001) have regarded it as a species in its own right, while others relegate it – with equal justice – to subspecific rank, considering it simply an island subspecies of the Crested Caracara (*Polyborus plancus*).

Irrespective of the taxonomic view taken, this bird is one of those that disappeared as a direct result of human persecution. Exasperatingly, the last individuals on record were a flock of eleven birds, of which the scientific collector Rollo Beck shot nine. There were no further records (see HBW 2, page 242).

## GALLIFORMES

In addition to the single species from this order that is definitely extinct, another may well be, and a third provides one of ornithology's little mysteries.

The species that may well be extinct is the Himalayan Quail (*Ophrysia superciliosa*), last reliably recorded during the nineteenth century. Inhabiting the undergrowth of steep Himalayan slopes at around 1650–2100 m, this quail has repeatedly been the object of speculation with regard to its possible continued existence, but, despite a number of claimed sightings, no convincing proof has emerged. Nevertheless, the difficulty of the terrain it inhabits means that the optimists continue to believe in its possible survival (see HBW 2, page 513).

The mystery bird is the Double-banded Argus (*Argus (argus) bipunctatus*). This form is known from a single feather found at an unknown location at some time before 1871. This feather, although similar to those of the two known species of argus pheasant, is markedly different to that carried by either. Does it come from a freak? Does it come from a distinct species? Is that species extinct? No-one knows.

## PHASIANIDAE

### New Zealand Quail

### *Coturnix novaezelandiae*

*Coturnix novae-zelandiae*  
Quoy and Gaimard, 1830  
Voy. 'Astrolabe', Zool. 1: 242.

It is difficult to account for the disappearance of the New Zealand Quail. A closely related, possibly conspecific, Australian species, the Stubble Quail (*Coturnix pectoralis*), flourishes in its homeland, yet the New Zealand birds failed to survive the coming of Europeans.

The species seems to have been common on the grass-covered downs of New Zealand's South Island until the mid-nineteenth century, but then, suddenly, its numbers plunged and within two decades it was all but gone. The factors responsible for this decline are unknown. Introduced mammalian predators, overhunting (presumably the birds provided the kind of "sport" that colonists were used to in their old homes), the burning off of land, or an unknown – and introduced – avian disease are all reasons that have been speculatively put forward.

The latest specimens were taken during the late 1860's and individuals were, apparently, seen up to the mid-1870's. After this they vanished.

## GRUIFORMES

This large and varied order includes the rails, a group of birds which has suffered a large number of extinctions, a fact that can be accounted for by the tendency of birds of this kind to disperse at random. Rails are particularly prone to colonize oceanic islands, diversify, and then lose the power of flight. Such a tendency makes them particularly vulnerable when their safe, island paradises become safe no longer, when they are invaded by mammalian predators.

Eleven extinct species are recognized here, although differing taxonomic views can lead to rather different lists. To these eleven may be added the Bar-winged Rail (*Nesoclopeus poecilopterus*), a Fijian species not reliably recorded since 1890, and the Kosrae Crane (*Porzana monasa*), from the Caroline Islands, not recorded since at least the mid-nineteenth century; both have already been covered by HBW 3, pages 161 and 189. Another supposed member of this latter genus, Miller's or the Tahiti Crane (*Porzana nigra*), is often listed as an extinct species but in reality this should be considered a hypothetical form (see Walters, 1988, and Fuller, 2000a). Also deserving of mention is the Mascarene Coot (*Fulica newtoni*), not included in the list herein, as there is no hard evidence that it survived until 1600, although there are seventeenth century reports of it from both Reunion and Mauritius. The difficult case of Sharpe's Rail (*Gallirallus sharpei*) has already been mentioned (see page 12).

## RALLIDAE

### Mauritian Red Rail

### *Aphanapteryx bonasia*

Scattered among the seventeenth century written accounts and illustrations that relate to the celebrated Dodo are descriptions and pictures of a flightless bird of a rather different kind. These pictures show a creature that in overall shape and appearance looks something like a kiwi. A long, down-curved beak, rather hair-like plumage and stout legs all add to this impression. The bird in question bore no genuine relationship to the kiwis, however. It was a rail and, like the Dodo, it came from the island of Mauritius.

Like its more famous fellow, the Mauritian Red Rail or Red Hen failed to survive the coming of Europeans by more than a few decades. The Dutch arrived on Mauri-

*Apterornis bonasia* Sélvs Longchamps, 1848  
*Rev. Zool.*: 292.

tius, with devastating effect, during 1598, and it is highly doubtful if there were any red "hens" left a century later.

Peter Mundy, an English traveller who penned fascinating reminiscences of his exploits, described the species as:

A Mauritius henne, a Fowle as bigge as our English hennes...of which we got only one. It hath a long, Crooked sharpe pointed bill. Feathered all over, butte on their wings they are soe Few and smalle that they cannot with them raise themselves From the ground...They bee very good Meat, and are also Cloven footed, soe that they can Neyther Fly nor Swymme.

Mundy was recalling events of 1638 and the fact that he and his companions got only a single individual surely indicates that the species was already rare. Earlier accounts suggest that the birds gathered in flocks and were fatally attracted to the colour red. By means of a piece of red material they could be induced to approach and then, of course, they were caught.

### Leguat's Rail

### *Aphanapteryx leguati*

*Erythromachus leguati* Milne-Edwards, 1874  
*Ann. Sci. Nat. Zool. Ser. 5, no. 19: 15.*

The Huguenot refugee François Leguat discovered a relative of the Mauritian Red Rail during his two-year sojourn on the island of Rodrigues:

Our Wood-hens are fat all the year round and of a most delicate taste. Their colour is always of a bright grey, and there is very little difference in the plumage between the two sexes. They hide their nests so well that we could not find them out and consequently did not taste their eggs. They have a red list about their eyes, their beaks are straight and pointed, near two inches long, and red also. They cannot fly, their fat makes them too heavy for it. If you offer them anything that's red, they are so angry they will fly at you and catch it out of your hand, and in the heat of the combat we had an opportunity to take them with ease.

It is curious to note how this last piece of information conforms to the reported behaviour of the Mauritius Red Rail.

An anonymous manuscript – alleged to have been written by a marooned sailor named Tafforet – dating from around 1725, described a creature that could not fly, was armed with a heavy beak, made a continual whistling, fed on tortoise eggs (Rodrigues was once home to a now extinct species of giant tortoise) and was a powerful runner.

Since no subsequent visitor to Rodrigues mentions any such creature it may be assumed that these birds became extinct soon after 1725.

In 1874 bones were found in a Rodrigues cave and these appear to correspond with the early accounts; they constituted the material on which Alphonse Milne-Edwards based his formal description of this species. Additional skeletal finds have subsequently been made.

### Wake Rail

### *Gallirallus wakensis*

*Hypotaenidia wakensis* Rothschild, 1903  
*Bull. Brit. Orn. Club 13: 78.*

The Wake Rail has acquired the grim celebrity of having been eaten out of existence by hungry Japanese soldiers during World War II. Unable to fly, these rails could scuttle about their island home quickly, but despite their agility any efforts to escape would have been no match for the concerted efforts of a few peckish men. Before World War II the rails were plentiful but by the time the Japanese garrison left Wake Island in 1945 there were none left.

Remote Wake Island is situated far out in the Pacific, hundreds of kilometres from the Hawaiian group. Despite its extreme isolation, rails something like today's Buff-banded Rail (*Gallirallus philippensis*) managed to colonize it at some period in the distant past, and from this ancestral stock the form developed that has become known as the Wake Rail. Over generations the size became smaller, the plumage lost its brightness and the wings became rudimentary. As Wake is small, low and scrub-covered, the rails probably had to make use of any food source that came their way; molluscs, insects and other invertebrates are likely to have provided the basic diet.

Other than the fact that breeding was observed to take place in July and August, and that individuals made the low chattering and clucking that is typical for a rail, nothing of substance is known of this species.

## Tahiti Rail

*Gallirallus pacificus*

*Rallus pacificus* J. F. Gmelin, 1789  
*Syst. Nat.* **1**(2): 717.

The Tahitian Red-billed or Tahiti Rail is known only from a painting that survives today in the collection of the Natural History Museum, London. This painting was produced by Georg Forster, one of the naturalists who sailed with Captain James Cook on his second epic voyage around the world during the 1770's. Forster's credentials are impeccable, so there need be no doubt that he saw just such a bird as that depicted.

The individual that served as a model for his picture was found on Tahiti, where it was known as *tevea*, *oomnaa* or *eboonaa*. No-one knows why it became extinct – or when – but it seems likely that this was connected with the introduction of cats and rats to the island.

## Dieffenbach's Rail

*Gallirallus dieffenbachii*

*Rallus dieffenbachii* G. R. Gray, 1843  
*Trav. New Zealand* **2**: 197.

The remote Chatham Islands lie way to the south of New Zealand and here, in isolation, two species seem to have developed from an ancestral stock that resembled the Buff-banded Rail. The less evolved of these is Dieffenbach's Rail, and this form seems to have developed from a comparatively recent invasion of the ancestral birds. Indeed there is some doubt as to whether or not this form had actually passed beyond the stage at which it could be regarded as just a subspecies. Apart from some minor plumage differences, it sports a sharply downturned beak and this is clearly an adaptation to the conditions prevailing on the island.

Nothing is known of the bird in life. It is known from just a single specimen collected during the 1840's and now in the collection of the Natural History Museum, London.

## Chatham Rail

*Gallirallus modestus*

*Rallus modestus* Hutton, 1872  
*Ibis* **Ser. 3, no. 2**: 247.

This species seems to provide a fairly typical example of the way in which rails develop on isolated islands. It is assumed that this is another form that has evolved from an ancestral stock resembling the Buff-banded Rail, but in this case the evolution was rather more advanced than in others.

Following the arrival of this ancestral stock, the birds diversified over aeons, assumed a neotenuous appearance (adults began to resemble juveniles), lost the power of flight, and their plumage began to assume a rather hair-like appearance. All these developments enabled the birds to make maximum use of the rather limited resources available on the Chatham Islands, by cutting down on what were, for them, unnecessary and costly forms of energy expenditure, but, of course, they rendered them horribly vulnerable if, and when, the situation changed. The coming of man and his introduction of mammals, either intentional or not, caused just such a change.

The species seems to have been on several islands of the Chatham group – Chatham Island itself, Pitt Island and Mangere – but it is from Mangere that the majority of surviving specimens come, and this seems to have been the last stronghold. From here the birds vanished around 1900. By this time much of the land had been burned off, sheep were grazing and cats had overrun the island.

All that is known of the species is that it nested in burrows or in hollow trees, ate insects and laid a creamy-white egg.

## Ascension Rail

*Atlantisea elpenor*

*Atlantisea elpenor* Olson, 1973  
*Smithsonian Contrib. Zool.* **152**: 7.

The evidence for the former existence of a small rail on Ascension Island is of two kinds. First, bones from a rail have been found on the island and, second, there exists a seventeenth century written account of just such a creature. This account was written by the much travelled Englishman Peter Mundy, the same man who also penned an account of the extinct rail of Mauritius. Mundy's descriptions are always reliable and in this case he also provided a crude but explicit drawing of the birds he saw. He wrote:

Alsoe halfe a dozen of a strange kind of fowle, much bigger than our Sterlings...colour grey or dappled, white and blacke feathers intermixed, eies red like rubies, wings very imperfitt, such as wherewith they cannot raise themselves from the ground. They were taken running, in which they are exceeding swift, helping themselves a little with their wings...It was more than ordinary dainety meat, relishing like a roasting pigge.

Nothing more is known of the species. Why and when it became extinct are also matters completely shrouded in mystery.

Figure 4.  
Ascension Rail  
sketched by  
Peter Mundy,  
who visited  
the island  
in 1656.

**Laysan Crane***Porzana palmeri*

Laysan is a tiny coral island around 1280 km to the north-east of Hawaii, and one of its few inhabitants was a small species of rail. Because it is so remote, the island was infrequently visited but, nevertheless, there are several good accounts of the bird in life. These consistently tell of how bold the tiny creatures were, hunting for flies between the feet of men, or entering huts and other buildings in search of food. All kinds of insects and their larvae were eaten and the rails would often squabble with Laysan Finches (*Telespyza cantans*) over the broken eggs of noddies and terns (*Sternidae*). Scraps were taken from the carcasses of dead seabirds, and vegetable matter was also consumed. In short, no food resource was neglected.

The Laysan Crane was flightless, but birds could move with incredible swiftness and agility when attacked by frigatebirds (*Fregata*) and other larger seabirds. The call was described as a warbling and chattering, and there was a peculiar evening chorus that began soon after darkness fell and lasted for just a few seconds. The birds all started their chorus in unison and then all fell silent together. The sound produced was said to be like a handful of marbles being thrown onto a glass roof and then descending in a series of bounds.

Breeding occurred between April and July. A nest was made of grass and leaves, and this material was arched over to make a roof with an entrance at the side.

During the 1890's these little birds were common but then rabbits and guineapigs were introduced to the island, and the habitat deteriorated. By 1925 the vegetation was gone, and Laysan was a desert. During this year two rails were seen, but by 1936 there were certainly none left. The species was not quite extinct, however. During 1891 a few individuals had been transferred to Eastern Island in the Midway Atoll, and here the small population flourished. By the start of World War II the birds were common. Then, alas, a US Navy landing craft drifted ashore bringing with it an accidental invasion of rats. Within two years the last Laysan Cranes were gone.

*Porzanula palmeri* Frohawk, 1892  
*Ann. and Mag. Nat. Hist.* 9: 247.

**Hawaiian Crane***Porzana sandwichensis*

A small species of rail once inhabited the main island of Hawaii and perhaps some other Hawaiian islands. A handful of specimens exist in the museums of the world but these have in themselves caused some controversy. Two of them are rather paler in colour than the rest, giving rise to the idea that there may have been two species rather than one. This claimed second species is herein tentatively treated as a separate race, *millsi*. On the other hand the general consensus of informed opinion is that the paler individuals may simply be immatures.

Apart from the probability that these birds were extinct by the end of the nineteenth century, nothing is known of them.

*Rallus sandwichensis* J. F. Gmelin, 1789  
*Syst. Nat.* 1(2): 717.

*P. s. millsi* (Dole, 1878)  
*Hawaiian Alm. Ann.* 1879: 54.

**Samoa Moorhen***Gallinula pacifica*

There seem to be eleven specimens of this species in the world's museums, the first collected during 1869 and the last perhaps a mere five years later. Since then the species has never more been located.

Little is known of it other than that it inhabited the Samoan island of Savaii. It was called the *puna'e* by the local inhabitants, it was probably flightless (or almost so), and it had exceptionally large eyes, from which fact it has been deduced that it was nocturnal or crepuscular in habit.

The reasons for its extinction are unknown but, presumably, introduced predators will have played some part.

*Pareudiastes pacifica* Hartlaub and Finsch, 1871  
*Proc. Zool. Soc. London* 1871: 25.

**White Gallinule***Porphyrio albus*

When British ships belonging to what was known as the First Fleet were dispatched under Governor Phillip to Australia during the late 1780's, their task was to found a penal colony to which British felons could be transported. Much of interest surrounds this rather unpleasant endeavour and one of the by-products of the epic journey was a great upsurge in knowledge concerning Australian natural history.

One of the creatures that was brought to attention as a result of the expedition was a rather strange and albinistic swamphen that occurred on Lord Howe Island, a small and isolated piece of land lying some 480 km off the eastern coast of Australia. These birds were white, or mostly so, and considerably larger and heavier than ordinary swamphens and they had comparatively formidable bills. In fact, they seem to have been evolving independently into an entity that was reminiscent of New Zealand's Takahē (*Porphyrio mantelli*).

*Fulica alba* Shaw, 1790  
In: White's *J. Voy. New South Wales*: 235.

Unfortunately for the birds, men who visited the island were easily able to kill them with sticks and this fact alone makes it highly likely that they were flightless. Just two specimens of the White Gallinule (or Lord Howe Swamphen) are in existence today, one in Vienna, the other in Liverpool.

Once man began to visit their island home regularly, the species' days were numbered, and it seems to have survived for only a few decades after the coming of the First Fleet.

## CHARADRIIFORMES

The Charadriiformes comprise a diverse group containing waders, gulls and auks. In addition to the three species discussed below, there are two others that are often listed as extinct, and may well be so, though herein the possibility of their survival is given the benefit of the doubt. These are the Javanese Wattled Lapwing (*Vanellus macropterus*), last definitely recorded in 1939, and the Eskimo Curlew (*Numenius borealis*) for which sightings are occasionally claimed right up to the present time, but which, if extant, could probably only number a handful of individuals (see HBW 3, pages 418 and 503).

## SCOLOPACIDAE

### White-winged Sandpiper

*Prosobonia leucoptera*

### Ellis's Sandpiper

*Prosobonia ellisi*

*Tringa leucoptera* J. F. Gmelin, 1789  
*Syst. Nat.* **1**(2): 678.

*Prosobonia ellisi* Sharpe, 1906  
*Bull. Brit. Orn. Club* **16**: 86.

Whether there was one extinct species of sandpiper occupying the Pacific islands of Tahiti and Moorea or whether there were, in fact, two remains something of an enigma. The naturalists who actually saw the birds in life and handled fresh specimens were convinced that there was only one, but more recent commentators have produced reasonable arguments that there were two: a form from Tahiti (*leucoptera*) with a more sandy-coloured breast; and another from Moorea (*ellisi*), with more reddish underparts. No definitive solution to this problem is possible.

Although there were once several specimens in existence, only one (an example now in Leiden) survives today. This is one of the more sandy-coloured individuals. The species was only ever seen by naturalists who sailed with Cook and one of them, Georg Forster, painted a picture of a Moorea bird showing the more reddish breast. It is on the basis of this painting that the form *ellisi* is named.

Clearly the birds – whether there was once species or two – became extinct on an early date. Other than the fact that Forster found it close to small brooks, nothing is known of it in life.

## ALCIDAE

## Great Auk

*Pinguinus impennis*

The Great Auk is one of the true stars of extinction. Its story rises and falls like a Greek tragedy. This was a creature that had evolved perfectly to take advantage of a particular ecological niche but its very adaptation rendered it totally incapable of withstanding the depredations of man. It is probably true to say that the species was doomed from the prehistoric day when man first invented the boat. Use of boats enabled men to visit lonely islands and skerries, to round capes and headlands and reach otherwise inaccessible stretches of coast, and thus to pursue Great Auks to their final refuges.

The weakness in the Great Auk's lifestyle lay in the fact that it had lost the power of flight, and when it waddled clumsily ashore to breed in large colonies on islands of the North Atlantic it was totally vulnerable to a predator as ruthless and inventive as man. In addition, its large size made it a natural target. For ten months of each year Great Auks lived at sea, and it was only the necessity of breeding that brought them ashore for a few brief and doom-laden weeks.

First, Great Auks were driven back from all their most accessible breeding haunts. Then they were steadily forced back into even more remote areas. By the start of the eighteenth century they bred only on a few far-flung islands, each of which was difficult to land upon. The greatest of the breeding colonies appears to have been at Funk Island, off the coast of Newfoundland, and here the birds assembled in vast numbers during the months of May and June. Unfortunately for the auks the island lay near to the end of a long stretch of open water on the sea route from Europe to America. Hungry sailors feasted on the defenceless creatures and discovered that not only did they provide a handy food source, but also their feathers and the oil from their bodies were very useful commodities. By the late eighteenth century this vast colony had been wiped out and for all practical purposes the Great Auk bred only on a few islands off the coast of Iceland. On one of these in particular, the species seemed safe. This was an island known as the Geirfuglasker (which loosely translated means "Great Auk island"). The birds were safe here simply because the prevailing currents were so fierce and unpredictable that the island was almost impossible to land upon. While the species was wiped out elsewhere, the stronghold on the Geirfuglasker still held out. Then, catastrophe befell. A submarine volcanic explosion during the winter of 1830 caused the Geirfuglasker to sink beneath the surface of the waves never to reappear. When the few surviving Great Auks returned to their breeding rock and found it gone, they were forced to choose another site. This they did and they selected the infamous island of Eldey, a great rock that held one major disadvantage: although difficult to land upon, such a feat was by no means impossible. And land man did. In the first raid upon the island 24 birds were caught. A year or so later 13 were obtained. Each successive raid brought a dwindling haul until in June of 1844 just two individuals – a male and a female – were killed. None was ever seen again.

*Alca impennis* Linnaeus, 1758  
*Syst. Nat.* 10: 130.

## Plate F7

Great Auk  
*Pinguinus impennis*

*A Last Stand.*  
*Great Auks in the mist*  
by Errol Fuller.

The story of the killing of these supposedly “last” two birds has acquired almost legendary status and it occurs in many variants. All of these variants derive from the notes of two Victorian ornithologists, John Wolley and Alfred Newton, who recorded the tale after conducting extensive interviews with the Icelanders who actually participated in the event. Their notes show that on either 2nd or 3rd June an eight-oared fishing boat left the Icelandic mainland and made for the island of Eldey. Here, three of the crew struggled ashore and spotted two Great Auks among hundreds of smaller seabirds. They pursued the pair, caught them both and strangled them. The men returned to the boat and with great difficulty managed to scramble back into it. Once safely back on the mainland the leader of the raiding party took the road to the Icelandic capital Reykjavik, where he hoped to sell the birds. On the road it seems that he met, by chance, a trader with an interest in Great Auks – and the dead birds were sold on the spot. Curiously, the skins themselves vanished and no-one knows for certain what became of them (there is, however, some evidence to show that they might be the specimens now in Los Angeles and Brussels), although the internal organs of these two birds, preserved in spirits are now at the Zoological Museum in Copenhagen.

After its extinction, the surviving relics of the Great Auk – in the form of eggs and stuffed birds – became highly sought after. Through the second half of the nineteenth century, and afterwards, such items changed hands for large sums of money. In 1890 a stuffed bird would have cost around £400 (the price of four or five ordinary-sized houses) and an egg only slightly less.

Although the species has acquired a sort of cult status, surprisingly little is known of it in life. We know it was flightless, that it lived in and around the waters of the North Atlantic and must therefore have preyed on fish and other oceanic creatures. We know it laid a large pyriform egg, that it came ashore – helplessly – to breed for a few weeks each year, and that it spent the rest of its time at sea. The rest is speculation.

## COLUMBIFORMES

The pigeons as a whole have been badly affected by extinction. The reasons for this are probably those that apply broadly in the cases of other badly affected groups, the rails and the parrots. Each of these groups shows a marked tendency to disperse to oceanic islands where the species that evolve show a terrible vulnerability to changing conditions.

In addition to the two members of the extinct family Raphidae, and the seven species of Columbidae covered below, two other pigeon species may well be extinct but are not included here as there is a faint possibility that they may still survive. These are the Red-moustached Fruit-dove (*Ptilinopus mercierii*) from the Marquesas Islands in the Pacific and the Choiseul Pigeon (*Microgoura meeki*) of the Solomon Islands; the last definite records of these two were, respectively, some 80 and 100 years ago. Both have already been covered (see HBW 4, pages 187 and 216).

## RAPHIDAE

### Rodrigues Solitaire

### *Pezophaps solitaria*

*Didus solitarius* J. F. Gmelin, 1789  
*Syst. Nat.* **1**(2): 728.

The island of Rodrigues, far out in the Indian Ocean, is one of the Mascarene group and here a dodo-like species evolved from an ancestral pigeon stock. This species has become known as the Rodrigues Solitaire.

The Huguenot refugee François Leguat, whose name occurs so regularly in the stories of extinct birds, took a particular liking to this species and it is from his account that most information concerning it is derived.

Leguat was marooned on Rodrigues during 1691 and stayed for around two years. He and his small band of followers became entranced by the strange bird they found there and Leguat penned a number of observations of the Solitaire. One of these constitutes the first recorded observation of territorial behaviour in birds:

All the while they are sitting...or bringing up their young one, which is not able to provide for its self in several Months, they will not suffer any other Bird of their Species to come within 200 yards round of the Place; but what is very singular, is that Males will never drive away the Females; only when he perceives one he makes a noise with his wings to call [his] Female, and she drives the unwelcome Stranger away, not

leaving it till 'tis without her Bounds. The Female do's the same as the Males, whom she leaves to the Male.

The only other early authority for the birds of Rodrigues is an anonymous author, usually thought to have been a marooned sailor by the name of Tafforet, who wrote a document that has come to be known as the *Relation de l'Île Rodrigue*. A translation of the part of this document that relates to the Solitaire reads:

The Solitary...weighs...40 or 50 pounds. They have a very big head, with a...frontlet, as if of black velvet. Their feathers are neither feathers nor fur...of a light grey colour, with a little black on their backs. Strutting proudly about...they preen their plumage...and keep themselves very clean...[They] run with quickness among the rocks, where a man, however agile, can hardly catch them...They do not fly at all, having no feathers to their wings but they flap them and make a great noise...I have never seen but one little one alone with them, and if anyone tried to approach it, they would bite him severely. These birds live on seeds and leaves of trees.

Confirmation of the one-time existence of this creature comes from bones found in caves on Rodrigues. Complete skeletons have been assembled and these show that there was an extraordinary divergence in the size of the sexes with the males being much bigger. The bones also confirm some anatomical details that were mentioned by Leguat.

The remarks in the *Relation* indicate that the birds were still plentiful during the 1720's, and the document is thought to date from around 1725. However, at some time soon afterwards, they seem to have declined rapidly. During 1761 the Abbé Pingré arrived on the island with the intention of viewing the Transit of Venus. He arrived in time to see the heavenly wonder but not, it seems, in time to see the Solitaire. If the species still existed at this time it was so rare that it stood at the very brink of extinction.

Solitaires seem to have been tasty birds and it can only be assumed that settlers who arrived on Rodrigues during the eighteenth century ate them out of existence.

## Dodo

### *Raphus cucullatus*

The Dodo is probably the most powerful of all icons of extinction. "Dead as a Dodo" is an expression familiar to almost everybody in the English-speaking world. The name is unforgettable and so too is the bird's appearance, an appearance made memorable through the paintings of Roelandt Savery and their many derivatives, chiefly, perhaps, John Tenniel's illustrations for Lewis Carroll's *Alice's Adventures in Wonderland*. On the Dodo's home island of Mauritius the image of the bird is everywhere – on crockery, T-shirts, sweets and all kinds of ornamental souvenir ware.

More has been written about the Dodo than about any other extinct bird, but the reader should beware. Dodo literature is studded with inaccuracies and ludicrous theories, and despite the flood of words almost nothing is known of the bird in life.

Dutch mariners arrived on the Dodo's home island of Mauritius during September of 1598. We have no way of knowing how the species was faring before this but we do know that the arrival of the Dutch meant doom for the Dodo. Within 40 years of Dutch arrival the Dodo was virtually extinct, unable to withstand the joint assaults of man and the mammals he introduced – pigs, rats and monkeys, creatures that may not have threatened the adult birds but certainly threatened the young and the eggs. The existing seventeenth century reports become very thin on the ground after 1640 and even more so do original pictures. Indeed, after 1638 all Dodo images are derivations of earlier ones. The Dodo may have been in existence for several more decades but as a species it was a spent force from around this time.

There is no doubt that hungry sailors visiting Mauritius played a large part in the extermination of the Dodo and a very considerable proportion of the sparse contemporary literature concerns the edibility of the bird. Apparently, the flesh was rather tough and not particularly good to eat so whenever possible the men turned their attention to smaller, tastier birds. The Dodo held one big advantage for them, however. Being large and flightless, it was easy to locate and catch.

Although it interacted with man for such a short period of time, this exotic creature quickly gained some celebrity. A few living individuals reached Europe; several ornithologists have tried to calculate the number, but the evidence is flimsy and we have no real idea of how many there were. Also, the Dutch seem to have taken live birds to India and Indonesia. It has even been suggested that Dodos were taken to Japan but there is no proper proof of this.

Figure 5. Rodrigues Solitaire by François Leguat, from his 1708 book *A New Voyage to the East Indies*.

*Struthio cucullatus* Linnaeus, 1758  
*Syst. Nat.* 10: 155.

Figure 6. Dodo.  
A hand-coloured lithograph,  
based on a 1626 painting  
by Roelandt Savery.

The actual natural history of the Dodo is shrouded in mystery. How it used its curious beak, what it ate, even what parts of Mauritius it inhabited are all matters of debate. Almost certainly the species lived on fruits, nuts and other vegetable matter that it found on the forest floor but the records seem to indicate that it occurred only in certain areas. Woods close to the shore were probably a favoured habitat. It certainly seems unlikely that the birds inhabited the entire island. Had this been the case, the extinction could not have happened so rapidly.

Despite the early date of disappearance, the Dodo has left a number of physical relics behind. First, there are bones. With just a few exceptions these come from a small area of swamp known as the Mare aux Songes, close to the southern coast of Mauritius. From this material several complete skeletons have been assembled and these confirm the impression (gained from seventeenth century pictures and writings) that this was a large and heavy bird. It does seem, however, that it may not have been quite so bulky and clumsy as previously supposed and probably adopted a rather upright stance.

The most famous Dodo relics of all are a head and a foot that were once part of an entire stuffed bird. The body of this specimen was destroyed long ago but the head and foot were preserved and they are kept today at the University Museum of Zoology, Oxford.

Many people leave museums convinced that they have seen a stuffed Dodo. They have not, for there are none in existence. What they have seen are carefully constructed models made from the feathers of other birds.

The best description of the Dodo in life comes from the pen of an English courtier named Thomas Herbert who visited Mauritius in 1628 during a round trip to Persia:

Her body is round and fat...her visage darts forth melancholy, as sensible of Nature's injurie in framing so great a body to be guided with complementall wings, so small and impotent, that they serve only to prove her bird. The halfe of her head is naked seeming couered with a fine vaile, her bill is crooked downwards, in midst is the trill [nostril], from which part to the end tis of a light green, mixed with pale yellow tincture; her eyes are small and like to Diamonds, round and rowling, her clothing downy feathers, her train three plumes, short and inproportionable, her legs suiting to her body, her pounces sharp, her appetite strong and greedy.

The actual date of extinction is a matter of some doubt. Although the Dodo was on its last legs as a functioning species by 1640, there is little doubt that individuals lingered for some time afterwards. The last record has traditionally been regarded as a mention made by one Benjamin Harry who was writing in 1681. Following a visit to Mauritius, Harry compiled a list of the island's products and Dodos were included in this list. It is by no means certain, however, that Harry actually saw these birds. He may merely have been compiling a list of items that he knew had come from the island. Anthony Cheke (1987), who has conducted much research on the ornithological history of the Mascarenes, believes that the last Dodo observation was made by a

certain Volquard Iversen and relates to the year 1662. Iversen was marooned on Mauritius for several months and claimed to have encountered Dodos on a small offshore island to which he waded at low tide. Even this record may not stand up to scrutiny, however. Some evidence suggests that the name Dodo was transferred to the Mauritius Red Rail during the second half of the seventeenth century, and Iversen's record may perhaps result from confusion over terminology.

## COLUMBIDAE

### Bonin Woodpigeon

*Columba versicolor*

The avifaunas of several islands to the south of Japan have been badly depleted, and one of these island groups, the Bonins (Ogasawara), has lost several distinct forms.

One of these was the Bonin Pigeon, a large, dark bird that was discovered in 1827 during the exploratory voyage of *HMS Blossom*. It seems to have survived until around 1890, the last known specimen being collected during 1889. The bird's general unwariness and the implication that it showed no fear of man doubtless contributed to its downfall. Very little is known of its habits but it seems likely that it required well-wooded territory where it probably fed upon fruit, seeds and buds. The species is known to have inhabited Peel Island (Chichijima) and Nkondo-shima and it probably lived on other islands of the Bonin group.

There seem to be only three specimens of the species in existence. One belongs to the Natural History Museum, London, a second is in St Petersburg and the third is in Frankfurt.

*Columba versicolor* Kittlitz, 1832  
*Kupfer. Nat. Vog.* 1: 5.

### Ryukyu Woodpigeon

*Columba jouyi*

This species, closely related to the last, occurred on the Ryukyu and Daito Islands, another of the island groups to the south of Japan. It was last recorded on the Daito Islands during 1936. Although certainly extinct on Okinawa where it was last seen in 1904, the species may possibly cling to existence on some of the smaller islands. Like its relative it appears to have required heavily forested country.

Nothing is known of the bird in life and reasons for its disappearance are unclear.

*Columba jouyi* Stejneger, 1887  
*Amer. Nat.* 21: 583.

### Passenger Pigeon

*Ectopistes migratorius*

The celebrated Passenger Pigeon has, perhaps, the most extraordinary story of any extinct bird. It may once have been the most numerous bird on Earth, and at the start of the nineteenth century vast flocks of this species blackened American skies. Yet during the course of 100 years the tremendous numbers dwindled until just a handful of birds remained. The last individual of all, a female named Martha, died in her cage at the Cincinnati Zoological Gardens at 1:00 p.m. on 1st September 1914.

Early descriptions of the massed flights of the Passenger Pigeon are remarkable. In 1759 a certain Peter Kalm wrote:

*Columba migratoria* Linnaeus, 1766  
*Syst. Nat.* 12: 285.

In the spring of 1749...there came from the north an incredible number of these pigeons to Pennsylvania and New Jersey. Their number, while in flight, extended 3 or 4 English miles in length, and more than one such mile in breadth, and they flew so closely together that the sky and the sun were obscured by them, the daylight becoming sensibly diminished by their shadows.

The big as well as the little trees...sometimes covering a distance of 7 English miles, became so filled with them that hardly a twig or a branch could be seen which they did not cover...when they alighted on the trees their weight was so heavy that not only big limbs and branches were broken straight off, but less firmly rooted trees broke down completely under the load. The ground below the trees where they had spent the night was entirely covered with their dung, which lay in great heaps.

During the 1830's John James Audubon penned his famous account:

The air was literally filled with pigeons, the light of noonday was obscured as by an eclipse; the dung fell in spots not unlike melting flakes of snow...pigeons were still passing in undiminished numbers and continued to do so for three days in succession.

**Bonin Woodpigeon**  
*Columba versicolor*

*Gallicolumba ferruginea*

**Mauritius Blue-pigeon**  
*Alcedo nitidissima*

**Plate F8**

These vast and spectacular flights rendered the Passenger Pigeon vulnerable in a quite remarkable way. So easy was it to shoot the birds that one simply had to point a rifle skywards and repeatedly pull the trigger. Hunting competitions were organized and for one of these it is known that a haul of more than 30,000 dead birds was necessary to claim a prize. With many hands turned against it there is little wonder that Passenger Pigeon numbers began to fall drastically.

However, it is simply not possible to shoot such a numerous species out of existence. It seems that there were additional factors and that these factors centered around the species' need to operate in such vast groups. The birds moved around nomadically, looking for rich crops of beechmast, acorns or chestnuts, and when an exceptionally good site was located the birds were attracted in huge numbers. The forests were steadily depleted, however, and so good crops became fewer and farther between. To compound this, so many thousands of pigeons were shot that their scouting capacity dropped, making it even more difficult for them to locate adequate food supplies. Once numbers had fallen below a certain level, even though that level may have been incredibly high, the Passenger Pigeon was doomed as a species. Clearly this was a creature that could only survive in huge numbers. The critical figure may have been a million individuals, it may have been twenty million; we shall never know. But at some point during the mid-nineteenth century, the figure was passed and

from that moment onwards the species was spiralling downwards to extinction. The decline became apparent during the 1870's. At the start of this decade the flocks seemed as healthy as ever, but by its end the ranks were noticeably thinned and by the end of the century the species was virtually gone from the wild, leaving only a few individuals in captivity. It seems that the decline was accelerated too by an outbreak of Newcastle disease, a paramyxoviral disease that attacks the digestive tract and nervous system, and is known to affect domestic poultry as well as many species of wild bird.

The Passenger Pigeon was quite unlike most other pigeons. Its body was beautifully streamlined, with a small head and long, pointed wings and tail. This body design allowed the bird to fly with great swiftness and agility. When wheeling, dropping or rising in the air, the beautiful, yet subtly marked, plumage would flash spectacularly in the sun.

Naturally, such enormous numbers had a marked effect on the vegetation. The birds ate acorns and nuts of all kinds as well as fruit, grain, insects and other invertebrates.

When they nested they did so in colossal colonies and sometimes these extended for many kilometres. Nesting sites of 65 km were recorded and it is estimated that 16 km by 5 km were characteristic. The nest was flimsily made from twigs, and one white egg was laid. The peak breeding period occurred in April and May, although breeding could take place at any time between March and September. Both parents helped with the incubation, and the single chick was cared for by the adults until it was around two weeks old. Then, suddenly, the old birds would depart leaving the fat chick abandoned and crying in the nest. After a while the baby bird would drop to the ground and a day or two later it would take to the air and leave.

## Liverpool Pigeon

### *Caloenas maculata*

Two hundred years ago there were two specimens of this species in existence. Now there is just one. No-one knows where it came from or when it was collected, although this was certainly at some time during the last half of the eighteenth century. The specimen is now in the collection of the Liverpool Museum, and it has been there since 1851, when it was bequeathed to the people of Liverpool by Edward Stanley the 13th Earl of Derby.

Stanley was one of the great collectors of the nineteenth century, a period that is rightly celebrated for the collecting zeal that inspired so many rich men. Not only did he collect preserved birds and other animals, he also collected live ones, and the menagerie he put together in the grounds of his home, Knowsley Hall, became famous throughout Europe. The Earl collected hundreds of pictures and albums of pictures relating to natural history and commissioned the famous artist Edward Lear to paint portraits of the animals in his menagerie. He assembled a magnificent library and acquired two copies of what is now the world's most valuable illustrated book, Audubon's *Birds of America* (a copy of this work recently changed hands for £8,000,000), one of which he promptly cut up to make a scrapbook featuring pictures of "birds of the world"!

Considering its antiquity, his specimen of the Liverpool Pigeon is in a remarkably fresh state of preservation. In appearance, the bird shows affinity to the widespread Nicobar Pigeon (*Caloenas nicobarica*), but notwithstanding the similarity it is clearly distinct. For reasons that are not entirely clear, the specimen has been overlooked by many commentators and there has been a tendency among those who do know of its existence to regard it as a freak. Few of these have actually seen it, however.

It is assumed that the specimen was brought back from an expedition to the South Pacific and that the species inhabited a Pacific island – but this is just a guess. Obviously, nothing is known of the living bird.

*Columba maculata* J. F. Gmelin, 1789  
*Syst. Nat.* 1(2): 780.

## Tanna Ground-dove

### *Gallicolumba ferruginea*

The Tanna Ground-dove is known today from just a single, rather crude, painting by Georg Forster that was produced during Captain Cook's second voyage around the world. This painting is in the Forster portfolio at the Natural History Museum, London, and in the margin the following words are inscribed:

Tanna, female, 17th August 1774.

Nothing more is known of the species. A specimen of it did once exist although this, like the species itself, vanished long ago. Concerning the events of 17th August Georg Forster's father, Johann Reinhold, made this spare record:

I went ashore, we shot a new pigeon and got a few plants.

*Gallicolumba ferruginea* J. R. Forster, 1844  
*Descr. Anim.*: 265. (Published posthumously).

The island of Tanna is one of the islands of Vanuatu, and for many years it had an ugly reputation on account of the ferocity of the native inhabitants. For this reason it was seldom visited during the nineteenth century, and at some time during that period the native pigeon seems to have passed away.

### Mauritius Blue-pigeon

*Alectroenas nitidissima*

*Columba nitidissima* Scopoli, 1786  
*Deliciae Florae Faunae Insubricae* 2: 93.

When the first Dutch mariners landed on Mauritius, they were hungry after weeks at sea on meager rations. Naturally, they caught Dodos and ate them. Soon, however, they tired of the rather tough meat on these easily caught creatures and turned their attentions to smaller, tastier birds. Among those that they mentioned particularly were small pigeons and these seemed to provide a welcome alternative to the cloying flesh of the Dodos. A remarkable pair of illustrations drawn in Mauritius and dating from 1601 show a dead individual of the species. It is in the journal, or log, of one of the first Dutch ships to visit Mauritius and, although anonymous, the pictures are brilliantly and expressively rendered. This journal is now kept at the Rijksarchiv in the Hague and it relates to the voyage of the ship *Gelderland*.

Despite the existence of the journal, almost two hundred years were to pass before the species was formally described and brought to zoological attention. In 1782 Pierre Sonnerat mentioned a specimen of the bird that he had collected in 1774, during his extensive travels to the East. However, as he did not adhere to the Linnaean principle of scientific naming, it was left to Giovanni Antonio Scopoli some four years later to give it its scientific name.

This striking pigeon, with strange wax-like, elongated head and neck feathers, is now represented in the world's museums by just three specimens, one in Mauritius itself, one in Paris and one in Edinburgh. The living bird, with its peculiar headdress and beautiful colouring, must have been a remarkable sight, contrasting markedly with the three dingy, antiquated stuffed examples that survive. These specimens date from the last part of the eighteenth century and the first decades of the nineteenth, the most recent having been collected in 1826. Soon after this date the species seems to have become extinct. Given the early disappearance of so many Mauritian birds it is perhaps surprising that this pigeon lasted so long.

Julien Desjardins, a specimen dealer who spent many years on Mauritius and who received the 1826 specimen, provided the only information of the bird in life. He described how it lived alone near riverbanks and fed on fruit and freshwater molluscs.

### Rodrigues Pigeon

*Alectroenas rodericana*

*Columba rodericana* Milne-Edwards, 1874  
*Ann. Sci. Nat. Zool. Ser. 5, no. 19*: 14.

This species is known from bones discovered on Rodrigues during the 1870's and described by Alphonse Milne-Edwards, the celebrated expert on fossil birds at the Paris museum. Milne-Edwards described the species primarily on the evidence of a sternum, and chose to assign it to the genus *Columba*, whereas later researchers have shown an inclination to place it in the genus *Alectroenas*, alongside the extinct pigeon of Mauritius *Alectroenas nitidissima*. Either designation may be correct.

This is another of those rather mysterious birds that seem to have been observed in life by the Huguenot refugee François Leguat. He wrote:

The pigeons here are somewhat less than our own [European pigeons] and all of a slate colour, fat and good. They perch and build their nests upon trees; they are easily taken being so tame, that we have had fifty about our table to pick up the melon seeds which we threw them, and they lik'd mightily...they never built their nests in the Isle, but in the little Islets that are near it. We suppos'd 'twas to avoid the persecution of the rats, of which there are vast numbers in this Island.

Presumably this description can be correlated with the evidence of the bones. Leguat's account clearly indicates two factors that contributed to the species' extinction – tameness and the depredations of rats.

## PSITTACIFORMES

A great many parrots are threatened with extinction or are in serious decline. Partly this is due to the vulnerability of island forms, for many parrots are inhabitants of small islands, but partly, and paradoxically, it is due to their great popularity. For

**Norfolk Kaka**  
*Nestor productus*

**Black-fronted Parakeet**  
*Cyanoramphus zealandicus*

**Raiatea Parakeet**  
*Cyanoramphus ulietanus*

**Newton's Parakeet**  
*Psittacula exsul*

**Cuban Macaw**  
*Ara tricolor*

**Carolina Parakeet**  
*Conuropsis carolinensis*

**Mascarene Parrot**  
*Mascarinus mascarinus*

centuries man has been unable to resist the temptation to interfere with populations, move them about and keep individuals as pets.

Nine extinct species are dealt with herein. Two others have already been considered “Almost certainly Extinct” in HBW, and so are not covered here, although elsewhere they have been listed by the present author as extinct (see Fuller, 2000a). These are the Paradise Parrot (*Psephotus pulcherrimus*) and the Glaucous Macaw (*Anodorhynchus glaucus*). There is much negative evidence to show that both are extinct, but perhaps there remains a very small chance that they survive (HBW 4, pages 382 and 419).

The names of a number of what can only be termed “hypothetical” parrot species sometimes occur on lists of the extinct. Among these are several amazons and macaws alleged to come from the West Indies that were described by nineteenth and twentieth century ornithologists on the basis of written reports made by travellers in earlier centuries. The problems with these reports are twofold. First, they are usually vague; second, parrots have been moved around so much by humans that a sighting of an unexpected parrot on one island need not signify a new species. These names cannot, therefore, be accepted as valid.

## PSITTACIDAE

### Norfolk Kaka

### *Nestor productus*

*Nestor productus* Gould, 1836  
*Proc. Zool. Soc. London* **1836**: 19.

This is one of these forms that can be interpreted either as a subspecies or as a full species in its own right. In this particular case interpretation is a subjective commodity and each of the interpretations has its merits.

The Kaka (*Nestor meridionalis*) is a relatively well-known representative of the New Zealand avifauna, widely distributed, although nowhere plentiful, on both main islands and on a number of smaller offshore islands. It is a fairly stocky parrot of medium size with striking but quite variable plumage.

Until around the middle of the nineteenth century a closely related bird occurred on Norfolk Island and its close neighbour Phillip Island, both of which lie in the Tasman Sea almost half way between New Zealand and Australia. The plumage of the Norfolk and Phillip Island birds is somewhat different to those from New Zealand, but it seems quite likely that the two could have interbred, had they come into contact. However, the two forms have acquired a fairly separate identity in ornithological literature and if museum specimens are compared it is quite easy to tell them apart – even without reference to locality data.

All birds on Norfolk Island were badly affected by the establishment of penal settlements for criminals transported from Britain. These were founded during the last decade or so of the eighteenth century and they were used during the first few decades of the nineteenth. There is no doubt that convicts and early settlers entirely disrupted the peace and tranquility of the island and the large, brightly coloured parrots would have made a very tempting target. Norfolk Kakas were probably caught primarily for food but there is no doubt that they were also taken as pets. The famous ornithological writer John Gould saw one in Sydney during his visit in the late 1830's and the last individual of all may well have been a bird that died in its cage in London in 1851, or soon after.

Almost nothing is known of the bird in the wild. Apparently it nested in holes in trees and laid up to four eggs. It frequented the rocks and the tree tops, was very tame, as might be expected in an island form, and was seen feeding on blossoms. The population seems to have been prone to a strange deformity of the beak.

As far as is known these parrots were first extirpated on Norfolk Island, and held out for a little longer on Phillip.

### Raiatea Parakeet

### *Cyanoramphus ulietanus*

*Psittacus ulietanus* J. F. Gmelin, 1788  
*Syst. Nat.* **1(1)**: 328.

This is another of the species known only from the records and specimens brought back by those who sailed with Cook on his three exploratory voyages around the world.

There is some doubt over which particular expedition encountered this bird, but it seems likely that the encounter took place when naturalists of the third voyage called at Raiatea (then called Ulietea) in the Society Islands of the South Pacific, during November 1777. At least two specimens were collected and these are now in the Natural History Museum, London and the Naturhistorisches Museum, Vienna.

Nothing is known of the species, nor can any realistic reasons be advanced for its extinction which, presumably, took place soon after Cook's last voyage, for the birds were never encountered again. Perhaps they were unable to withstand the attacks of introduced mammals or maybe man's meddling with parrots was a factor.

**Black-fronted Parakeet***Cyanoramphus zealandicus*

Like the Raiatea Parakeet, this was another inhabitant of the Society Islands, but as far as is known this particular species was restricted to Tahiti.

Both species are closely related to the well known *Cyanoramphus* parakeets of New Zealand but they are physically separated from these by 3220 km of open sea. Probably, they had quite similar lifestyles although this cannot be confirmed as there are no records concerning the two extinct species.

Again like the Raiatea Parakeet, this species was first brought to light by naturalists who sailed with Cook, although in this particular case it was also recorded by a few later visitors.

A painting by Sydney Parkinson, made during Cook's first voyage, is kept at the Natural History Museum, London, and there are also a handful of specimens in existence – one in London, two in Liverpool, one in Paris and one in Perpignan.

The last record of the species dates from 1844, but nothing is recorded of the bird in life.

*Psittacus zealandicus* Latham, 1790  
*Index. Orn.* 1: 102.

**Newton's Parakeet***Psittacula exsul*

A greyish-blue parakeet belonging to the familiar ring-necked group once lived on the Mascarene island of Rodrigues. Curiously, it survived for much longer than most of the endemic bird species of the island. Certainly, individuals were still alive during the 1870's, although it is clear that all were gone soon after that.

Little is known of the species but it seems that the two early chroniclers of the birds of Rodrigues, François Leguat and the anonymous author who is usually considered to be a certain Monsieur Tafforet, both saw this species and made observations of it. Certainly, both authors mention parakeets. One complication of these early reports is that Leguat mentioned seeing green as well as blue parakeets. There may have been different colour morphs of the species or the two colours might be explained by the occasional arrival of storm-blown individuals belonging to the more familiar *Psittacula* species. Possibly, such individuals could interbreed with the endemic birds. In addition to these complicating factors, there is skeletal evidence to show that more than one parakeet species once inhabited the island.

Leguat and his followers saw birds – presumably Newton's Parakeets – feeding on the nuts of an olive-like tree, and they taught some of these parakeets to speak, surely an indication of just how tame such birds were. Apparently they became bi-lingual; they could speak in both French and Flemish! When Leguat and his little band of followers fled the island they took a parakeet with them on their voyage to Mauritius.

Although the species was obviously common during the period of Leguat's visit (1691), it was rare by the nineteenth century. Just two specimens are known and both are in the collection of the University Museum of Zoology, Cambridge. Both were collected during the 1870's, the last on 14th August 1875.

The reasons for extinction are unknown, but it is likely that the bird's original tameness and the infestation of the island by mammals were primary causes.

*Palaeornis exsul* A. Newton, 1872  
*Ibis Ser.* 3, no. 2: 33.

**Mascarene Parrot***Mascarinus mascarinus*

Like the preceding species, just two specimens of this striking, middle-sized parrot exist. One is in Paris, the other in Vienna. Both probably date from the last years of the eighteenth century or the early years of the nineteenth. A record of an individual surviving in a European aviary until 1834 (see Hahn, 1841) is now considered to be false.

Very little is known of the species other than the fact that its home was the Mascarene island of Reunion. Why it vanished and when is not known but it can be assumed that it became extinct during the first decades of the nineteenth century.

*Psittacus mascarin.* Linnaeus, 1771  
*Mantissa:* 524.

**Broad-billed Parrot***Lophopsittacus mauritianus*

Pictures drawn by Dutch explorers visiting the island of Mauritius during the early seventeenth century clearly show a rather strange and aberrant parrot, and these pictures can be correlated with bones found on the island. The bones, like the pictures and a few contemporary written descriptions, indicate the former existence of a large-headed parrot.

Apart from the fact that such a bird once existed, little can be meaningfully said of it. It certainly still lived during the early seventeenth century, but it probably became extinct not long afterwards. It may have lasted until the last decades of the seventeenth century or it may have been lost well before this.

*Psittacus mauritianus* Owen, 1866  
*Ibis Ser.* 2, no. 2: 168.

### Plate F10

#### Broad-billed Parrot *Lophopsittacus mauritianus*

Broad-billed Parrots on Mauritius. The exact appearance of this species is unknown, but skeletal remains and early accounts permit a degree of confidence in this reconstruction by Julian Hume. Also pictured are Mauritius Parakeets (*Psittacula echo*), currently listed as Critically Endangered.

#### Rodrigues Parrot

#### *Necropsittacus rodericanus*

*Psittacus rodericanus* Milne-Edwards, 1867  
*Ann. Sci. Nat. Zool. Ser. 5, no. 8:* 151.

A parrot comparable in size to a large cockatoo with an outsize beak once inhabited the island of Rodrigues. An almost complete skull of this creature has been found and this relic can be matched with an account in the anonymous document – written around 1725 – known as the *Relation de l'Île Rodrigue*. This account describes a long-tailed parrot with a large head. The writer suggests that the species was green in colour and lived on islets to the south of the main island. Probably it had been penned back to these refuges on account of the incursions of rats. To find water the parrots had to fly across to the main island of Rodrigues itself, surely an indication that the islets would not have been the birds' first and original choice as a home. Individuals were seen eating small black seeds from a tree that smelled of lemons.

Probably the species became extinct during the late eighteenth century.

#### Cuban Macaw

#### *Ara tricolor*

*Psittacula tricolor* Bechstein, 1811  
*Allgem. Ueb. Vög. 4:* 64.

This distinctive and beautiful macaw, around a third smaller in size than its largest relatives, was an inhabitant of the island of Cuba.

The most recent record of a living bird comes from La Vega, close to the Zapata Swamp, where an individual was killed during 1864. It is thought that a few birds survived for a decade or two after this date, but there is no actual proof of this. Presumably, the species' decline was due to human interference: the taking of birds for food or their capture as pets.

Although it has a very distinctive identity, almost nothing is known of the species in life. It is assumed that its habits were similar to those of its more familiar, extant relatives.

Attempts have been made to create artificial Cuban Macaws by selectively breeding their near relatives. Some parrot fanciers have claimed that a degree of success has been achieved but the word of many parrot breeders is notoriously unreliable – and in any case such created creatures would have little, if any, real connection with the actual species.

#### Carolina Parakeet

#### *Conuropsis carolinensis*

*Psittacus carolinensis* Linnaeus, 1758  
*Syst. Nat. 10:* 97.

*C. c. ludovicianus* (J. F. Gmelin, 1788)  
*Syst. Nat. 1(1):* 347.

The Carolina Parakeet, like its compatriot the Passenger Pigeon, declined from vast numbers to just a few individuals within the period of a century. This was once considered a pest species, with communal feeding habits, that ranged across the southern and eastern USA. It ruined orchards, wrecked corn fields, destroyed grain stocks and thereby aroused the anger of man. The species seems to have had few defensive skills. When individuals were shot, their companions would fly squawking above the dead or wounded and eventually they would settle among their downed fellows. Naturally, they then made easy targets themselves.

A parrot having the capability of inhabiting the USA is in itself something of a peculiarity, and there are surprising records of this species flying over snow-covered fields. In the years of its abundance the species liked forested lowland and showed a preference for land close to water. It lived mostly among buttonwood, cypress or sycamore and roosted in hollow stumps into which individuals would crowd and cluster together. At dawn the birds would flock to the top branches of the trees and then they stayed quiet for much of the day. Late afternoon and early evening would see great bursts of activity. When the birds decided to eat they would fly swiftly down to the chosen feeding area and arrive in a blaze of colour.

As far as breeding is concerned, there are conflicting descriptions. Some records tell of several parakeets laying their eggs together in tree holes, while others indicate that fragile nests were made from twigs and that these were sited in the forks of branches.

Two races of the species are commonly recognized, the nominate form and a western subspecies named *ludovicianus*. These two races are rather poorly distinguished, however.

Through much of the nineteenth century the Carolina Parakeet was a particularly common bird. Even as late as the 1880's it could be found in some numbers. Yet soon after this the species could hardly be found in the wild at all.

As the century drew to its close, a few individuals still survived in captivity, most particularly a group in the same Cincinnati Zoo that provided a home to the last Passenger Pigeon. The very last Carolina Parakeets were a pair named Lady Jane and Incas, and by 1917 these two birds had been cage-mates for something like 32 years. Then, Lady Jane died, leaving Incas the sole representative of the species. He survived, alone, for just a few months until February 1918, when he died in his cage surrounded by his keepers. They were in unanimous agreement: their bird had died of grief. His little body was frozen in a block of ice and sent for preservation to the Smithsonian Institution in Washington but, curiously, it never arrived or, if it did, it was stolen. Perhaps this hardly matters; there are several hundred specimens of this species in the world's museums.

There are several alleged late records dating from the 1920's and 1930's that supposedly relate to Carolina Parakeets still surviving in the wild, but these are probably bogus.

## CUCULIFORMES

Delalande's or the Snail-eating Coua (*Coua delalandei*), a large, ground-dwelling cuckoo-like bird from Madagascar is almost certainly extinct, and has already been covered thus in HBW (see HBW 4, page 581). It has not been definitely recorded since 1834 but partly because rumours of its continuing existence circulated during the 1920's, there has been reluctance in some quarters to add the species to the ranks of the extinct.

## STRIGIFORMES

The Laughing Owl (*Sceloglaux albifacies*) of New Zealand is usually considered to be extinct but for the purposes of HBW the optimistic view has been taken that there is still a remote chance of its survival (see HBW 5, page 239). It has not been reliably recorded since the early decades of the twentieth century, however, and more recent reports are probably false.

It seems clear that at least two now-extinct owl species occupied the Mascarenes during recent historical times, but only one of these has left definitive specimen material behind, and is discussed below. The other has come to be known as *Otus commersoni*. A fairly detailed description of this creature was made by the naturalist/dealer Julien Desjardins, who saw a dead specimen during 1836, and there is a drawing of what seems to be the same species made by one Philippe Sanguin de Jossigny around 1770. This was a largish owl with ear tufts that inhabited the island of Mauritius. Since there is no remaining specimen material of any kind, it is impossible to assign this form to any particular owl group. Other claimed owl species from the Mascarenes were named as *Bubo leguati*, *Strix sauzieri* and *Strix newtoni*, but these forms must be considered even more hypothetical.

Figure 7. *Otus commersoni*, as drawn by Philippe Sanguin de Jossigny around 1770.

## STRIGIDAE

### Rodrigues Little Owl

*Athene murivora*

*Athene murivora* Milne-Edwards, 1874  
*Ann. Sci. Nat. Zool. Ser. 5, no. 19:* 13.

The anonymous author of the *Relation de l'Île Rodrigue* (c. 1725) mentions a small owl that preyed on little birds and lizards and could be heard calling in fine weather.

This brief account is often correlated with some fairly fragmentary skeletal material that was found on the island around a century and a half later. This correlation is, of course, a little tenuous but it is by no means unreasonable.

The skeletal remains were assigned to the genus *Athene* by the celebrated French comparative anatomist Alphonse Milne-Edwards who, during the last decades of the nineteenth century was the leading expert in fossil and sub-fossil birds. Unfortunately, his suggestion that the remains could be assigned to *Athene* may not be correct. First, the remains by no means represent a complete specimen. Second, the *Athene* species with which Milne-Edwards compared the Rodrigues material has more recently been reassigned to the genus *Ninox*. This highlights the difficulty of making judgements when assessing incomplete skeletal material. What the evidence of the bones does show is that this species had legs of particular strength and length for an owl of this rather small stature. It can be deduced, therefore, that it was more terrestrial than most owls.

The reasons for its extinction are unknown, as too is the time of this event.

## CAPRIMULGIFORMES

The Jamaican Poorwill (*Siphonorhis americana*), not definitely recorded since the 1860's, is often treated as extinct, but the secretive nature of nightjars, in conjunction with recent observations of "unidentifiable" nightjars in remoter parts of the island, give some cause for hope to persist (see HBW 5, page 344). Optimists take heart from the recent rediscovery of the New Caledonian Owlet-nightjar (*Aegotheles savesi*), not definitely recorded since 1880 (or perhaps 1915) until rediscovered in 1998.

## APODIFORMES

Although the hummingbirds (Trochilidae) make up a rather homogeneous family, their classification is a very complex matter. Just a small part of the problem is that there are a great many taxa described from single or few specimens of doubtful provenance, a number of which have subsequently been reclassified as hybrids or aberrant individuals. One of the problems with describing a species from just a single individual is that it can be so easy to misunderstand the true nature of that example.

One such case is that of a form recently described as the Bogota Sunangel (*Helianthus zusii*), on the basis of a specimen that was purchased in Bogotá, Colombia, in 1909 and is now in Philadelphia. Many hummingbird specialists are not inclined to accept it as a valid species, reckoning it probably to be a hybrid, though there is much dispute as to its claimed parentage! Another poorly known form sometimes listed as a threatened species, but recently reported to be probably of hybrid origin, is the Tachira Emerald (*Amazilia (Polyerata) distans*). In such cases, taxonomic difficulties override the debate as to whether or not such forms are extinct. One apparently extinct form has, however, received somewhat more widespread acceptance as a valid species.

## TROCHILIDAE

### Brace's Emerald

*Chlorostilbon bracei*

*Sporadinus Bracei* Lawrence, 1877  
*Ann. New York Acad. Sci. 1:* 50.

Although there is indeed fairly general acceptance of Brace's Emerald as a valid species, the same doubts hang about it as in the aforementioned cases, and the present author considers it to be a rather poorly established species. However, a number of hummingbird experts have spoken in its favour and in line with the designations of these specialists it is included here.

In fact, there is very little that can be meaningfully said of it (see HBW 5, page 533). The single known specimen was collected in July 1877 and was apparently

found on New Providence in the Bahamas. No such bird had ever been seen there before, and there is a reasonable possibility that it may have been a wind-blown vagrant. There has been an attempt to correlate fossil remains found on the island with the preserved skin, but any attempt to make proper sense of tiny hummingbird bones amongst the mass of valid taxa described is really perhaps asking too much.

## CORACIIFORMES

The large and diverse order Coraciiformes includes the kingfishers (Alcedinidae), and in this family is a very poorly known form that may constitute an extinct species. This is a bird rather similar to the Micronesian Kingfisher (*Todiramphus cinnamominus*) and known as the Ryukyu Kingfisher (*Todiramphus* (c.) *miyakoensis*) after the islands to the south of Japan that it presumably inhabited. Unfortunately, it is one of those creatures known only from a single specimen, taken in 1887, and this extreme limitation makes interpretation difficult, especially as the bill colour is not known. It is probably either an extinct species or an extinct subspecies; either interpretation has its merits. However, there is also some doubt as to whether it might have been brought to the islands by chance vagrancy or through human intervention, or indeed that it might be a mislabelled specimen, so any systematist is in a difficult position in trying to decide. An interesting, if rather sad, related case is that of the nominate race of the Micronesian Kingfisher, endemic to the island of Guam: it is now probably extinct in the wild there, although it still survives in captivity.

## PICIFORMES

There are two species in this order that are probably extinct, although optimists still express hope for their survival. These are the Imperial Woodpecker (*Campephilus imperialis*) and its celebrated relative the Ivory-billed Woodpecker (*Campephilus principalis*). Both are dealt with elsewhere in this volume (see page 534).

## PASSERIFORMES

As might be expected, an order as vast as the Passeriformes contains quite a number of extinct species. In all, 26 are covered herein. In addition there are two species that are often regarded as extinct and that in all probability are. These are the Bush Wren (*Xenicus longipes*) and the Aldabra Brush-warbler (*Nesillas aldabrana*). Despite relatively recent records of each, in 1972 and 1983 respectively, there is only a remote chance that either survives. Both species will be fully covered in HBW in due course.

Several other species hover around the very brink of extinction. Gurney's Pitta (*Pitta gurneyi*) is one such species and, despite great conservation efforts over the last

15 years, it could be gone by the time this volume is published. So too could the Po'o'uli (*Melamprosops phaeosoma*), a species that at the time of writing seems to have only three surviving representatives, all of which are males! Another Hawaiian bird for which there is very little hope is the Molokai Creeper (*Paroreomyza flammea*), last recorded in 1963 and probably now extinct.

On the brighter side, the Four-coloured Flowerpecker (*Dicaeum quadricolor*), once confidently considered extinct, was recently rediscovered, but its hold on survival is very tenuous and it could vanish at any time. Similarly, the Sao Tome Grosbeak (*Neospiza concolor*), not recorded since 1888 until rediscovered in 1991, is presumed to survive with only a tiny population that urgently needs safeguarding.

## ACANTHISITTIDAE

### Stephens Wren

### *Xenicus lyalli*

*Traversia lyalli* Rothschild, 1894  
*Bull. Brit. Orn. Club* 4: 10.

Although so tiny in size the Stephens Wren was an altogether remarkable creature. It may have had the smallest natural range of any known bird. It may have been the only flightless passerine. It may have been the only creature discovered and then exterminated by a single animal – a lighthouse keeper's cat.

During 1894 this single domesticated predator brought to its owner a series of tiny corpses. These grisly little events occurred on the small island of Stephens lying in the Cook Straits, the channel that separates New Zealand's North Island from the South. The lighthouse keeper in question – a Mr Lyall, after whom the species is scientifically named – was something of an amateur ornithologist. He preserved the specimens and, realizing that the birds might be rather unusual, passed them on to a dealer. Soon the majority of them were shipped to Europe where most were bought by Walter Rothschild, the celebrated natural-history collector, who was then busy assembling his wonderful museum at Tring in Hertfordshire, England. Thus, *Xenicus lyalli* became known to science. By the time its existence was broadcast to the world, via the ornithological journal *Ibis*, the species was already extinct. The cat had stopped bringing in dead specimens and the birds were never seen again. It seems likely that forest clearance for the construction of the lighthouse, in 1894, may also have made a significant contribution to the bird's demise.

The only human observation of Stephens Wrens was made by the lighthouse keeper himself. He saw the birds twice, both times in the evening. Disturbed from holes among the rocks, they ran fast in the dusk, like mice. They never tried to take to the air and this suggestion of flightlessness is borne out by the poorly developed wings which indicate weak flight at best.

Skeletal remains of what seems to have been a flightless wren have been found on the New Zealand mainland. Some writers believe that this proves that Stephens Wrens were once widespread in New Zealand and that the birds discovered during 1894 were simply a relict population, but it seems far more likely that the skeletal remains come from a similar but quite separate creature. There are a number of objections to the case for the Stephens Wren being associated with the mainland skeletal remains. First, what material were the bones compared with? Second, how did a wren that was flightless, or almost so, manage to reach Stephens Island?

Sir Walter Buller (1905), the great chronicler of New Zealand birds, quoted from a correspondent of *The Canterbury Press* who had written the following:

And we certainly think that it would be as well if the Marine Department, in sending lighthouse keepers to isolated islands where interest-

Plate F12

inches 2  
cm 5

Stephens Wren  
*Xenicus lyalli*

ing specimens of native birds are known or believed to exist, were to see that they are not allowed to take any cats with them, even if mouse-traps have to be furnished at the cost of the state.

## TURDIDAE

### Bay Thrush

### *Turdus ulietensis*

This is another of those species known today only from a painting by Georg Forster. This painting, now in the collection of Sir Joseph Banks and wrote a description of it for his book *General Synopsis of Birds* (1781-1785), giving it the name "Bay Thrush". Latham was a pioneering ornithologist, but headstrong, and in his early works he simply gave common English names to the birds he described, deliberately ignoring the fast-gaining Linnaean system of scientific naming. By the time he realized his mistake, he was too late: the lapse had left the field open for Johann Friedrich Gmelin, who in the meantime had produced his own book *Systema Naturae* (1788-1789), just a few years after Latham's. Gmelin attached scientific names to many of the birds that Latham had originally described and, because of this, it is Gmelin's name that is associated with so many of Latham's original descriptions.

*Turdus ulietensis* J. F. Gmelin, 1789  
*Syst. Nat.* 1(2): 815.

Although no actual specimen is in existence, there was one once, and presumably this was the bird from which the picture was painted. The ornithological writer John Latham saw it in the collection of Sir Joseph Banks and wrote a description of it for his book *General Synopsis of Birds* (1781-1785), giving it the name "Bay Thrush". Latham was a pioneering ornithologist, but headstrong, and in his early works he simply gave common English names to the birds he described, deliberately ignoring the fast-gaining Linnaean system of scientific naming. By the time he realized his mistake, he was too late: the lapse had left the field open for Johann Friedrich Gmelin, who in the meantime had produced his own book *Systema Naturae* (1788-1789), just a few years after Latham's. Gmelin attached scientific names to many of the birds that Latham had originally described and, because of this, it is Gmelin's name that is associated with so many of Latham's original descriptions.

Naturally, a species represented in such a flimsy manner as is the Bay Thrush is bound to be surrounded by mystery – and this the Bay Thrush most certainly is. Most importantly, it is by no means sure that the species was actually a thrush. Georg Forster and his father Johann Reinhold were efficient naturalists who sailed with Cook, but when they saw this creature they were rather uncertain of its affinities and described it as a thrush with some degree of reluctance. A particularly un-thrushlike feature was a notch in the bill.

Whatever its precise relationships, this bird seems to have been a valid and distinct species. The reasons for its extinction are entirely unknown but this event must have happened soon after the visit of Cook and the Forsters for no other naturalist ever mentioned seeing the species.

The Forsters themselves gave a few fleeting details about the bird in life. They said it had a soft, fluting voice and lived among thickets in valleys. Apart from these bare facts, nothing is known of the species.

### Plate F13

Grand Cayman Thrush  
*Turdus ravidus*

Kittlitz's Thrush  
*Zoothera terrestris*

### Grand Cayman Thrush

### *Turdus ravidus*

The Grand Cayman Thrush became extinct towards the middle of the twentieth century, but considering the comparative lateness of this date very little is known of it. One of the few things on record is a description of its song, which was apparently rather weak and hesitant, more, perhaps, a subdued warbling than a melodic triumph.

*Mimocichla ravida* Cory, 1886  
*Auk* 3: 499.

As the name indicates, the species came only from the island of Grand Cayman, in the West Indies, where it inhabited dense woodland. It was closely related to a widespread West Indian species, the Red-legged Thrush (*Turdus plumbeus*).

The Grand Cayman birds were large and beautiful grey thrushes that first came to public attention during 1886, when C. B. Cory described the species. He found it to be common on the island, but its decline was to be rapid. By the outbreak of World War I, it was rare and could only be found in remote areas of woodland. No specimens were taken after this time and the last recorded sighting occurred before the start of World War II. Destruction of habitat was probably a key factor in the species' disappearance, as it seemed to need areas of dense woodland.

The last stronghold appears to have been at the eastern end of the island. Severe hurricanes during the years 1932 and 1944 are thought to have played some role in the final destruction of the species.

### Kittlitz's Thrush

*Zoothera terrestris*

*Turdus terrestris* Kittlitz, 1830  
*Mém. Acad. Imp. Sci. St. Pétersb.* **1**: 244-245.

The name of Baron Friedrich Heinrich von Kittlitz is associated with the stories of several extinct birds. During the late 1820's he explored a number of Pacific islands during a round-the-world expedition on a Russian corvette called the *Senjavin*.

In June 1829 Kittlitz landed on Peel Island (Chichi-jima), the largest island in the Bonin group (Ogasawara-shoto). Kittlitz was one of only a very few Europeans to see the Bonins in something approaching their pristine state. Within a few years of his visit, the original ecosystem had been shattered. Just two years after he left, a group of American, British and Polynesian colonists arrived and settled. Then whalers began to call and started to use the Bonins as a suitable place to replenish their stores and careen their vessels. Rats arrived and the devastation of the endemic birdlife was horrendous.

Kittlitz made his landing place at a spot called Port Lloyd that had been visited and named just a year before by a British expedition under the command of a Captain Beechey in *HMS Blossom*. Surprisingly, Kittlitz found a seemingly common bird that the British had entirely overlooked, the handsome ground thrush that now bears his name. During his short stay, Kittlitz saw this bird quite often but no later naturalist ever did. He sailed away, apparently taking four specimens with him, and the bird was never seen again. His specimens are today divided between the museums of Frankfurt, St Petersburg, Leiden and Vienna.

Whether Kittlitz's Thrush occupied other islands in the Bonin group is not known.

## ZOSTEROPIDAE

### Robust White-eye

*Zosterops strenuus*

*Zosterops strenua* Gould, 1855  
*Proc. Zool. Soc. London* **1855**: 166.

So impressed was he by the comparatively large size of this species, for a white-eye, that the famous nineteenth century ornithologist and writer John Gould felt inclined to give this bird the common name of "Robust Zosterops", and this same sensation is perhaps recalled somewhat in the scientific name that he gave it. Gould had developed a considerable interest in the avifauna of Australia and published his celebrated book *The Birds of Australia* between the years 1840 and 1848. It was later, while he was undertaking research for a *Supplement* to this work, that he became aware of this particular species.

The species was endemic to the island of Lord Howe, a tiny piece of land, 11 km long by 1.6 km wide, that lies far out in the Tasman Sea between Australia and New Zealand. During the mid-nineteenth century, when the bird was first identified, it was

Plate F14

Robust White-eye  
*Zosterops strenuus*

found to be common, and the population stayed healthy for the next 60 years or so. Then in 1918, an incident occurred that proved fatal for many of the birds of Lord Howe. A ship, the *SS Makambo*, was accidentally grounded at a site known as Ned's Beach. Black rats (*Rattus rattus*) left the stricken vessel and poured ashore – and the consequences were disastrous. In a very short space of time the white-eyes were gone. A search made just ten years later could find no trace of them.

There are a few records concerning the habits of the species. When it was common it was regarded as something of a pest. It was destructive to fruit and crops, and was even said to suck the eggs of other bird species! Its own eggs were laid during November and December. They were blue and, typically, the clutch consisted of two or three. The nest was cup-shaped and made from rootlets and grasses with a soft lining of disintegrated leaves and other suitable materials.

Curiously, another kind of white-eye lived on tiny Lord Howe. This was a race of the widespread Silvereye (*Zosterops lateralis*), and to distinguish the larger birds belonging to the species *Z. strenuus* local people gave them the name "big grinnels".

## MELIPHAGIDAE

### Kioea

### *Chaetoptila angustipluma*

In terms of extinct birds the Hawaiian Islands are one of the world's black spots. The losses at species and subspecies level have been enormous and there is no sign that this process is letting up. There are several species and races that are unlikely to see out the next decade, such as the Po'o'uli, mentioned above.

Many Hawaiian species are known only from skeletal material, and it is not known when such creatures died out. Perhaps it was comparatively recently, perhaps it was some way back in time. Other species are known just from small series of specimens taken by ornithological collectors during the last decade of the nineteenth century, at which time there was a great spate of scientific interest in the Hawaiian Islands. What can be said with certainty is that the coming of man entirely shattered the ecosystems of the islands. It is clear that the Polynesian arrival had a devastating effect. Although the coming of Europeans, centuries later, probably increased the pace of extinction, the real damage was already done, and the endemic avifauna consisted largely of scattered, fast-diminishing populations.

One such badly affected species was the Kioea, a large and handsome honeyeater. The species was first noticed during the visit to Hawaii of Charles Pickering and Titian Ramsay Peale as part of *The United States Exploring Expedition* of 1838-1842. At the time Peale wrote of it:

It is very active and graceful in its motions, frequents the woody districts, and is disposed to be musical, having most of the habits of a Meliphaga [honeyeater]; they are generally found about those trees that are in flower.

Clearly Pickering and Peale experienced no great difficulty in finding individuals, but the birds were rapidly becoming rarer. In the period leading up to 1859, during which year the last known specimen was taken, a local shopkeeper with an interest in natural history, J. Mills, killed two or three individuals on wooded slopes below the crater of the volcano Kilauea. After Mills's last record, Kioeas were never seen again. Clearly, and notwithstanding the fact that Pickering and Peale located birds reasonably easily, the species was approaching extinction even as it was being discovered.

Four specimens survive today and there may never have been more. Of these, one is in Honolulu, one in New York, one in Washington and one in Cambridge, England.

Apart from the brief account given by Peale, there is almost nothing on record concerning the species' habits. Although Peale described the birds as inclined to be musical, the call was described as a loud "chuck", but this is the sum of additional knowledge.

The species is said to have been an inhabitant of the high plateau between the mountains and the edge of the forest but whether or not this kind of area was representative of the original range cannot be said. Although the Kioea was only ever located on the island of Hawaii, fossil evidence shows that the species was also once present on Oahu and Maui, and it was also claimed to have occurred on Molokai.

### Hawaii 'O'o

### *Moho nobilis*

The ancient kings and princes of Hawaii chose this unfortunate creature to be their "royal" bird. As is so often the case when monarchs choose, being the "chosen" one

*Entomiza angustipluma* Peale, 1848  
*US Expl. Exped.* 8: 147.

*Gracula nobilis* Merrem, 1786  
*Av. Rar. Icon. Descr.* 1: 7.

does not necessarily confer safety – and it definitely did not in this case. The honour merely meant that 'O'os were expected to provide plumes for the famous robes, capes and helmets that are today so prized by ethnologists, but which were once an integral part of the whole culture of pre-European Hawaii. The downfall of the 'O'o lay in the beautiful tufts of yellow feathers that grew below the wings and on the lower abdomen. These were ripped from the living bird and then woven into a bed of coarse netting; gradually, after the unwilling input of many hundreds of individuals, the cloak began to take shape.

After the feathers were stolen from the bird, those who had trapped it were supposed to let it go. Whether or not they did is something of an open question. 'O'os fried in their own fat were, apparently, a great delicacy and it is hard to imagine hungry Hawaiians passing up the chance of a tasty morsel, particularly as any chance of being caught defying the law would presumably be remote. Even if the plumes were carefully removed and the bird released there is no guarantee that it would be capable of surviving, for the shock alone might be sufficient to cause death, but perhaps it could.

The species was first scientifically discovered by naturalists who sailed with Cook on his third voyage around the world. Cook himself did not survive this expedition and was killed at Kealakakua Bay, Hawaii, during February 1779. The voyage itself was completed, however, and when the ships eventually arrived in England specimens of *Moho nobilis* were among the treasures brought back. John Latham in his *General Synopsis of Birds* (1781-1785) described the "Yellow-tufted Bee-eater" from these specimens.

Although the species must once have been common on Hawaii, by the time of the coming of Europeans it was in decline and no European observer described it as anything but shy and wary. No wonder! It was seen to take nectar from flowers but it also

tucked into bananas, as well as insects and their larvae. In flight it showed a dipping action and the wings moved so rapidly that they made a continuous buzzing sound. These birds frequented the topmost branches of the trees and, perhaps as a result of this preference, the nest and eggs were never found, although an experienced ornithologist, R. C. L. Perkins, did see young individuals that were recently out of the nest.

The call was harsh and clear, and from it the name 'O'o is derived. Since there is often confusion, it might be added that the pronunciation of this name should be in the form of two o's separated by a glottal stop, "oh-oh", rather than "oooww".

The records indicate that the species was once widespread over the whole island of Hawaii, as it was evidently able to live at quite high altitudes.

Hunting for plumes obviously depleted numbers, but other factors probably also played a part in bringing about its extinction. Perhaps some kind of avian disease carried to Hawaii by an introduced species was partly responsible or maybe it was just the general breakdown of the ecosystem that was responsible for the species' disappearance.

The last genuine report of the Hawaii 'O'o probably concerns an individual heard singing on the slopes of the volcano Mauna Loa around the year 1934.

### Oahu 'O'o

#### *Moho apicalis*

The main islands of Hawaii each had their own distinctive species of 'O'o. All are closely related but their respective island isolations led to certain clear differences.

The Oahu 'O'o was distinguished chiefly by its strikingly marked black and white tail. Like its relative on Hawaii it sported yellow flank plumes and undertail-coverts.

This was probably the first of the 'o'os to become extinct. A certain Herr Deppe, about whom virtually nothing is known, collected a series of specimens during 1837 from the hills behind Honolulu. Never again was the species encountered or, if it was, no-one ever mentioned it. Specimens do exist for which there is no provenance noted, so it is possible that a later collector found the species. Three that are known to have been taken by Deppe are in the museums of Berlin, Vienna and New York, but in addition to these there is a second specimen in New York, two examples in London, one in Paris, and one in Cambridge, Massachusetts.

Nothing is known of the living bird.

*Moho apicalis* Gould, 1861

*Proc. Zool. Soc. London* 1860: 381.

### Molokai 'O'o

#### *Moho bishopi*

The 'o'o that inhabited the island of Molokai was discovered rather later than the others but it was known to science as an extant species for only a very short period. Towards the end of the nineteenth century there was a sudden surge of interest in the birds of Hawaii, and several teams of collectors ranged over the islands in search of specimens. It is a curious fact that a number of Hawaiian birds are known solely from this period. Clearly the species in question were all at the point of extinction when they were discovered, and were it not for the collecting zeal that inspired these Hawaiian expeditions during the 1880's and 1890's, their existence and passing would probably have gone entirely unnoticed by the world of ornithology. Two beautifully illustrated books resulted from the collections made at this time, *Aves Hawaiiensis* (1890-1899) by S. B. Wilson and A. H. Evans and *The Avifauna of Laysan and the Neighbouring Islands* (1893-1900) by Walter Rothschild, and it is from the words and pictures contained in these books that almost all knowledge of certain lost species is derived.

The Molokai 'O'o provides just such a case. Described in 1893 by Walter Rothschild from specimens procured by men in his pay, it was gone by the early years of the twentieth century, the last definite record coming from the year 1904. A few later sightings were claimed but these may or may not be reliable.

Curiously, and remarkably, the species was reported from the nearby island of Maui during 1981 but this claimed sighting is almost certainly a misidentification. Nevertheless, there is some evidence to show that the species did once inhabit Maui. A certain H. W. Henshaw, who was a very reliable observer, reported seeing an individual during June, 1901.

Virtually nothing is known of the species in life. It differed from the two previous species by showing bright yellow cheek tufts and by carrying a tail with much less white on it.

*Acrulocercus bishopi* Rothschild, 1893

*Bull. Brit. Orn. Club* 1: 41.

### Kauai 'O'o

#### *Moho braccatus*

The fourth species 'o'o clung to survival for much longer than the others. It was also the most divergent of the four. Whereas the other three are very similar looking crea-

*Moho braccatus* Cassin, 1855

*Proc. Acad. Nat. Sci. Philadelphia* 7: 440.

tures that show their close affinity quite clearly, the Kauai 'O'o was comparatively aberrant. By no means so flashy in appearance, it was an altogether more sober-looking bird. Clearly, it was taking a rather different evolutionary path on its home island which is farther west and a little more remote than the other 'o'o islands.

It was probably this very remoteness that enabled the species to survive longer than its relatives, and, although it was extremely rare from the beginning of the twentieth century, a few individuals held out until the 1980's. Their stronghold was a wild place known as the Alaka'i Swamp, a wet montane plateau broken up by ravines.

This area acquired something of a worldwide celebrity as a natural refuge for endangered birds and several rare species and races clung to existence here and nowhere else. Although it provided a sanctuary of sorts for many years, the Alaka'i Swamp was not in itself enough to save the Kauai 'O'o. The small colony that had established itself there dwindled slowly until by 1981 it seemed that just a pair survived. The female of this pair disappeared during 1983 as a result of the devastation caused by Hurricane Iwa. The male continued to be seen until 1985. A rather evocative photograph of this individual exists. It was taken by Hawaiian bird expert H. Douglas Pratt and shows the bird sheltering forlornly in the branches of a tree. The flute-like call of this bird may have been heard during 1987 but the bird itself was never seen again.

Although the Kauai 'O'o managed to linger on until comparatively recently, its main decline was remarkably rapid. George Munro, a man who spent much of a very long life studying Hawaiian birds, recorded that in 1891 the species was common and occurred from sea-level right up to the mountain tops. In 1899 he left the island and did not return for 29 years, but when he did finally go back, he failed to see or hear a single individual.

## CALLAEATIDAE

### Huia

### *Heteralocha acutirostris*

*Neomorpha acutirostris* Gould, 1837  
*Synop. Birds Australia* 1: pl. 11.

Perhaps the most celebrated of extinct passerines is the Huia (pronounced hoo-ee-ah). This strange, funereal-looking creature fascinated all of those who came into contact with it. First, it caught the imagination of the Maoris, who accorded it a special place in the natural order of things. Among the great treasures of ethnology are items known as *waka-huias*. These are intricately carved wooden boxes that the Maoris made expressly to hold the black tail feathers with white tips that characterized the Huia. To this war-like people the feathers themselves held an almost magical significance. They were worn in battle, given as tokens of friendship or respect, and mourned over in times of grief.

After the European invasion of New Zealand, the birdlife came under intense scrutiny and no species fascinated ornithologists more than the Huia. This was probably largely due to a unique peculiarity of the Huia's anatomy. The beak of the male differs markedly from that of the female. At first sight this might not seem of any particular importance but no other known bird species shows a comparable difference: although

Plate F16

plumages may vary vastly between the sexes, beaks are always fairly similar. In the case of the Huia, however, the beak of the male is powerful and rather crow-like whereas that of the female is long, slender and down-curved. This difference was so unexpected that when specimens first reached ornithologists they were thought to constitute two separate but related species, the female being given the name *acutirostris* and the male *crassirostris*.

What was the reason for this divergence? The answer to this question has to be that pairs co-operated in feeding. If two birds could tap different food sources then the territory that they needed to occupy would be smaller. Perhaps the great wonder is why such a useful-seeming adaptation is not commoner. It could, of course, be argued that the very fact of the Huia's extinction indicates that the strategy does not really work.

The male Huia could use its chunky beak to break up rotting branches or trunks, leaving the female free to come along behind and use her long, slender bill to probe into the distressed material for insects and their larvae. A favourite food item was, apparently, the huhu, a large plump grub of the nocturnal beetle *Prionoplus reticularis*; another was the weta (*Hemideina megacephala*).

As might be expected in pairs of birds that are so dependant on each other, extreme distress was shown by any individual that lost its mate. There are several accounts that detail the behaviour of birds whose mate had been shot. Instead of flying off at the sound of the gunfire, the survivor would stay and search for its downed fellow. Doubtless, this kind of unwariness was one of the prime reasons for the species' extinction. Probably it fell prey to four-legged mammalian predators as easily as it fell prey to man.

The range of the Huia was always rather restricted. It seems to have occurred only on New Zealand's North Island – although there are one or two indications that it may have been present at the very north of the South Island. Even on the North Island only certain areas seem to have suited it. The famous chronicler of New Zealand birds Sir Walter Buller commented on the fact that in winter Huia's needed to descend from any mountainous territory occupied, in order to avoid the extremes of cold. Probably it was this liking for warmth that prevented Huia's from successfully inhabiting the rather cooler South Island.

Largely thanks to the works of Buller, a body of information exists on the lifestyle of this bird. The call was as the name; Huia is simply a phonetic rendering of it. It was described as soft and fluting and altogether haunting. The species laid 2-4 greyish eggs that were marked with brown and purplish spots and blotches, and breeding occurred during the Southern Hemisphere summer, chiefly around the month of November.

There is no doubt that the species' general demeanour rendered it ripe for extinction, but other factors probably played a part. Chief among these is the fact that large areas of the North Island became cultivated or were given over to grazing, so the woodland that formed the Huia's natural habitat became ever more fragmented. The last fully accepted sighting of living Huia's dates from the year 1907, but it is almost certain that a few birds lingered on after this date.

The best description of the bird in life comes from the pen of Buller (1887-88):

The Huia never leaves the shade of the forest. It moves along the ground, or from tree to tree, with surprising celerity by a series of bounds or jumps. In its flight it never rises, like other birds, above the tree-tops, except in the depths of the woods, when it happens to fly from one high tree to another...They are generally met with in pairs, but sometimes a party of four or more are found consorting together...this species builds its nest in hollow trees, forming it of dry grass, leaves and the withered stems of herbaceous plants, carefully twined together in a circular form, and lined with softer material of a similar kind.

## TURNAGRIDAE

### Piopio

### *Turnagra capensis*

The Piopio, or New Zealand Thrush, may have been two species rather than one. Two quite distinct kinds existed, and they are usually regarded as races of the same species: nominate *capensis* of the South Island; and race *tanagra* of the North Island. There are good reasons for supposing that they should be treated as separate species. First, the plumages are very different. Second, the structure of the beak is not quite the

*Tanagra capensis* Sparrman, 1787  
*Mus. Carlsonianum* 2: 45.

*T. c. tanagra* (Schlegel, 1865)  
*Nederlandsch Tijdschrift Dierkunde* 3: 190.

Plate F17

same, being considerably heavier and stouter in North Island birds. Third, each had a clearly definable and isolated geographical range, so they had no scope for interbreeding. It is perhaps the extreme rarity of specimens from the North Island that has prevented this idea from being investigated further. A third suggested race, *minor*, identified from specimens taken from tiny Stephens Island, a short distance offshore from the South Island in the Cook Straits, is only doubtfully distinct from the South Island form.

Just as the question of species is somewhat doubtful, so too is the bird's place in any systematic list. There is no general agreement as to where this creature's relationships lie and it has been associated with various passerine groups. Certainly it is not a thrush. This term was used simply as a comforter for early settlers in New Zealand who were anxious to see in the new land anything that could remind them of their old homes. Thus, there are New Zealand robins, New Zealand crows, New Zealand wrens and New Zealand thrushes, none of which have any real connection with the species that inhabited the "old" country, but which simply bore a vague, superficial resemblance to them. Systematists have aligned the Piopio (a Maori word that is derived from the bird's call) with the whistlers and the bowerbirds. The bowerbird hypothesis is, perhaps, the more likely, but the Piopio could easily belong close to another group altogether.

In the early days of European settlement Piopios were common birds, at least on South Island. The species was able to occupy many differing types of environment from sea-level up to the higher alpine country; the preference was for wooded country close to water. Its fate was almost certainly sealed by the fact that it was so tame and confiding. Individuals would hop around doors and windows in the hope of picking up scraps of food, or drop unwarily onto the forest floor. This left them horribly vulnerable to the attacks of dogs and cats, and the species steadily succumbed. Although much later dates are sometimes given, it seems that the last reliable record of the North Island Piopio comes from the year 1902. A few South Island birds survived for rather longer but by the early years of the twentieth century this form too was realistically finished. The most recent record which has any claim to credibility comes from Lake Hauroko in 1949.

Piopios lived on a fairly wide variety of different kinds of food. They would eat insects, worms, fruit, buds, seeds, leaves and any kitchen scraps that they could get hold of. A cup-shaped nest was built in the trees from twigs and mosses, with a lining of soft grasses or down. Two white eggs, spotted and blotched with brown, were laid in December.

The musicality of the species was mentioned by Buller (1887-88). Describing a captive individual, he wrote:

It was when I obtained a caged Piopio that I first became acquainted with its superior vocal powers...He often astonished me with the power and variety of his notes. Commencing sometimes with the loud strains of the Thrush, he would suddenly change his song to a low flute-note of exquisite sweetness; and then abruptly stopping, would give vent to a loud rasping cry, as if mimicking a pair of Australian Magpies confined in the same aviary. During the early morning he emitted at intervals a short flute-note, and when alarmed or startled uttered a sharp repeated whistle.

## STURNIDAE

## Kosrae Starling

*Aplonis corvina*

Three starlings of the genus *Aplonis* have vanished. The species from Kosrae Island, one of the Caroline group in the Pacific, is known from just a series of specimens collected by F. H. von Kittlitz in December 1827. Five skins exist today, three in St Petersburg and two in Leiden; there may be another in Frankfurt but it has not proved possible to verify this rumour. Kittlitz took both adult and immature individuals and expressed the opinion that he would not have believed these to belong to the same species had he not shot an intermediate example.

His observations reveal that the species lived on small mammals, lizards and insects. Its call was loud, and individuals were solitary in their habits. He recorded that it seemed rare at the time of his visit, and doubtless it was well on the way to extinction, as no later naturalist ever managed to locate it.

Kosrae had become a popular resort for visiting whalers, who used the island to repair their vessels and generally recuperate after their exertions. Rats were introduced and these animals quickly overran the island. They had a greatly detrimental effect on the bird populations, and doubtless their presence was a major factor in the starling's extinction.

*Lamprotornis corvina* Kittlitz, 1832  
*Kupfer. Nat. Vog. 2: 12.*

## Mysterious Starling

*Aplonis mavornata*

This species is known from just a single skin in the collection of the Natural History Museum, London. For many years this skin was a complete mystery and its origin was entirely unknown, but thanks to some comprehensive detective work conducted

*Aplonis mavornata* Buller, 1887  
*Birds New Zealand 1: 25.*

by Storrs Olson of the Smithsonian Institution in Washington, its origin is now relatively clear.

The bird was collected by Andrew Bloxam, a naturalist who served aboard *HMS Blonde* when it sailed to Honolulu carrying the bodies of Liholiho and Kamamalu, King and Queen of Hawaii, who had died of measles during a trip to London. While in the Pacific the *Blonde* called at the Cook Islands and on the afternoon of 9th August 1825 Bloxam went ashore on the island of Mauke. Here, during a visit of no more than two hours, he shot a pigeon, a kingfisher and a starling. Nothing more is known of his unique starling. Bloxam simply stated that his bird was killed "hopping about a tree".

### Norfolk Starling

*Aplonis fusca*

*Aplonis fuscus* Gould, 1836  
*Proc. Zool. Soc. London* **1836**: 73.

*A. f. hulliana* Mathews, 1912  
*Nov. Zool.* **18**: 451.

The third extinct member of the genus *Aplonis* inhabited the islands of Norfolk and Lord Howe. Both these Tasman Sea islands have lost several of their endemic birds and the starling vanished during the first half of the twentieth century. The species has been divided into two races, the nominate from Norfolk Island and race *hulliana* from Lord Howe.

Although the reasons for extinction on Norfolk Island are unclear, it is quite apparent why the birds vanished from Lord Howe. They were among the creatures doomed by the grounding of a ship, the *SS Makambo*, in 1918 on a stretch of shore known as Ned's Beach. Rats escaped from the vessel and quickly infested the previously rat-free island. Within just a few years the starlings were gone.

Little is on record concerning the species. In the days of its abundance it was something of a pest, often feeding on fruit and crops. The nest was loosely built in a tree hollow from twigs and grasses. The birds laid 3-5 bluish eggs, speckled and blotched with red. Lord Howe birds went locally by the name *cudgimaruk*, a name derived from the call.

### Reunion Starling

*Fregilupus varius*

*Upupa varia* Boddaert, 1783  
*Table Planches Enlum.* 43.

This large and rather beautiful species, also known as the Bourbon Crested Starling, was characterized by an extraordinary lace-like crest. It was an inhabitant of the Mascarene island of Reunion (formerly called Bourbon). It was known locally by the name *huppe*, which is also the French name for the Hoopoe (*Upupa epops*). It is perhaps not surprising, then, that the starling was originally placed in the Hoopoe's genus, *Upupa*.

Like so many island birds, this was a tame and confiding species. Islanders described how easily individuals could be knocked down with sticks. Despite this, the Reunion Starling survived for much longer than many other Mascarene bird species. It seems to have been relatively common right through into the early years of the nineteenth century, although by the middle years of that century it had disappeared altogether.

Nothing, apart from its appearance, is known of this species. Indeed, its taxonomic placement is also disputed, as some authors consider it to be a helmet-shrike (Prionopidae).

### Rodrigues Starling

*Necropsar rodericanus*

*Necropsar rodericanus* Slater, 1879  
*Philos. Trans.* **168**: 427.

The skeletal remains of a starling were found on the island of Rodrigues during the 1870's. Although there may be no connection, these bones have been associated with a brief account in the document known as the *Relation de l'Île Rodrigue*, which was probably written by a marooned sailor named Tafforet during 1725. A translation reads:

A little bird is found which is not common...One sees it on the Islet de Mat, which is to the south of the main island, and I believe it keeps to that islet on account of the birds of prey which are on the mainland, and also to feed with more facility on the eggs of the fishing birds which feed there, for they feed on nothing else but eggs, or some turtles dead of hunger, which they...tear out of their shells. These birds are a little larger than a blackbird, and have white plumage, part of the wings and tail black, the beak yellow, as well as the feet, and make a wonderful warbling.

Whether these words should really be matched with the bones cannot be said with any degree of certainty.

## FRINGILLIDAE

## Bonin Grosbeak

*Chaunoproctus ferreorostris*

A large, spectacular grosbeak-like bird once lived on the Bonin Islands to the south of Japan. It is known from nothing more than two series of skins that were collected during the 1820's, skins that are in themselves a little puzzling. Some are rather larger than others, giving rise to the supposition that individuals may have been collected from different islands and that each island may have supported its own population.

*Coccothraustes ferreorostris* Vigors, 1829  
*Zool. J. 4: 354.*

All the known specimens derive from two expeditions. The first of these was the voyage of *HMS Blossom*, which vessel called at Peel Island (Chichi-jima), one of the Bonins, during June 1827. The tameness of the birds led the leader of the expedition, Captain Beechey, to assume that there had been no permanent human presence on the island. When the *Blossom* sailed away several grosbeak specimens were aboard.

Just months later F. H. von Kittlitz landed on Peel during the voyage of the Russian corvette *Senjavin*. Whether Kittlitz took birds from elsewhere is not known. His brief notes provide the only record of the bird in life. He noticed them on the forest floor, singly or in pairs, and described the call as a soft, pure and high piping.

No naturalist ever saw the grosbeak again. By the 1850's, when Peel Island was searched by members of an American naval expedition, there was no sign of it.

## DREPANIDIDAE

## Ula-ai-Hawane

*Ciridops anna*

Although it was once well known to the natives of Hawaii, by the time that Europeans began their ornithological exploration of the island, this species has virtually disappeared.

The striking red, black and silver Ula-ai-Hawane is known from just five specimens, two in New York (one of which is either an immature or a female, and shows a greenish plumage), one in Cambridge (Massachusetts), one in Honolulu and one in Tring. The first of these was taken by an amateur naturalist and shopkeeper by the name of Mills about the year 1859. The last was collected from Mount Kohala in 1892. Probably the species became extinct soon after this date, although the experienced and reliable Hawaiian ornithologist George C. Munro reckoned he might have glimpsed an individual as late as 1937.

Quite clearly, this is one of those Hawaiian species that stood at the brink of extinction even as it was being discovered to science. Native Hawaiian knowledge of the species indicated that it was once widely distributed on the island of Hawaii, although it was only ever seen close to the hawane palm.

*Fringilla anna* Dole, 1878  
*Hawaiian Alm. Ann. 1879: 49.*

## Koa Finch

*Rhodacanthis palmeri*

*Rhodacanthis palmeri* Rothschild, 1892  
*Ann. and Mag. Nat. Hist. Ser. 6, no. 10:* 111.

*R. p. flaviceps* Rothschild, 1892  
*Ann. and Mag. Nat. Hist. Ser. 6, no. 10:* 111.

The Koa Finch is something of a mystery. Was it one species or was it two? Were the "Greater" and "Lesser" Koa Finches both members of the same species?

During 1891 Henry Palmer was busy collecting specimens on the Hawaiian Islands for Walter Rothschild. The enormously wealthy scion of the famous banking family was at this time frantically acquiring material for his museum at Tring, Hertfordshire, England. Nothing interested him more than rare, extinct and curious birds, and he was later to write his famous book *Extinct Birds*, 1907. Palmer had been commissioned to sail to Hawaii in search of whatever he could find. He linked up with George C. Munro, and together the two men combed Hawaii.

One of their "finds" was a series of large "finches" that they took from the koa forests in the Kona district of Hawaii. First of all it should be made clear that these were not finches at all; they were Hawaiian honeycreepers that had evolved a finch-like form, in order to exploit a vacant ecological niche. The original collectors, Palmer and Munro, were quite clear in their minds about the nature of the birds they had discovered. They felt that these creatures belonged to a single, rather variable, species, and it is worth noting that the two forms were collected on the very same trees. They then dispatched the specimens of their new bird to Rothschild.

When the preserved specimens reached Rothschild in England, he formed a different conclusion to that of his collectors, and he delightedly separated his new possessions into two groups; nothing pleased Rothschild more than to be able to name a new form! The larger individuals, with more orange heads, he assigned to a new species that he called, in honour of his collector, *Rhodacanthis palmeri*. To cover the smaller birds with heads that were rather more yellow he proposed the name *Rhodacanthis flaviceps*. Rothschild identified eight individuals that he felt belonged to this second species, two males and six females. After Palmer's original collecting success, no further specimens that could be assigned to *flaviceps* were ever taken or seen. However, the larger birds were observed again, and captured. Over a period of five years a few individuals were encountered. Then these birds vanished too. There is no record later than 1896.

Palmer's notes were bequeathed by Rothschild to the Natural History Museum, London, but, unfortunately, many of them were destroyed by tidy-minded museum workers, so we will never know exactly what was in his mind.

The argument for or against two species is a fairly basic one. Does one agree with the experienced field ornithologists who actually saw the living bird, or does one take notice instead of undoubted differences that were noticed by cabinet naturalists? It is possible that the smaller, yellower birds were immatures or first-year birds, and this idea might tidily explain why they were never encountered after 1891. There were no more immatures because the species was standing at the edge of extinction and no longer breeding properly. The last sighting of the species actually involved an observation of some very young birds but, probably, these did not live long.

The big problem with the evidence of the specimens is that it is difficult to correlate it with the birds in life. Although the most extreme examples of each form appear to be rather different, there are areas of overlap between some of the other specimens. The real truth is probably unresolvable, and is simply a matter of interpretation.

Unfortunately, knowledge of the living bird in no way matches the amount that has been written concerning the supposed status of the species – or pair of species. The best description of the bird in life was given in 1903 by R. C. L. Perkins, a man who left behind some of the most evocative writings on the extinct birds of the Hawaiian Islands:

Although spending most of its time in the tops of the loftiest koa trees, *Rhodacanthis* occasionally visits the lesser trees...chiefly for the sake of the caterpillars that feed upon them...Its chief food, however, is the green pod of the koa tree, which it swallows in large-sized pieces and its blue bill is often stained with the green juice and fragments of the pods...The song...consists of four, five or even six whistled notes, of which the latter ones are much prolonged...Although the notes are not loud, they are very clear, and...easily imitated...Were it not for this fact *Rhodacanthis*, when keeping to the leafy crowns of tall koa trees...would be most difficult to get sight of...The green plumaged young...are fed partly on fragments of koa pods.

## Kona Grosbeak

*Chloridops kona*

*Chloridops kona* Wilson, 1888  
*Proc. Zool. Soc. London 1888:* 218.

The Hawaiian honeycreepers form one of the most striking illustrations of adaptive radiation, but, unfortunately, so many of them are extinct that the example is now historical rather than living.

**Ula-ai-Hawane**  
*Ciridops anna*

*Rhodacanthis palmeri*  
*palmeri*

**Koa Finch**

*Rhodacanthis palmeri*  
*flaviceps*

**Kona Grosbeak**  
*Chloridops kona*

**Greater Amakihi**  
*Hemignathus sagittirostris*

*Hemignathus obscurus procerus*

**Akialoa**

*Hemignathus obscurus*  
*obscurus*

**Hawaii Mamo**  
*Drepanis pacifica*

**Black Mamo**  
*Drepanis funerea*

At some point in prehistory an ancestral honeycreeper stock somehow arrived at the Hawaiian Islands and found a situation that was ripe for exploitation. Due to the remoteness of the islands there were many ecological niches that were not successfully occupied. The ancestors of the honeycreepers adapted accordingly and lifestyles were adopted that would in more normal circumstances be the prerogative of other kinds of birds. Thus, there are honeycreepers that came to resemble finches, some that developed almost parrot-like bills, still others that acquired long, slender, down-curved beaks useful for probing, and yet others with more general all-purpose beaks. This fascinating diversity has been horribly diminished by the process of extinction.

The Kona Grosbeak was a perfect example of the way in which the ancestral honeycreepers adapted. It had evolved a short and incredibly powerful bill that enabled it to exploit food types that more normally developed birds could not. Indeed, the sounds of hard seeds and nuts being split by the awesome bill of this species betrayed its presence to field collectors.

This is another bird that was best described by R. C. L. Perkins (1903). He wrote:

It is a dull, sluggish bird, and very silent – its whole existence may be summed up in the words “to eat”. Its food consists of seeds of the aaka, and as these are very minute, its whole time seems to be taken up in cracking the extremely hard shells...Its beak is nearly always dirty, with a brown substance adherent to it, which must be derived from the sandal nuts.

The species was discovered on the slopes of the famous volcano Mauna Loa in the Kona district of Hawaii during 1887. It was seen again several times during the next few years, but the last sighting occurred in 1894 and it is assumed that these birds became extinct soon after that date.

### Greater Amakihi

### *Hemignathus sagittirostris*

*Viridonia sagittirostris* Rothschild, 1892  
*Ann. and Mag. Nat. Hist. Ser. 6, no. 10*: 112.

The Greater Amakihi, a rather non-descript little honeycreeper coloured olive green, was discovered by the world of ornithology during 1892 when Rothschild's collector Henry Palmer took four specimens. In December 1895 a few individuals were collected, and the species was located again during 1900. The following year it was found once more, since which time it has never been seen again.

By the time of its ornithological discovery the species was restricted to a very small part of the island of Hawaii, the dripping rainforest to either side of the Wailuku River at elevations of 300-900 m.

Whenever it was seen, this species was observed creeping along the branches of ohia trees or in the foliage. Individuals ate insects and their grubs and other invertebrates. They were also seen to feed on the nectar of the ohia flower.

The habitat that this species occupied is long gone and the area is now covered with sugar cane.

### Akialoa

### *Hemignathus obscurus*

*Certhia obscura* J. F. Gmelin, 1788  
*Syst. Nat.* **1**(1): 470.

*H. o. lanaiensis* Rothschild, 1893  
*Bull. Brit. Orn. Club* **1**: 24.

*H. o. ellisianus* (G. R. Gray, 1859)  
*Cat. Birds Trop. Isl. Pac. Ocean*: 9.

*H. o. procerus* Cabanis, 1889  
*J. Orn.* **39**: 331.

Because it is so poorly known, the honeycreeper family, in particular its extinct members, arouses a certain amount of controversy. It is classified and reclassified over and over again, and drastic revisions of the family are made from time to time. Unfortunately, these revisions are, of necessity, made from specimen material rather than from any real recourse to the living birds. For this reason these revisions should be viewed with a certain degree of caution. They tend to be prone to the whims and prejudices of individuals, and also subject to the dictates of fashion.

In no case is this better exemplified than in the instance of the Akialoa. Perhaps the Akialoa constitutes one species, perhaps two, perhaps even four. It has been divided into two, a “Greater” and a “Lesser”, and into four with each inhabited Hawaiian island being held to have its own species. The specimen material is very difficult to interpret, however. The forms from Lanai (*lanaiensis*) and O'ahu (*ellisianus*) are known only from very, very few specimens, so there is no real series on which to base conclusions. The other two forms, nominate *obscurus* from Hawaii and *procerus* from Kauai, are known from rather more skins, but even in these cases comparisons are clouded by various factors. The main problem is that the Akialoa was a generally variable bird and individuals of each kind show some overlap in terms of size and colour. It is possible that individuals became brighter in colour when they were breeding, although it should be said that there is no real evidence of this. Bill length is held to be a significant character, but this too is variable: there is evidence to show that towards the end of its existence as a species, the Akialoa's beak tended to be rather

shorter than in earlier years. Perhaps this was because the birds were generally in poor health, and collectors who took specimens during the 1890's noticed that individuals were often covered in sores, tumours and swellings, particularly on the head and feet; or maybe the new circumstances on the islands were inhibiting proper growth.

The most sensible way forward is, perhaps, to regard the Akialoa as a single species with four races. Bearing in mind the paucity of specimen material available, no other course seems meaningful.

However they may be interpreted, the birds that are known as Akialoas were among the most intriguing of the honeycreepers. The extraordinarily delicate beak is in complete contrast to the shorter, stumpy bills of the Koa Finch and the Kona Grosbeak. The lower mandible was often considerably shorter than the upper, and with this strange device individuals were able to suck nectar from the flowers of ohias and lobelias, and they could also probe into cavities for insects and their larvae. R. C. L. Perkins noticed them clinging to tree trunks like "true" creepers when they were feeding.

While it is known that there were Akialoas on Hawaii, O'ahu, Lanai and Kauai, it is quite possible that birds were present on other islands. It is surprising to find, for instance, that they were never reported from Molokai and Maui. Perhaps they vanished from these islands at a comparatively early date. It is likely that the Akialoas from Oahu became extinct around 1840, although there are claimed records, made by experienced ornithologists, of possible sightings made during the late 1930's. The Lanai and Hawaii populations disappeared around 1900, but Kauai birds held out for much longer. Their stronghold was the same Alaka'i Swamp that was home to the last Kauai 'O'os. A few individuals were still in existence during the early 1960's but the last record of them seems to date from 1967.

The obvious frailty of the Akialoa reflects the fragility of the honeycreepers as a whole. In addition to all the other factors that depleted them, the danger that the mosquito posed cannot be overstated. Once this insect arrived in the Hawaiian Islands, birds that lived at lower altitudes were seriously affected by the bites of these creatures. Even those species living at altitudes that were unattractive to mosquitoes could be vulnerable. Sometimes they would descend to lower levels to ride out the effects of hurricanes, and then the bites could prove fatal. Captive birds that have been brought down from altitude have been observed to die within minutes of sustaining a bite.

## Hawaii Mamo

### *Drepanis pacifica*

The Hawaii Mamo suffered in the same way and for the same reason as the Hawaii 'O'o. The rich yellow feathers of the uppertail- and undertail-coverts attracted the attention of the kings and princes of Hawaii, and these feathers were used in the making of ceremonial cloaks and other artifacts. The most famous cloak of all, that of Kamehameha I was made from the feathers of an extraordinary number of birds. An estimate has been made that 80,000 individuals were used before the garment could be brought to completion.

The Hawaii Mamo was one of the first Hawaiian birds to come to the attention of Europeans and specimens were brought back from the Pacific to England by the naturalists who participated in James Cook's third voyage. Surprisingly little is known of it, however. The birds fed on nectar, particularly from the flowers of arborescent lobelias, but they are thought also to have eaten insects. The call was described as a single, long, rather mournful and haunting note.

The species was only ever noticed on the island of Hawaii and it was last seen during 1898.

*Certhia pacifica* J. F. Gmelin, 1788  
*Syst. Nat.* 1(1): 470.

## Black Mamo

### *Drepanis funerea*

A bird very closely related to the Hawaii Mamo once lived on the island of Molokai. Here it was discovered by R. C. L. Perkins at an altitude of 1525 metres during June 1893. What is known of the species comes largely from Perkins's account.

Individuals were only ever seen low down in the underbrush. Dangerously, for a creature that spent its time close to the ground, the birds were rather tame, and Perkins found it easy to observe them at close quarters. He believed that they fed exclusively on nectar, and he wrote:

*Drepanis funerea* A. Newton, 1894  
*Proc. Zool. Soc. London* 1893: 690.

I saw three adult males of this bird in one low bush passing from flower to flower and spending only a few seconds over each...Even those flowers which were at a height of no more than a foot from the ground were carefully explored. The crown of the head of each of these birds was plentifully encrusted...with the sticky white or purplish-white pollen of the lobelias and gave them a singular appearance...they will sit quietly

preening their feathers when they have a very comical appearance, much stretching of the neck being necessary to enable them to reach the fore parts of the body with the tip of their long beaks.

Following Perkins's discovery of the species, it was found on several more occasions, but was last seen in June 1907. There is no real chance that it could have survived as the habitat in which it lived has been virtually destroyed.

## PARULIDAE

### Bachman's Warbler

*Vermivora bachmanii*

*Sylvia Bachmanii* Audubon, 1833  
*Birds Amer. 2: pl. 185.*

This tiny species divided its time between the south-eastern USA and Cuba, where it wintered. It was first identified by the Reverend John Bachman, a close personal friend of the famous painter and writer John James Audubon. Bachman was a resident of Charleston, and in July 1833 he found, in a local swamp, a small yellow and black bird that he did not recognize. He sent it on to Audubon for formal identification and the famous ornithologist quickly realized that it was something entirely new. Audubon, quite naturally, gave the species his friend's name.

For a period of more than 50 years after that nothing further was heard of the new creature. Then, in 1886, a hunter by the name of Charles Galbraith shot a bird he had never seen before, just north of New Orleans. The next year he shot six more of the same birds, and during the following year he killed no less than 31. At this point he decided to have his mysterious specimens identified. They proved to be Bachman's Warblers.

A year later, in March 1889, on a single day 21 warblers of the species struck a lighthouse on the Florida Keys. Just three years later a hunter killed 50 individuals on Florida's Suwannee River.

Through the first half of the twentieth century it proved possible to locate Bachman's Warblers from time to time, but then the observations proved much less frequent. By the 1980's the species was probably extinct, although, given its tendency to disappear, there is a faint chance that it might still survive.

Although Bachman's Warblers were always surrounded by a certain amount of mystery, their nests were found on a number of occasions. These were built low down in dense patches of bramble, situated along forested river courses.

Reasons for the species' extinction are unclear. The effect of hurricanes, changing land use, and the fragmentation of suitable territory have all been proposed as factors. Another suggestion is that the species was coming into increasing contact with the parasitic Brown-headed Cowbird (*Molothrus ater*), due to extensive forest clearance, and that the encroachments of this bird proved irresistible.

## Hypothetical Species and Mystery Birds

No account of the world's recently extinct birds can be quite complete without some mention of "hypothetical" extinct species and "mystery" birds. The names of such creatures frequently litter the lists of extinct species and create endless confusion.

Hypothetical species can be defined as birds that have been scientifically named, mainly by nineteenth and twentieth century ornithologists, on the basis of early traveller's tales or antique paintings, and of which no specimen material exists. The problems associated with such names are self-evident. First, they contravene the rules of zoological nomenclature by being too vague. Second, there is no actual proof that the described creatures ever existed, or that they were what they seemed to be. The names may be founded upon mistakes, misunderstandings or even plain old-fashioned lies.

Mystery birds are seemingly distinct kinds that are known from just a single specimen, or a very small number of specimens, that, for a variety of reasons, may not be exactly what they seem to be.

Although the two categories are obviously related, it is easiest to discuss them separately.

It is a surprising fact that so many hypothetical species have been named (by ornithologists who should have known better!), and that they have gained a significant place in ornithological literature – but such is the case.

Most are forms resurrected from the accounts of travellers from the seventeenth or eighteenth centuries, and given formal, albeit invalid, scientific identities by more modern writers. The problems with such accounts are several. First, they may have been – and usually were – written by men with no real background in natural history. Second, they may have been based on hearsay. Third, the accounts may be flimsy and superficial in the extreme. Fourth, there was often a tendency among early travel writers to fill up the pages of their books with accounts of creatures that were entirely, or partly, fanciful. The fourth category obviously speaks for itself and needs no further discussion. Similarly, the problems with the second and third categories are perfectly apparent. A more complex set of problems is posed by the first. When men have no knowledge of natural history (or even when they do), they are likely to misinterpret what they see. A description of a new creature may be entirely truthful in spirit, yet still be absolutely misleading in effect. Perhaps the observer saw something that was new to him but was otherwise well known. Perhaps he casually mentioned a crow when the bird he had seen was actually a starling, and the words get in the way of the truth. Sometimes, the description may be entirely inaccurate.

Early paintings of birds that cannot be precisely aligned with any known species are also problematical. To take a picture, even when painted by an artist of talent, at face value, is often unrealistic. The problem here is one of intention. There is often no way of knowing whether an artist was trying to produce a true likeness, whether his intention was simply decorative, or whether it lay somewhere between the two. There

Figure 8. White Dodo.  
Chromolithograph based on  
painting by F. W. Frohawk.

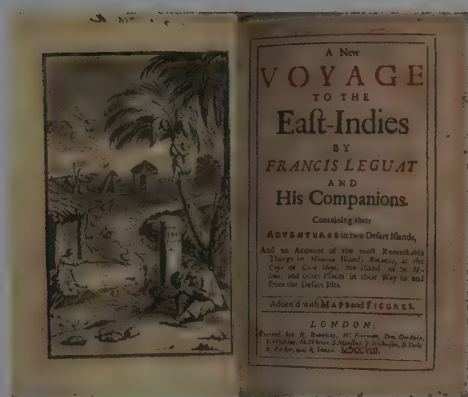

Figure 9. The opening pages of François Leguat's 1708 book, *A New Voyage to the East Indies*, in which he supplies much of the very scant information that is known about several extinct Mascarene forms.

is also the matter of technique. Many of the pictures on which names have been based were drawn by men with little or no skill. Yet, nuances of detail on such pictures have been taken absolutely seriously by some ornithologists when, quite clearly, such details may simply be the result of inadequate drawing ability. These pictures may be charming and curious, and they may show something of genuine interest. On the other hand they may not! When scientific names are proposed solely on the basis of such pictures these names should be regarded as invalid.

The inclusion of several species known today only from the paintings of Georg Forster, who was by no means an efficient technician, may seem to contravene these ideas, but it should be borne in mind that Forster's pictures were originally backed up by specimen material. Unfortunately, in the cases in question, that material has not survived.

The best known of all hypothetical species is the so-called White Dodo of Reunion. The evidence that such a creature existed is flimsy in the extreme yet many ill-judged words have been written about it (including some by the present author), and it was given the technical name *Raphus solitarius*. Two accounts from the early seventeenth century suggest that there may have been a creature that looked something like a White Dodo on Reunion, but these are far too vague to enable the building of any kind of sensible hypothesis. Another strand of evidence concerns a well-known series of seventeenth century Dutch paintings by Pieter Holsteyn (later copied by another painter named Pieter Witthoos) that show a White Dodo. Unfortunately, however, there is absolutely nothing to link these pictures to Reunion. Nor is there anything to show that the model for the pictures was anything other than an albinistic Dodo of the more ordinary kind. Similarly, because we know nothing of the intention of the original artist, it is quite fair to suppose that he made his Dodo white simply because he wanted to. What can be said with some certainty is this: had a Dodo-like bird evolved independently on the island of Reunion, it would have looked radically different from its relative on Mauritius, rather than looking just like a regular Dodo that had been bleached. It would necessarily have developed in a different direction, in much the same way as did the dodo-like solitaire of the island of Rodrigues. This creature, while showing many dodoesque features, has a number of entirely independent ones – and this is only to be expected of a flightless creature evolving independently on a separate island. It is quite possible that a relative of the Dodo did actually live on Reunion, but there is not one scrap of hard evidence to show this.

Another hypothetical species that has acquired almost equal celebrity has come to be known as Leguat's Giant (*Leguatia gigantea*). This is a bird that the Huguenot refugee François Leguat claimed to have seen on Mauritius during the 1690's. His description makes it clear that this was a slender, very tall creature. As Leguat was generally a very truthful recorder it may be assumed that he really did see something, but just what that something was is difficult to say. The likelihood is that he may have seen a flamingo and that he was entirely unfamiliar with such a creature.

The list of hypothetical species is fairly endless, and by and large such mythical birds are properly beyond the scope of this work.

The problems associated with mystery birds are equally difficult to resolve. If a bird is known from just a single specimen or just a very small number of specimens, there can be all kinds of difficulty involved in assessing the correct position. This is especially so if the bird was never observed properly in the wild. The possibility that such birds may be simply freaks or perhaps hybrids between better-known species cannot be discounted. Naturally, if birds turn up just once and then many years pass without anything similar being found, there is always the possibility that the species – if species it truly is – has become extinct.

There are, in fact, a surprisingly large number of birds known from only very limited specimen material. The family of birds-of-paradise (Paradisaeidae), for instance, contains more than 20 mysterious forms known only from excessively rare and isolated specimens. These are generally considered to be hybrids between some of the better-known kinds, but some may not be.

Ultimately, such decisions are often based on individual prejudices, as the actual hard evidence is not sufficient to build a proper determination.

The case of the Lanai Hookbill (*Dysmorodrepanis munroi*), a honeycreeper from the Hawaiian island of Lanai, provides a good example. It may be a "good" species and, if it is, it is almost certainly extinct. On the other hand, it may be a freak. Just a single example of this creature is known and this was collected during 1913 by George C. Munro, whose name so often occurs in accounts of Hawaiian birds. The specimen shows a very distinct but rather peculiar arrangement of the beak and experts interpret this in two contrasting ways: some argue that the beak's peculiar nature is the sure

mark of a freak; others suggest that it is a clear and distinct indication of a "good" species.

In some respects similar is the case of Townsend's Bunting (*Spiza townsendi*). This is a form described by the celebrated John James Audubon from a unique specimen taken in Pennsylvania. No similar bird has ever come to light, but, since the specimen shows some relationship to the Dickcissel (*Spiza americana*), the form is usually relegated to the status of freak or hybrid.

Ross's Plover (*Thinornis rossi*), a strange shorebird from New Zealand waters was described from a single specimen taken in 1840, during the exploratory voyage of the British vessels *Erebus* and *Terror*. Usually, it is regarded as an aberrant, perhaps young, individual of the Shore Plover (*Thinornis novaeseelandiae*), itself a very rare bird. It may or may not be. Similarly, Cooper's Sandpiper (*Calidris cooperi*), collected during the nineteenth century on Long Island, New York, might be a "good" species, although nowadays the general consensus is that it is a hybrid of the Curlew Sandpiper (*Calidris ferruginea*) and the Sharp-tailed Sandpiper (*Calidris acuminata*).

The big problem with all these forms (and there are a considerable number of them) is that we shall simply never know what they really were.

To these forms can be added many that are simply known from fragmentary bone material. For the purposes of a work like this there is little point in pursuing such insufficient yet tantalizing material. Such a pursuit leads to endless list-making, argument and counter-argument. Those recently extinct creatures that we know from clear-cut specimen material are tantalizing and mysterious enough in themselves and, most regrettably, it seems inevitable that, unless conservation action is given full institutional backing right away, there will soon be many more well-known, and not so well-known, names to add to the ranks of the extinct.

Errol Fuller

## *Introduction to Volume 7*

The previous volume was accompanied by a poll aimed at establishing the preferences of the majority of readers with reference to how the remainder of the HBW series should proceed. The question was essentially whether we should continue our recent trend of longer, fuller texts, more photos, and more extensive coverage of subspecific variation on more plates, resulting in a few more volumes than previously envisaged, or take a step backwards from these possible excesses and aim for levels of coverage closer to those used at the start of the series, and thus stick to the previously projected 12 volumes (See Introduction to Volume 6). We were particularly keen that our readers should participate actively in the overall planning of the rest of the series, as you, the users, are in the best position to judge collectively what the best course may be.

The results of the poll have been quite revealing. The number of replies received, alone, is worth mention—almost 3000 from over 40 countries. Such a large response seems to be a good indication that the matter caught the interest of many readers. A remarkable total of 93% of those who answered the poll indicated that they were in favour of the option of dealing with the species in greater detail, whereas only 7% stated they would prefer the series be kept at 12 volumes—indeed, many of these kindly expressed their intention to continue to support the project even in the event that the series were to be extended. Given that the option chosen by the vast majority of our readers coincides with the one that we, the editors, also prefer, it is now established that the series will definitively be extended to a total of 16 volumes, so that there will be enough space to deal comprehensively with the ever-increasing volume of information available and also to illustrate the species extensively by means of both plates and photos. We are convinced that the overall results of this decision will be clearly more useful, and also a richer celebration of the enormous variety present in Class Aves. The HBW website (<http://www.hbw.com>) provides more details of the poll results.

Turning to the present volume, we are delighted to be able to start it with a foreword dedicated to one of the subjects most frequently requested by our readers: extinct birds. To cover this topic comprehensively, we always felt that a good deal of space would be needed, especially as we wanted this to be a highly illustrated foreword; to this end we felt that Volume 7 was ideal for the purpose. For this huge subject, we have been fortunate indeed to be able to count on the expert authorship of Errol Fuller, who has recently published a second, revised edition of his spectacular *Extinct Birds*, as well as producing recent monographs on two of the most evocative of extinct bird species, the Great Auk (*Pinguinus impennis*) and the Dodo (*Raphus cucullatus*).

Because so little is known about so many extinct forms, there are often considerable doubts as to their taxonomic status. In many cases, there is even some doubt as to whether they really are extinct, or might survive in small numbers in some remote area. All in all, we felt that it would be rather confusing for readers if such doubtful cases

differed in treatment from the versions already adopted in HBW to date, and we are particularly grateful to the author for kindly adapting his own preferred list, that of *Extinct Birds*, to fit the HBW version, in all cases. One of the major omissions from his list comprises a series of species already covered in HBW (most of them listed as “Almost certainly Extinct”), each with its own species account, map and illustration. It seemed pointless to waste available space by repeating the material on each of these species, even though a realist would probably have to admit that the chances of the continued survival of some of them must be very close to nil.

We particularly wanted to maintain HBW standards of extensive illustration, and to this end a series of plates was specially commissioned to depict all the recently extinct bird species whose appearance in life is sufficiently known. Of course, in this matter too there were borderline decisions, including two that were particularly notable for the similarity of their cases: the Tanna Ground-dove (*Gallicolumba ferruginea*) and the Bay Thrush (*Turdus ulietensis*) are each known merely by a single painting by the same person, but, while the former was considered to allow just enough certainty to permit its illustration, the latter presented too many areas of uncertainty, so no illustration was attempted.

Each species in the foreword has its original name placed alongside, together with the other relevant details of its original description. In contrast, and as in the main body of HBW texts, subspecies are listed using only their currently accepted names, with the describer and year of publication following, with or without brackets depending on the original genus, in accordance with ICZN norms. In this foreword, all references of scientific descriptions are listed immediately after the basic details of their respective descriptions.

This concluding non-passerine volume is accompanied by a practical plastic-coated index of the groups covered in the first seven volumes, allowing even a novice on birds quickly to locate any of the families in this first part of the series. Although most readers will already be reasonably familiar with the traditional taxonomic sequence followed by HBW, we believe that the existence of several other sequences, some varying drastically from the traditional one, could raise some doubts as to where exactly a certain family is covered in the HBW series; it is hoped that the index will prove handy for rapid clarification. There are two ways of using the index. On one side, there is a visual scheme in taxonomic sequence, in which each non-passerine family is symbolized by one of its most representative members, followed by the volume and the page number on which the corresponding family section starts. On the other side of the index there is an alphabetical list of the scientific and English names of all of the orders and families covered in Volumes 1-7, as well as the English names of all species groups included in the families. For example, in order to find out where the family Hawks & Eagles is covered, the reader can look it up under Accipitridae, baza, buzzard, chanting-goshawk, cuckoo-hawk, eagle, fish-eagle, fishing-eagle, hawk, honey-buzzard, kite, sea-eagle, serpent-eagle, snake-eagle, vulture, etc. Additional scientific ranks, such as suborders and subfamilies, are not included, as they would be of very limited use in such a reference system. Logically, an index of all of the passerines will be included in the last volume of the series.

The sources of French, German and Spanish names have been the same as in previous volumes, with Normand David and Peter Barthel once again kindly helping out in any doubtful cases with the French and German names, respectively. The latest group of Spanish names was published in *Ardeola* 48(1): 107-110.

## Acknowledgements

As in previous volumes, we owe a great debt to many museums, and those working there. Chief amongst these are the British Museum of Natural History at Tring (Robert Prys-Jones, Michael Walters, Mark Adams, Cyril Walker, Effie Warr, Alison Harding), the American Museum of Natural History in New York (Joel Cracraft, George Barrowclough, Mary LeCroy, Paul Sweet, Shannon Kenney, Peter Capainolo, Terry Chesser, Maria Rios), the Louisiana State University Museum of Natural Science (Van Remsen, Steve Cardiff, Donna Dittmann, Mario Cohn-Haft, Dan Lane, Alexandre Aleixo, Jason Weckstein, Rob Faucett, John O'Neill) and the Smithsonian Institution, National Museum of Natural History in Washington (James Dean, Gary Graves, Pam Rasmussen, Richard Zusi). Also of great assistance have been the Field Museum in

Chicago (David Willard, Shannon Hackett), the Kenya Natural History Museum (Leon Bennun, George Amutete, Kuria), the Colección Phelps de Venezuela (Miguel Lentino, Margarita Martínez, Clemencia Rodner, Robin Restall), the Delaware Museum of Natural History (Gene Hess), the Museum of Comparative Zoology in Harvard (Alison Pirie, Peter Alden, Jeremiah Trimble), the National Museums of Scotland in Edinburgh (Bob McGowan), the Natuurhistorisch Museum at Leiden (René Dekker, Martien van Oijen), Liverpool Museum (Tony Parker), the Departamento de Zoologia of the Universidade de São Paulo (Luís Fábio Silveira) and the Academy of Natural Sciences at Philadelphia (Nate Rice).

We are similarly indebted to a whole host of libraries, which time and again come to our rescue. Yet again, the contribution made by Effie Warr and Alison Harding of the British Museum of Natural History at Tring has been immense. We are very grateful too to the Museu de Zoologia of Barcelona (María Ángeles Iglesias), the Sociedad Española de Ornitología in Madrid (Blas Molina) and the Estación Biológica de Doñana (José Cabot). Our warm thanks are also due to Gustaf Aulén, Raül Aymí (Grup Català d'Anellament), Juliane Diller (Ornithological Society of Bavaria), Yeser Elmas and John Rose (Natural History Museum, London), John C. Fisher (Western Foundation of Vertebrate Zoology), Diego Giraldo-Canas (*Caldasia*), Juan Carlos Guix, Janet Hinshaw (University of Michigan), Fritz Hirt (SVS International Operations, Switzerland), Hans Källander (*J. Avian Biology*), Kanitha Kasina-Ubol (Siam Society), Chichiro Kikuchi (*Birder*, Japan), Blaise Mulhauser (Muséum d'Histoire Naturelle, Neuchâtel), Jevgeni Shergalin, Jeremy Speck (BirdLife UK), Oscar A. Spitznagel (Aves Argentinas/Asociación Ornitológica del Plata), Ante Strand (Swedish Ornithological Society) and Xu Weishu (China Ornithological Society).

For assistance with many assorted doubts connected with nomenclature and scientific descriptions, we are once again very grateful to Alan Knox, and also to Murray Bruce, Normand David, Edward Dickinson, Miguel Lentino, Flávio Lima and Michael Walters. We should also like to mention Alan P. Peterson's excellent web on Zoological Nomenclature, which has helped us out on many occasions.

The texts have benefited notably through the input of referees and the addition of much material, often unpublished. We should like to thank all who have contributed, particularly Nick Athanas, Judy Davis, Geoffrey Field, Al Gilbert, Michael S. Husak, Andy Kratter, Dan Lane, Juan Mazar-Barnett, John O' Neill and Pam Rasmussen. Robert Ridgely once again very kindly reviewed all the maps of South American species, making notable improvements in many cases. We are also very grateful to Jeff Price for checking and commenting on both the maps and the Status and Conservation sections for all the North American species.

Liberal access to Guy Tudor's own personal collection of reference photos has again been a major boon, and we are very grateful to him for his continued support. We have again benefited greatly from our agreements with VIREO at the Academy of Natural Sciences in Philadelphia (Doug Wechsler), and with the National Sound Archive of the British Library (Richard Ranft). Our grateful thanks also to David Ascanio, Mario Cohn-Haft and Barry Walker, for help with particular bird calls.

The various authors and artists involved in the present volume would like to thank Mark Adams, Dean Amadon, Allison V. Andor, J. Phillip Angle, John C. Arvin, the late Luis Baptista, Eustace Barnes, George Barrowclough, John Bate, Ernest Baurenfeind, William Belton, Christine Blake, Walter J. Bock, Cordula Bracker, Pat Brunauer, Greg Budney, Phil Burton, Scott Cannop, Steve Cardiff, Juan Manuel Carrión B., Marcelo Carvalho, J. C. Chebez, Lisa Choegyal, Mario Cohn-Haft, Nigel Collar, Peter Colston, Paul Coopmans, Tim Crowe, J.C. Daniels, René Dekker, Jared M. Diamond, Tony Diamond, Bob Dowsett, Françoise Dowsett-Lemaire, Siegfried Eck, Renate van den Elzen, Christian Érard, Patricia Escalante-Pliego, Alan Feduccia, John Fitzpatrick, Jon Fjeldså, Bruce Forrester, Irma Franke, Dawn and Clifford Frith, Anita Gamauf, Kimball Garrett, Cecilia and Nathan Gichuki, Frank B. Gill, Derek Goodwin, the late Mary Lou Goodwin, Shannon Hackett, Jürgen Haffer, Bill Hardy, Ed N. Harrison, Sebastian K. Herzog, Gene K. Hess, Nancy Hilgert de Benevides, Heinrich Hoerschelmann, Elizabeth Höfling, Julian Hume, S. A. Hussain, C. W. Hustler, Hussain Isack, Lois Jammes, Jerry Jennings, Ned K. Johnson, Leo Joseph, Stuart Keith, Lloyd Kiff, Ben King, Guy Kirwan, Claus König, Dan Lane, Scott Lanyon, Wesley E. Lanyon, Mary LeCroy, Miguel Lentino, Richard Liversidge, Huw Lloyd, Nancy Lopez de Kochalka, Michel Louette, Sue Luck, Joe Marshall, Mary Jo MacConnell, Sjoerd Mayer, Juan Mazar Barnett, Klaus Michalek, Sandra Bos Mikich, Marie-Yvonne and Gérard Morel, Gene Morton, David Moyer, Jorge R. Navas, Alvaro José Negret, David Newbitt, F.C. Novaes, Storrs Olson, John O'Neill, David C. Oren, Fernando Pacheco, Robin Panza, Ken Parkes, Bob Payne, Ray Paynter, Chris Perrins, D. Stefan Peters, Town Peterson, Roberto Philips, Derek Pomeroy, Pilai Poonswad, Robert Prys-Jones, Richard

Ranff, Pamela S. Rasmussen, Josef Reichholf, Van Remsen, David Ricalde, Robert Ridgely, Mark Robbins, Scott Robinson, Clemencia Rodner, Francisco Sagot, Paul Salaman, Pedro Scherer-Neto, Thomas Schulenberg, Herbert G. Shifter, K. L. Schuchmann, Lucia Severinghaus, Fred Sibley, Dick Sloss, Karl Somadikarta, Barbara and David Snow, Gary Stiles, Bob Stjernstedt, Morten Strange, Paul Sweet, Dante M. Teixeira, Christopher W. Thompson, Russell Thorstrom, Emil Urban, John-Pierre Vande weghe, Paulo Vanzolini, Jacques Vieillard, François Vuilleumier, Amy Weibel, David R. Wells, Bret Whitney, David Willard, Hans Winkler, Christopher Witt, Hafiz S. A. Yahya and Richard Zusi, and the Academy of Natural Sciences of Philadelphia, the American Museum of Natural History, the Bombay Natural History Society, the British Museum (Natural History) at Tring, the California Academy of Sciences, the Carnegie Museum of Natural History, the Colección Phelps de Venezuela, the Museo Nacional de Historia Natural in La Paz, the Collection of Cornell University, the Dickey Collection of the University of California, the Divisão de Museu de Historia Natural at Curitiba (Brazil), the Durban Natural Science Museum, the Field Museum of Natural History in Chicago, the Edward Grey Institute of Field Ornithology, the Institut Royal des Sciences Naturelles de Belgique, the Koninklijk Museum voor Midden-Africa at Tervuren, the Los Angeles County Museum of Natural History, the Moore Collection of Occidental University in Los Angeles, the Musée d'Histoire Naturelle at La Chaux de Fonds (Switzerland), the Musée d'Histoire Naturelle in Paris, the Museo de Ciencias Naturales in Cali, the Museo de Historia Natural Javier Prado in Lima, the Museo de Historia Natural Noel Kempf Mercado in Santa Cruz (Bolivia), the Museo de Historia Natural de Paraguay, the Museo de la Universidad Nacional in Bogotá, the Museu Nacional de Brasil in Rio de Janeiro, the Museu Paraense Emilio Goeldi in Belém (Brazil), the Museu de Zoologia at Universidade de São Paulo, the Museum of Comparative Zoology, the National Museum of Natural History (Smithsonian Institution) in Washington, the Museum of Natural Sciences at Louisiana State University, the Museum of Vertebrate Zoology of University of California, the Museum und Forschungsinstitut Alexander Koenig in Bonn, the Museum Zoologicum Bogoriense in Bogor (Java), the National Museum in Bulawayo, the National Museums of Kenya, and the Vienna Natural History Museum.

Santiago Guallar again provided useful help with some of the bibliography sections. Many, many thanks to all those who helped us in a wide variety of ways, and especially to Yolanda Aguayo, María Josep de Andrés, Elisa Badia, Dolors Buxó, Juan Antonio Cantí, Cam Christie, Xavier Fosch, Fortunato Frias, Ricard Gutiérrez, Rosa Llinàs, Isabel Martínez, Rafael Martínez, Albert Martínez-Vilalta, Eva Muñoz, María Teresa Obiols, Jim and Mary Ramsay, Olga Rius, Javier Rodríguez, César Ruiz, Eloi Ruiz-Olalla, Arantxa Sánchez and Aurea Vilalta.

We are very grateful to Julian Hume and Errol Fuller for their kind permission to use their plates in the foreword. Errol Fuller also generously supplied all of the archival material used in his foreword. Finally, we are delighted to be able to close our acknowledgement section once again with our warm thanks to Toni Llobet for producing the illustration that graces the back cover of the volume.

# Order GALBULIFORMES

Class AVES  
Order GALBULIFORMES  
**Family GALBULIDAE (JACAMARS)**

- Small to medium-sized slender perching birds with small feet, rounded wings, and very long bill used to catch insects in flight; plumage varies from brightly coloured and iridescent to fairly dull.
- 14-34 cm.

- Neotropical.
- Wooded, mostly lowland habitats.
- 5 genera, 18 species, 37 taxa.
- 2 species threatened; none extinct since 1600.

### Systematics

Given their relatively obtrusive behaviour and conspicuous coloration, it is perhaps not surprising that 17 of the 18 jacamar species have been known for at least 100 years, and most for far longer than that. Indeed, the only more recent taxon that currently stands as a full species, the Purus Jacamar (*Galbalcyrrhynchus purusianus*), was described in 1904 after specimens had masqueraded for many years as females of the White-eared Jacamar (*Galbalcyrrhynchus leucotis*). Before the mid-1700's, and even long after then, the jacamars had been confused with the kingfishers (Alcedinidae). A separate genus was first applied to the jacamars in 1760, by Brisson, who gave them the name *Galbula*, a classical term the legitimate proprietor of which is believed to be the Golden Oriole (*Oriolus oriolus*). It may be of incidental interest to note that, although the name *Galbula* had been used earlier by Möhring, in 1752, Brisson is the only pre-Linnean author whose generic names are recognized when they are additional to those of Linnaeus himself. The jacamars were finally divided into a separate family, the Galbulidae, by Bonaparte, in 1850, although it was then placed between the trogons (Trogonidae) and the kingfishers. This family designation still stands today.

This link between jacamars and kingfishers is a feature of early ornithological writings. In 1743, the Paradise Jacamar (*Galbula dea*) was given the name "Swallow-tailed Kingfisher", and over a century later the superficial similarities between these two groups still led to their being associated taxonomically. The first three jacamars described, in 1758, 1766 and 1776, respectively, were allocated to the kingfisher genus *Alcedo*. In 1847, G. R. Gray classified the jacamars as the fourth subfamily of his "Alcedinidae", and in 1852 Cassin perpetuated this link by including the Galbulidae as a subfamily of the "Halcyonidae", where it was stranded incongruously between two groups of Asian forest kingfishers, the "Dacelininae" (*sic*) and the "Tanyispterinae". In 1840, following an investigation of the feather tracts of birds, a study known as pterylography, C. L. Nitzsch arranged the jacamars alongside another outwardly similar group, the bee-eaters (Meropidae), together with the motmots (Momotidae) and the rollers (Coraciidae), a course that may have prompted Reichenbach to include jacamars within his "Meropinae" in 1852. After a multitude of other taxonomic arrangements, the ordinal placement of the jacamars remains a source of debate and confusion.

Convincing evidence connects the Galbulidae and the puffbird family Bucconidae as sister taxa, despite past inconsistencies in the broader systematic placement of the two families.

Together they form the clade Galbulae, a treatment that has been almost universally adopted for some 250 years (see page 103). Notwithstanding this close association, few authorities would dispute the fact that the Galbulidae and the Bucconidae represent separate families. Most obviously, the jacamars have a bill that is conspicuously longer, straighter and thinner than that of the puffbirds, their plumage is usually so much sleeker, brighter and glossier, and they have a more slender shape and a noticeably smaller head than do the Bucconidae. Galbulids differ further from bucconids in many minor features of bone, muscle and feather design. For example, while both families possess an aftershaft on the contour feathers, there are constant differences between them in the structure of this feature: the aftershaft of puffbirds is a simple group of barbs, whereas that of jacamars is a single shaft that is subdivided. These two structures are apparently homologous and thus, along with many other minor differences between the bucconids and the galbulids, tend to support their close relationship rather than undermine it. While the anatomy and life-history strategy of puffbirds are almost certainly more primitive, no living bucconid appears likely to be a precursor or ancestor of jacamars. Although the Swallow-winged Puffbird (*Chelidoptera tenebrosa*) has a foraging strategy which resembles that of jacamars, this similarity is evidently superficial and due to convergence.

Following A. Wetmore's classification, these two groups, combined as the Galbulae, have traditionally been treated as a suborder of the Piciformes, with the other families of that order combined in the suborder Pici, but whether this accurately reflects evolutionary history remains to be resolved. Although cladistic analysis of skeletal and muscular morphology has suggested monophyly of the Piciformes, this view is by no means universally held. The Galbulae and the Pici have been unified largely on the basis of a complex derived morphology of the hind limb, in particular the arrangement of the digital flexor tendons, associated with zygodactyly. Nevertheless, an alternative viewpoint holds that this feature is doubtfully homologous in the Galbulae and the Pici and, moreover, that no other features unequivocally corroborate the hypothesis of monophyly. To some researchers, the skeletal, muscular and tendinal anatomy of zygodactyly differs between these two groups, the difference being perhaps as great as that which separates them from the parrots (Psittaciformes) and the cuckoos (Cuculiformes). This suggests that the zygodactylous condition evolved independently along different pathways, with similar functional results. If this is the case, it tends not to prove any close relationship between the Galbulae and other piciform families.

The four species of *Brachygalba* form a superspecies of rather short-tailed jacamars that range from eastern Panama to Bolivia and southern Brazil. In addition to their shortened tail feathers, they have short wings and a highly reduced inner hind toe. With seven accepted races, the Brown Jacamar is the most variable species in the genus. However, two of these races were initially combined into a separate species, while another, known from only a single specimen, might be anything from a separate species to merely an aberrant individual of another race, so a detailed revision is required.

[*Brachygalba lugubris melanosterna*,  
Serra dos Carajás,  
Pará, Brazil.

Photo: Luiz Claudio Marigo]

Indeed, separation of the Galbulae and the Pici has often been proposed. In 1880, W. A. Forbes, on the basis of several morphological features, singled out the trogons, bee-eaters, rollers and cuckoo-rollers (Leptosomidae) as potential relatives, adding that "it is amongst these that the nearest living allies of the Jacamars and consequently the Puff-birds must be found". More recently, a considerable body of evidence has been compiled which indicates that jacamars are not piciforms at all, and should be moved to the Coraciiformes. P. J. K. Burton analysed the foraging behaviour and morphology of the Galbulae, concluding that in almost every aspect of feeding-apparatus structure they share important characters with the typical Coraciiformes and virtually none with the Piciformes. These shared characters include a desmognathous palate, and similarities in mandibular musculature, tongue design and cranial osteology. In addition, the lacrimal-ectethmoid bone complex is well developed in the Galbulae but highly reduced in other piciform families, a feature which the latter have in common with the Passeriformes, and the coracoid of the Galbulae is similar to that found in the Coraciiformes. Analysis of egg-white proteins suggested that the Galbulae might, after all, prove to be closer to the kingfishers than to the piciforms. The list of anomalies is extensive: galbulids and buconids both have a naked oil gland, in contrast to the tufted gland of other piciforms; their incubation period is long for piciforms, but similar to that of burrow-nesting Coraciiformes; their skulls are characteristically similar in design; and the tongue bears a distinctive median groove on the dorsal surface that is absent in all other apparently related families.

While electrophoretic analysis of 20 protein-coding loci supported the grouping of the Galbulidae with the Bucconidae as sister groups, it suggested that the Piciformes were polyphyletic. Indeed, it showed the genetic distance between the Galbulae and a coraciiform, the Blue-crowned Motmot (*Momotus momota*), to be considerably smaller than that between the Pici families and the motmot. It has even been suggested that the Galbulae derive from ancient stock not far removed from that which gave rise to the Old World rollers, and even to the cuckoo-rollers of Madagascar and the Comoros, perhaps not too far-fetched a notion given other faunal similarities between those unusual Afrotropical islands and the Neotropics.

In view of the continuing controversy, it is often argued that retention of the Galbulae as a suborder of the Piciformes is not

quite satisfactory. Indeed, C. G. Sibley advocated that a separate order, Galbuliformes, should be erected to accommodate the uniqueness of the Galbulidae and the Bucconidae as a group. Such an arrangement highlights their divergence, and avoids placing them too close to either the Piciformes or the Coraciiformes. Herein it has been considered the best option available on current evidence. It must be stressed, however, that further work is essential to clarify the true relationships of all these groups.

The resemblance of the New World jacamars to the Old World bee-eaters, in both their morphology and their behaviour, has often been noted. Although the taxonomic relationship between coraciiform and traditional piciform families is controversial, it appears that bee-eaters and jacamars are, at best, distant relatives. Both families nevertheless contain a good proportion of smallish, brightly plumaged birds, often extensively green in colour, with a long, pointed bill and short legs. Both are energetic, are vocal and have gregarious tendencies. Moreover, they exhibit remarkable similarities in breeding biology: both are cavity-nesters, their eggs are similar in colour, shape and size, they have long incubation and short nestling periods, and they show a lack of nest sanitation. Furthermore, an absence of a distinct juvenile plumage is a feature common to both families. This situation can perhaps best be explained by convergent evolution resulting from the considerable ecological congruence between the two groups; their diets and foraging techniques are in some cases almost identical.

The members of the Galbulidae are, for the most part, remarkably uniform in structure and behaviour, the only exceptions being the notably divergent genera *Galbalcyrrhynchus* and *Jacamerosops*. The latter was formerly considered sufficiently distinct to be separated in a subfamily as the *Jacameropinae*, although this subdivision is no longer regarded as acceptable. Most other jacamar species are only weakly differentiated, a fact that indicates a fairly recent radiation of the family at species level, and probably even at genus level, from very few ancestors in the Pleistocene period.

According to the taxonomic view that currently finds favour, there are five genera of jacamars. The genus *Urogalba* was previously used for the Paradise Jacamar, and *Psilipornis* for the Yellow-billed Jacamar (*Galbula albirostris*), but both have since been subsumed by *Galbula*, which, with ten species, is the most diverse jacamar genus. The next most diverse is *Brachygalba*,

The New World Galbulidae, such as the White-chinned Jacamar, and the Old World Meropidae, or bee-eaters, are somewhat similar in shape and structure, often with brightly coloured plumage, and with a sharply pointed bill and short legs. Moreover, both groups contain species that excavate nesting cavities in vertical banks and forage primarily on aerial insects. These similarities result from convergence, because genetic and morphological data indicate that jacamars are only distantly related to bee-eaters and other coraciiform families.

[*Galbula tombacea* tombacea, Amacayacu National Park, Amazonas, Colombia. Photo: Otto Pfister]

containing four species. Otherwise, *Galbalcyrhynchus* consists of two closely related taxa and, finally, there are two monotypic genera, *Jacamerops* and *Jacamaralcyon*. Members of the genus *Brachygalba*, sometimes referred to as "short-tailed jacamars", are smaller than those of the genus *Galbula*, with shorter wings and tail and a slightly shorter bill. They also possess a greatly reduced inner hind toe, such that only one hind toe is often visible in the field. Despite its obvious similarities to *Brachygalba*, the Atlantic Forest genus *Jacamaralcyon* seems worthy of retention owing to its unique toe morphology, its longer tail, its plumage colour and its elongated head feathers. Close ecological similarities between the two groups are, however, evident in south-east Brazil: there is no overlap zone between the Three-toed Jacamar (*Jacamaralcyon tridactyla*) and the Brown Jacamar (*Brachygalba lugubris*) where their ranges meet, or at least did so until recently, in the state of São Paulo.

It is convenient to separate these genera into eight zoogeographic groups, five of which are superspecies complexes containing two or more allopatric or parapatric relatives. Geographical isolation is maintained in some cases by natural barriers. For example, the Green-tailed Jacamar (*Galbula galbula*) and the south Amazonian form *rufoviridis* of the Rufous-tailed Jacamar (*Galbula ruficauda*) are separated by the Amazon itself and the lower River Tapajós. In some cases, however, similar species occupy adjoining areas without any natural barrier separating them. Thus, the White-chinned Jacamar (*Galbula tombacea*) and the Bluish-fronted Jacamar (*Galbula cyanescens*) are closely related species living in the upper Amazon; although they occupy adjacent ranges, they are, however, parapatric and have never been recorded interbreeding. The two examples given here involve members of the "Green-tailed Jacamar superspecies", an assortment of five morphologically similar, predominantly bright green and rufous species that also includes the Coppery-chested Jacamar (*Galbula pastazae*). Fifteen of the 18 jacamar species fit neatly into such superspecies groupings, while the remaining three species are monotypic. Incidentally, a large proportion of other Neotropical groups, such as the manakins (Pipridae) and the toucans (Ramphastidae), can be similarly arranged in groups of superspecies.

An analysis of the distribution of superspecies-members in the jacamars, among other families, led J. Haffer to propose

the theory that speciation had occurred during periods in which populations were separated from one another. He suggested that widespread ancestors of these forms were isolated in forest refugia during arid or cold phases of the Quaternary period. Under these circumstances of restricted distributions, reproductive isolating mechanisms evolved in some cases, through random mutations and selection, and these ruled out interbreeding when secondary contact was established later, after intervening areas had been recolonized by forest habitat. In cases where isolating mechanisms were sufficiently developed to prevent interbreeding, species have remained parapatric where contact is resumed, this being a result of their overlapping ecological niches. This hypothesis, derived in part from the study of jacamar distributions, provides probably the best explanation for the speciation mechanisms that led to the current patterns of diversity observed in the Amazon Basin.

Within the Galbulidae, there remain several cases in which the taxonomic status of forms is disputed. The Purplish Jacamar (*Galbula chalcothorax*) was treated by Haffer as a subspecies of the Bronzy Jacamar (*Galbula leucogastra*). Because the two are separated geographically, and stable morphological differences exist between them, it would seem better, however, to treat these taxa as distinct species, together forming a superspecies.

A number of uncertainties surround the constituent subspecies of the Brown Jacamar. The southern form *melanosterna* was initially described as a full species, but was subsequently relegated to the rank of a subspecies of the Brown Jacamar. Nevertheless, as both it and the race *naumburgi* are divergent, and no contact zones are known between them and other races of this wide-ranging species, a reassessment of their taxonomic status would seem desirable. In addition, the form *phaeonota*, known only from the type specimen, was described as a separate species, but it, too, is now generally regarded as a subspecies of the Brown Jacamar; further research is necessary to confirm its taxonomic placement or, indeed, its validity as a taxonomic entity at all.

Another problem concerns the southern form *rufoviridis* of the Rufous-tailed Jacamar. This was long treated as a separate species, under the name of the Spot-tailed Jacamar, but this status has been retracted on the grounds of the southern taxon's general morphological similarity to other subspecies of the Ru-

The two members of the genus *Galbalcyrhynchus* differ from other galbulids in having a chunky body, a dagger-like bill, bright red irides, a short, squared-off tail and dark chestnut plumage. The White-eared Jacamar is nearly identical in appearance to the Purus Jacamar (*Galbalcyrhynchus purusianus*), the latter differing only in lacking white ear-coverts.

So close is the resemblance that Purus Jacamars were initially thought to be female White-eared Jacamars! The two species occupy largely non-overlapping ranges in northern South America but come into contact along the upper River Ucayali in eastern Peru, apparently without interbreeding.

fous-tailed Jacamar. It is, however, obstructed from those races by three other, more divergent forms regularly treated as species, namely the Green-tailed, Bluish-fronted and White-chinned Jacamars. This is a situation which, when it comes to designating populations as subspecies of other taxa, is usually regarded as not permissible. The taxonomic status of *rufoviridis* is, therefore, deserving of review.

Finally, a specimen of a galbulid taken from near Zanderij, in Surinam, is apparently a hybrid between a Green-tailed Jacamar and a Bronzy Jacamar. In size it is closer to the former, while in weight and coloration it is intermediate between those two species. This is the only reported instance of hybridization in the family, and it is of added interest in view of the fact that the two putative parent species are not considered to be particularly closely related.

### Morphological Aspects

Jacamars range in size from the Brown Jacamar, the smallest individuals of which are roughly 14 cm in length and weigh only 17 g, to the much larger Great Jacamar (*Jacamerops aureus*) and Paradise Jacamar. In the case of the last two, the subspecies *amazonum* of the latter reaches 34 cm in length, while the most bulky individuals of the Great Jacamar can weigh up to 76 g. Galbulids tend to have rather a small head, a long, slender bill, relatively small zygodactylous feet and, in many cases, colourful plumage.

Externally, the nostrils have a well-developed operculum, and their elliptical or sigmoidal apertures are situated towards the culmen at the base of the bill. Behind them emerge a few conspicuous forwardly directed bristles, the anterior ones in the rictal series. The posterior cranium and occipital region extends relatively far back, creating a sloping profile of the head reminiscent of the head shape of the bee-eaters. The wings of galbulids are relatively short and rounded, with ten primaries, the outermost of which is short, and twelve secondaries. The tail is often long, full and graduated, presumably an adaptation for agility in flight, although this function is mysteriously superfluous to members of the genus *Brachygalba*, which have a shorter, narrower tail, and *Galbalcyrhynchus*, with a very

short, square-ended tail. Twelve rectrices are usually present, with the outermost pair highly abbreviated. In the genera *Brachygalba* and *Jacamaralcyon*, this abbreviation is taken to its conclusion and only five pairs of rectrices remain. The primary moult follows a simple descendant, centrifugal sequence, while moult of the secondaries and the rectrices is apparently irregular. The oil gland is naked.

Osteologically, the vomer is absent and the post-orbital process is very long. There are 14 cervical and five dorsal vertebrae, and two distinct cervical ribs and five pairs of true ribs.

The visceral anatomy is characterized by a fairly muscular gizzard, the absence of a gall bladder, and a very short intestine with large capacious caeca. Galbulid flesh has a strong distasteful odour, likened to that of trogons. The tongue is quite long, being around 2.5 cm in the Rufous-tailed Jacamar, and is a thin, flat, simple structure lacking extreme modification; in other words, it is longer than the shortened tongue of the kingfishers, but shorter than the long specialized tongue of the woodpeckers (Picidae). There is apparently a suggestion of a brush-tip on the tongue of the Great Jacamar, a character shared with a puzzling assortment of species without any apparent underlying ecological basis.

The typical jacamar bill looks, as put by T. W. Sherry, "better suited to opening letters than catching insects". It is elongated and sharply pointed, somewhat like that of bee-eaters, but, in contrast to its Old World counterpart, a jacamar usually holds its bill at an oblique angle, pointing upwards, not unlike a hummingbird (Trochilidae). Two genera do not comply with this morphological format: *Galbalcyrhynchus* has a deeper, heavier, dagger-like bill reminiscent of that of kingfishers, with a strong dorsal ridge, while *Jacamerops* has a shorter, deeper, somewhat flattened and decurved bill. The typical jacamar has been likened, both in appearance and in behaviour, to a motmot or a trogon, a comparison that could never be applied to its closest relatives.

Aerial insectivores tend to have a bill of one of two types. A broad and short bill, forming a cavernous aperture when opened, is possessed by, for example, the swallows (Hirundinidae), nightjars (Caprimulgidae) and broadbills (Eurylaimidae). The second type, slender and pincer-like, is a characteristic of the New World jacamars, as well as the Old World bee-eaters. Three hypotheses

have been advanced for the design of this second type of hunting instrument. First, a long bill keeps stinging or venomous insects, such as Hymenoptera, away from vulnerable portions of the face, and also provides leverage for beating prey against a perch. It has even been postulated, somewhat speculatively, that such a bill allows the predator to hold insects sufficiently far from its eyes that it can identify an individual prey and decide whether it is palatable. Secondly, given the importance of Lepidoptera and Odonata in the diet, bill morphology may be an adaptation for capturing long-winged prey. For example, a long bill could serve to reach past the obstacle of the fragile wings so that the insect's body can be grasped firmly. If it is the wings alone that are grasped, the prey frequently escapes (see Food and Feeding). Finally, and perhaps most importantly, a direct relationship exists between bill length and the linear speed at which mandible tips can move. This biomechanical fact is presumably crucial, as it means that long-billed birds should be able to capture fast-moving prey more readily than can short-billed birds. These hypotheses are not mutually exclusive, and it is likely that the various factors have operated in combination to shape the bill of jacamars.

The legs of jacamars are short and weak, with the tarsi scutellated anteriorly but smooth posteriorly. The feet are small and zygodactylous, the second and third digits pointing forwards and the first and fourth permanently reversed. The two front digits are syndactylous, being linked at the base to roughly as far as the middle of the second phalanx and thus forming a "shovel", somewhat like the three front digits of kingfishers. In both cases, this feature may perform a useful function during the excavation of nest-holes (see Breeding). The galbulids show a tendency towards digit reduction. In the genus *Brachygalba*, the first digit, or hallux, is vestigial, while in the Three-toed Jacamar, the sole member of the genus *Jacamara*, the hallux is entirely absent, the fourth digit remaining as the only hind toe. In the latter genus, the first metacarpal, equivalent to the thumb, is well developed.

The colour of galbulid soft parts is often diagnostic, but can also be confusingly variable. For example, the iris of *Galbalcyrhynchus* is coral-red, while that of the four *Brachygalba* species is sometimes red, but may also be whitish or strikingly light blue, seemingly enamelled. The Three-toed Jacamar has dark brown irides, although they are often spotted or entirely

yellowish-brown or red. It has been suggested that, in this last species at least, eye colour develops in tandem with age, but this has not yet been proven. Variability in this characteristic requires further study in order to elucidate its correlates. In contrast, the eyes of *Galbula* and *Jacameros* are usually dark brown, sometimes paler or warmer brown, but never strikingly pale or bright. Jacamars tend to have a rather large area of bare skin in the orbital and loreal region that is usually blackish, greyish or brownish, although it is also occasionally brightly coloured. In the Yellow-billed Jacamar, for example, it is conspicuously yellow, and in *Galbalcyrhynchus* it is pinkish-red. Bill coloration adheres to a similar pattern of variation: most species have a black bill, while that of the Yellow-billed Jacamar is yellow and that of *Galbalcyrhynchus* is pinkish-red. A pale bill is also found in the White-throated Jacamar (*Brachygalba albogularis*) and in some subspecies of the Brown Jacamar.

The plumage of *Galbula* and *Jacameros* is colourful, often with rich rufous on the tail and underparts and with an iridescent or metallic sheen, chiefly of green, blue or bronze, on the upperparts and the breast. The long bill and glossy plumage prompted early naturalists to associate galbulids with kingfishers, and these brightly plumaged jacamars also recall overgrown hummingbirds in shape and coloration. Some jacamar species, however, principally those in the genus *Brachygalba* and the related *Jacamara*, are much more dull. These tend to be dark brown with white patches, and only hints of gloss and colour. The sexes of all jacamars generally display only minor dimorphism, the females often being slightly duller than the males, particularly on the abdomen, and they are most readily identified by the throat colour. Males tend to have a conspicuous patch of white on the throat that is replaced by a buffy or rufescent patch on females, a difference already apparent in the young prior to fledging. Immatures are often duller still, in addition to which they retain a distinctly shorter bill for several months after fledging. Furthermore, in species with bright soft-part coloration, the colours tend to be less bright on young birds. Apart from these differences, there is usually no distinct juvenile plumage pattern and, consequently, jacamars can be quite difficult to age.

Interestingly, immature Pale-headed Jacamars (*Brachygalba goeringi*) appear to be more colourful than their parents, espe-

Blue-necked Jacamars and Yellow-billed Jacamars (*Galbula albirostris*) are closely related galbulids that are easily recognized by their striking emerald-green upperparts and extensively yellow bill. The lower mandible is completely yellow in both species, but in Blue-necked Jacamars the upper mandible ranges from completely black to mostly yellow, as in this bird. Some authors treat these taxa as a single species, but intergrades are unknown in the potential zone of overlap in eastern Peru. The specific epithet of the Yellow-billed Jacamar means "white bill," which suggests that the type specimen's bill had perhaps faded prior to examination by scientists.

[*Galbula cyanicollis*, Imperatriz, Maranhão, Brazil. Photo: Haroldo Palo, Jr.]

All jacamars occupy wooded habitats, primarily lowland or riparian forest, and they seldom occur at elevations above 1000 m.

Most species favour the edge or the canopy of the forest rather than the interior or the understorey.

Pale-headed Jacamars conform with this general trend and tend to occupy the drier end of the habitat spectrum, being found at the edge of second-growth and gallery forest and in open woodland and savanna. They often perch conspicuously on bare branches, where they may be readily visible to aerial predators; this may explain their sombre plumage, an aid in camouflage.

[*Brachygalba goeringi*,

cially on the upperparts, where they are quite strongly glossed with green. It has been suggested that, since ontogeny generally accords with phylogeny, the bright plumage of immatures implies a bright ancestor, and that sombre plumage is a more recent adaptation. It has been speculated that ancestral *Brachygalba* might have ascended from the lower-stratum foraging niche of *Galbula* and adopted prominent perches on the treetops and open boughs of the canopy, where they perhaps proved more vulnerable to the depredations of raptors. Hence, they evolved more subtly coloured plumage as camouflage.

## Habitat

The jacamar family is exclusively Neotropical, occurring from southern Mexico to southern Brazil. Records of the Rufous-tailed Jacamar from Argentina, including a lost specimen, remain unconfirmed and are, therefore, treated as provisional. Within this general range, jacamars are absent from all but a few associated islands.

Galbulids are principally arboreal, resorting to other habitats only when nesting. As a result of this, all are associated with more or less wooded habitats, 13 of the 18 species being found in the Amazon Basin and 15 occurring in Brazil. Underlying this distributional trend is the predilection of many species for lowland or riverine forest, although within this general habitat they occupy a broad variety of niches, from the understorey to the upper canopy, and from forest edge to deep forest. The presence of banks, termitaria or the exposed bases of uprooted trees for nesting is presumably vital. Most jacamars are species of low altitudes, or the nearby foothills, which they tend to ascend to 600 m, occasionally 1000 m or, rarely, 1300 m. Only the Coppery-chested Jacamar preferentially frequents higher altitudes in the submontane zone of the Andes, where its presence has been confirmed at localities lying between 600 m and 1600 m, although most often at 1000-1300 m.

Despite the marked association of all jacamars with woodland and forest, the Great and Yellow-billed Jacamars are perhaps the only galbulids regularly encountered within these habitats. Most members of the family are restricted almost exclusively to the edge or the canopy of forest. The Rufous-tailed Jacamar, for example, prefers forest borders, treefalls, streamsides and scrubby second growth near forest, although it does occur locally inside undisturbed forest. Alternatively, the Paradise Jacamar and the Bronzy Jacamar tend to perch almost

solely on bare branches in the canopy, and they do so regardless of the canopy height, which may be anything from 2 m to 50 m. Unlike the puffbirds, which are notoriously unobtrusive in their behaviour, the jacamars are conspicuous by nature, which allows one to be relatively certain that the predominance of records of these birds at forest edge reflects real ecological patterns. At the same time, however, the preponderance of sightings of canopy-frequenting species at edges and gaps in forest is doubtless due in part to the greater ease with which they are detected when thus situated.

Ten species of jacamar are associated strictly with humid forest and its borders. The Rufous-tailed Jacamar, apart from its northern subspecies *melanogenia*, does not, however, fall within this category, as it also inhabits scrubby deciduous cactus-rich woodland along the Caribbean coasts of Venezuela and Colombia, wooded *llanos*, savannas, and dry *cerrado* and *caatinga* woodlands in Brazil. All *Brachygalba* and *Jacamaralcyon* species occur in highly patchy habitats and are not really linked to humid forest at all. For example, the southern race *melanosterna* of the Brown Jacamar occupies the dry central Brazilian tableland, avoiding humid habitat to the north, while the Three-toed Jacamar inhabits drier, vine-entangled woodland and forest patches in south-western Brazil, generally shunning nearby tracts of humid Atlantic Forest.

Similarly, ten species of galbulid show a preference for riverine or lacustrine vegetation in at least parts of their range. The scarce White-throated Jacamar is apparently restricted to riparian regrowth and river islands in the lowlands of eastern Brazil and Peru. The Bluish-fronted Jacamar, the Purus Jacamar and the White-eared Jacamar are often found around oxbow lakes or along Amazonian rivers, and even the widespread Rufous-tailed Jacamar shows a distinct association with riverine forest, this being especially so in the case of the subspecies *melanogenia* of Central America. In addition, many jacamar species frequent the borders or interior of the cyclically flooded forest known as *várzea*, and at least two of these, the Yellow-billed and Great Jacamars, also occur in permanently flooded forest, or *igapó*. According to H. Sick, the Blue-necked Jacamar (*Galbula cyanicollis*), along with the Green-and-rufous Kingfisher (*Chloroceryle inda*), occupies *várzea* in the Belém area of northern Brazil only when these forests are flooded twice daily by tides.

The association of jacamars with watercourses and successional habitats is reflected in the fact that, in primary forest, the distribution of the latter is related to that of the former. The course

of large Amazonian rivers is in constant flux, as the waters regularly drift across their floodplains for more than 25 m each year. These constantly shifting river channels cut back forest on the outer side of meanders, leaving bare alluvial deposits in their wake. On these deposits, vegetation proceeds through a roughly 300-year sequence of relatively well-defined stages, at the end of which stands mature rainforest. In an attempt to clarify the importance of these regenerating riverine forests for birds, S. Robinson and J. Terborgh studied the dynamics of an avian community along the River Manu, in Peru. They found that Bluish-fronted Jacamars generally avoided early successional stages, characterized by, for example, monocultures of *Tessaria integrefolia*, followed by stands of the cane *Gynerium sagittatum*, and then by gap-loving trees such as *Cecropia*; populations were most dense, with 13 territories per 100 ha, in mid-successional stages with a mixed canopy and *Ficus/Cedrela* forest, and became less dense again, at three territories in 100 ha, in mature floodplain-forest. This pattern was repeated by the less abundant Purus Jacamar. These two galbulids, along with a suite of other species, were most abundant in relatively narrow bands of successional forest created by fluctuating river courses, a fact that has important implications for the assessment and conservation of bird populations.

At many Amazonian localities, between four and six species of jacamar co-exist. Most of them are remarkably similar in their dietary requirements and foraging methods, and it appears that they are able to achieve this sympatry by means of a rough partitioning of the habitat among them. For example, north of Manaus, in Brazil, the Yellow-billed Jacamar generally occupies the understorey, mid-levels and edge of primary and secondary forest. The Great Jacamar inhabits the same forests, but largely avoiding secondary formations, and most often frequenting middle levels and the lower canopy. The Paradise Jacamar, meanwhile, is a supracanopy species, foraging from emergent bare boughs high above the ground. A fourth species, the Bronzy Jacamar, tends to perch on top of second growth, scrub and lower-stature sandy forest. By foraging in different places, they minimize competition for resources. Similarly, C. H. Fry found that four galbulids living alongside each other in Minas Gerais, in south-eastern Brazil, "avoided competing by favouring different habitats"; these were the Bronzy, Brown, Paradise and Rufous-tailed Jacamars. Niche separation by habitat selection is thus one factor that allows increased jacamar diversity. Another factor is diet, one example of which is provided by the Yellow-billed Jacamar and the Great Jacamar. These two species sometimes forage at similar heights in forest, but, with their morphologically dissimilar bills, they target insects of different sizes and types and are therefore less likely to impinge on each other's success.

More often than not, however, the diet and the habitat selection of related jacamars overlap so extensively that sympatry is precluded. This is the case in upper Amazonia, where the ranges of the White-chinned Jacamar and the Bluish-fronted Jacamar meet abruptly in continuous forest; there is no overlap in the ranges of the two species, and no interbreeding between them. Where habitat is less continuous in the contact zone of related species, they may exhibit locally divergent habitat preferences. The Green-tailed Jacamar usually occupies a niche similar to that exploited by the Rufous-tailed Jacamar, and the two usually exclude each other in areas where they come into contact. In a small area of Guyana, however, they are reported to be sympatric and apparently ecologically separated, with the Green-tailed frequenting riverine habitat and hilly areas, and the Rufous-tailed Jacamar being associated with extensive isolated savannas. At the same time, it should be noted that this apparent ecological separation was questioned by G. F. Mees, who found the Green-tailed Jacamar only on inland savannas in Guyana.

The tolerance of disturbance and of man-modified habitats shown by most jacamar species is presumably a result of their preference for edge habitats. In some parts of its range the Rufous-tailed Jacamar occurs in leafy suburban gardens, and the Purus Jacamar has been seen on roadside wires in settled areas. The Three-toed Jacamar has been recorded around busy picnic spots and tiny, highly degraded woodlots (see Status and Conservation).

## General Habits

The Galbulidae are almost entirely diurnal. Nevertheless, according to Sick, the Rufous-tailed Jacamar apparently forages in near-darkness on occasion, disclosing its activities by tapping prey loudly against a branch. Fifteen species, the great majority of the family, are most often encountered as singletons or pairs, and less frequently as trios or small groups, the last possibly being family parties. The remaining three, the White-eared, Purus and Three-toed Jacamars, almost always forage and apparently also breed in groups of four to six individuals, with up to ten sometimes recorded. The composition of these groups and the kinship within them are unknown. The nineteenth-century chronicles of J. Natterer, usually a scrupulously accurate observer, contain a reference to one flock of around 30 Brown Jacamars on the banks of the Rio Grande in Minas Gerais, Brazil. Whatever the reason for this unusual congregation, no similarly large gathering has been reported since. Although gregariousness is rare among jacamars, some species, such as the Yellow-billed Jacamar, frequently troop with antwren (*Myrmotherula*) flocks or follow mixed-species foraging parties in the lower storey of rainforest, and this is a habit occasionally indulged in also by, for instance, the Rufous-tailed Jacamar. Other galbulids, including the Bronzy and the Paradise Jacamars, regularly associate with mixed flocks in the canopy, and the Rufous-tailed Jacamar is again one of several species that occasionally do so.

For much of the day, jacamars habitually perch motionless between foraging flights, like the puffbirds. They sometimes remain still for long periods of time, moving only the head, but they are, nevertheless, considerably more active than puffbirds. They make much more rapid side-to-side movements of the head, hence appearing far more alert, and they tend to call and to make aerial sorties much more frequently. The head movements of the smaller galbulids, such as the Green-tailed Jacamar, tend to be much more rapid than those of the Paradise Jacamar or the Great Jacamar. One Three-toed Jacamar moved its head rapidly, at a rate of about 84 movements per minute, while looking for prey. When perching, most species appear to direct their attention obliquely upwards, holding the bill at a jaunty angle of about 45°. Paradise Jacamars tend to carry the bill at a slightly shallower angle, perhaps 20°; this is probably because they perch at greater heights, and prey animals are therefore more often level with or lower than the bird itself. At least some species, including the Great Jacamar, have the habit of about-facing rapidly, suddenly switching the direction of their view. A single perch, or cluster of perches, may be used continuously for up to an hour.

The flight of jacamars is usually swift, darting and fairly brief when chasing prey or switching perches. Long distances are sometimes covered, however, when moving between foraging patches or escaping danger, and at these times the birds fly with bursts of rapid wingbeats interspersed with sailing glides, such that their progress can appear erratic or undulating.

Little is on record regarding the comfort behaviour of the family. Head-scratching is apparently performed by the indirect method, the leg being brought over the wing. Interestingly, this is in contrast to the Bucconidae, which employ the direct method in which the leg is raised beneath the wing. The Galbulidae, as most other birds, clean the bill frequently by wiping it on a branch, although sometimes they use the feet, too. The Rufous-tailed Jacamar is often observed dust-bathing on dirt or gravel roads, but there appear to be no confirmed records of sunning by any members of this family.

Roosting takes place in burrows, at least in the case of some galbulid species. Groups of Three-toed Jacamars, for example, roost communally in burrow systems, all group-members assisting in the digging of these. The burrows are usually sited in situations similar to those used for nests, in banks 0.8-6 m high. Two such roosting cavities were 62-72 cm deep, 6-9 cm high and 6 cm wide. It is not known whether nesting by this species takes place in cavities previously used for roosting, but this is perhaps likely. It is, however, certain that Three-toed Jacamar chicks, once they have fledged, return to the nesting cavity for nocturnal roosting, sometimes accompanied by adults. Similarly, a family of two adult and four juvenile Pale-headed Jacamars used its

With its streamlined body, needle-like bill, and elongated central tail feathers, the Paradise Jacamar is distinctive enough to have warranted placement in its own genus, *Urogalba*, prior to being moved to its present position in *Galbula*.

The four currently accepted races exhibit subtle differences in size and plumage coloration that may only represent variation through a cline.

During the early taxonomic history of the Galbulidae, this species played a central role in the mistaken notion that jacamars were kingfishers (Alcedinidae). Indeed, as the first galbulid known to science, the Paradise Jacamar received the name "Swallow-tailed Kingfisher" in 1743, and was later placed in the kingfisher genus *Alcedo* by Linnaeus. From the mid-nineteenth century onwards, jacamars and puffbirds (Bucconidae) have been recognized as close relatives, and often considered to be allied to one or another family within either the Coraciiformes or the Piciformes. In the last decade or so, however, jacamars and puffbirds have increasingly been separated in their own order, Galbuliformes, based on a combination of morphological, DNA-DNA hybridization and electrophoretic studies.

nest-burrow as a dormitory for at least two months after the chicks had fledged. The young tended to enter the hole around 1.5 hours before darkness fell, with the adults entering later. The dual use of the burrow by this species, and the greater number of individual birds which it must accommodate, can perhaps explain why the burrow itself is about twice as long as the nest-burrow of the Rufous-tailed Jacamar, a species that appears never to use the nest as a family roosting site after fledging. The use of nest-holes for roosting has never been recorded for the puffbirds, the single other family in the Galbuliformes, although this may be a reflection of the limited amount of field study which the Bucconidae have received. Among the Piciformes, a better-known order, it is a common habit of woodpeckers, certain barbets (Capitonidae) and toucans.

Jacamars are highly sedentary animals that defend resources within a multi-purpose territory occupied by a pair or a group. At least in the case of breeding Rufous-tailed Jacamars, these territories appear to be rather small, as foraging adults are almost always within view from the vicinity of the nest. Antagonistic interactions sometimes occur as a result of competition for mates, territories and nest-sites. Disputes between males of the Rufous-tailed Jacamar tend to involve sustained bouts of loud complex singing, sometimes with aggressive dashes by one bird towards another, but real physical contact is rare. Although the male is apparently the more aggressive, both sexes contribute to territory defence. Pairs of Rufous-tailed Jacamars, for example, have been observed co-operating in order to repel other hole-nesters from the vicinity of active nests. One instance of this was witnessed in Venezuela, where Southern Rough-winged Swallows (*Stelgidopteryx ruficollis*) were "violently attacked and driven off", as were Blue-crowned Motmots. The hirundine does at least occasionally breed in cavities excavated by jacamars, although it is not known whether it ever succeeds in usurping the occupants or merely uses abandoned nests. Given the formidable weapon of the jacamar's bill, the latter seems the more likely. Indeed, jacamars sometimes use the bill with some ferocity during aggressive encounters with conspecifics, as has been recorded in captivity for species of *Galbula*. Moreover, when two groups of Purus Jacamars, each containing five individuals, interacted aggressively at Cocha Cashu, in Peru, four of the birds were seen to lock bills and pull back and forth, while the remaining six perched and sang at close range.

## Voice

Disregarding the unusual voice of the Great Jacamar, the most common jacamar vocalizations consist of single, high call notes that are often given liberally throughout the day, either from a perch or in flight, and which are audible at long range. The call of the Rufous-tailed Jacamar, for example, is a frequently repeated "peeup" or "pee", usually terminating abruptly; it is uttered by both sexes, and is sometimes repeated three to ten times in succession. A very rapid trill is also occasionally given by that species. Similar sharp foraging calls are emitted by all *Galbula* species for which information is available, these alternatives being described as "quep" for the Coppery-chested Jacamar, "keelip" for the White-chinned Jacamar, and so on. These calls are essentially similar throughout the genus, as is the tendency for them to be delivered in series, sometimes so rapidly that trills are produced. The smaller *Brachygalba* species give analogous single calls. That of the Pale-headed Jacamar is transcribed as "weet", while the call of the Dusky-backed Jacamar (*Brachygalba salmomi*) is written as "feet", that of the Brown Jacamar as "chewee" and the White-throated Jacamar's call as "psueet". Again, these calls are similar for all four members of the genus, but they are distinctly different in quality from *Galbula* calls, being weaker, thinner, and more plaintive or upslurred. Similarly, they are given in series when excited, and then develop in some cases into an insect-like trill. The call of the Three-toed Jacamar is a clipped "churr", and that of the White-eared Jacamar is a loud "kyew".

Some jacamars are remarkable among non-passerine birds for their elaborate, protracted songs. According to A. F. Skutch,

male Rufous-tailed Jacamars are capable of singing "so splendidly that few true songbirds (Oscines) could surpass them". The delivery varies in tempo, with slow drawn-out notes accelerating into melodious or chuckling trills, ascending in pitch until very high notes are reached, whereupon slow notes are resumed. This sequence is interspersed with twittering and a low, nasal "bee-bee-bee". These impressive performances can last for several minutes, but they are much less frequently heard than are the usual calls. Similar song types are also part of the vocal repertoire of *Brachygalba* species. A singing Pale-headed Jacamar, for example, gives the usual short call in a rapid series that accelerates in pace and ascends in tone, ending in a sharp trill. When the bird is excited, this sequence is sometimes uttered repeatedly, resulting in an undulating series of sharp crescendos, twitters and high, thin trills. At these times, the jacamar turns its body rapidly from side to side, and jerks the tail at each syllable, or flicks it up and down rhythmically, as if beating time.

The general pattern of vocalizations given by those two species is repeated, so far as is known, by all members of their respective genera. There appears to be a continuum between low-intensity calls and high-intensity peeping, trilling, twittering and tail-flicking. At the lowest intensity, a single sharp note is emitted, this being the standard foraging or contact call. This is sometimes extended into a series when the individual is excited, and, when this excitement increases still further to stimulate song, the series is either given in crescendo or is expanded to include a terminal high-pitched trill. At the far end of the spectrum is a variable and protracted medley of all different components of the repertoire; although this longer sequence is heard less frequently, it incorporates calls given singly, in level series and in ascending series, mixed with high, thin trills and extra ornamentations such as protracted notes and low buzzy notes. Jacamar vocalizations can thus be viewed as a continuous hierarchy of elements based on simple sounds, rather than the more dichotomous pattern, found among many passerines, of simple call notes on the one hand and very different complex songs on the other.

It appears that, in the genera *Brachygalba* and *Galbula*, complex songs are given only by males. They sometimes countersing at close range to each other in disputes over mates or territories, each apparently trying to match or to better the other's efforts with sheer volume and repertoire size. Group vocalizations in which both sexes take part are a feature of the more gregarious jacamars. While the song of an individual Three-toed Jacamar is a modest sequence of short, relatively weak whistles, the complex group song lasts for up to 20 seconds and involves various shrill ascending whistles, apparently uttered by up to six birds simultaneously. In groups of the White-eared Jacamar and the Purus Jacamar, the individual members also combine their vocalizations in order to increase the overall volume and complexity of the sound, especially during interactions with neighbouring groups.

The three most aberrant galbulids in terms of morphology appear also to have the most divergent vocalizations. The Great Jacamar sings at long intervals with an unusual long, high-pitched, hawk-like whistle, first rising and then falling in pitch, but it is otherwise rather silent. The White-eared Jacamar gives a prolonged rising trill, presumably the song, which is reminiscent of the voice of a woodcreeper (Dendrocolaptidae); it also utters very loud single "kyew" or "cue" calls, these accelerating into a chatter when excited. The Purus Jacamar gives a descending "peeueur" whistle and a sharp "pee".

Unlike passerines, which rarely sing before fledging, nestling Rufous-tailed Jacamars develop songs like those of the adults and can be heard trilling and calling regularly and for long periods. These vocalizations emanating from the nest are audible from some distance, at least 21 m, and the young jacamars, when they are about two weeks old, often emit them almost throughout the day. Interestingly, observations at the nest of a pair of Pale-headed Jacamars suggested that the nestlings were far less vocal, only rarely trilling when the adults appeared at the cavity entrance.

When held in the hand, jacamars produce a bill-snapping sound with the mandibles.

Of the 18 species of Galbulidae, fifteen are decidedly non-social and are typically encountered as singletons or in pairs. Larger parties, consisting of perhaps three or four individuals, often prove to be family members. Thus, this group of four Brown Jacamars may rightly consist of two parents and their progeny from the latest breeding attempt. A nineteenth-century report by a reputable observer of 30 Brown Jacamars in a flock in Minas Gerais, Brazil, is a mystery in that no such concentrations have been encountered since. Several species, including Yellow-billed (Galbula albirostris), Rufous-tailed (Galbula ruficauda), Bronzy (Galbula leucogastra) and Paradise Jacamars (Galbula dea), are known to join mixed-species foraging flocks in the forest canopy or at army ant swarms.

### Food and Feeding

With the sole exception of the Great Jacamar, all jacamars are exclusively insectivorous. Their diets consist almost entirely of winged prey, caught in flight. They usually operate from temporarily favoured perches upon which they wait passively for insects to fly within range. On sighting appropriate prey, the jacamar embarks on a swift, darting flight which, once the prey is caught, with an audible click of the mandibles, switches to a sweeping glide. This is often followed by a return to the same perch, or a nearby one, where the insect is beaten and consumed. The clicking sound is all the more audible when the target is missed, and the mandibles then snap shut without obstruction. Aerial pursuits are often spectacular, aerobatic and prolonged, and at such times the jacamar is even more unwary than usual, sometimes flying within a metre of an observer.

The Paradise Jacamar tends to forage from high, exposed perches in the canopy, from which, after having sighted flying prey, it executes a dive. There is some evidence to suggest that it favours flowering trees so that it can capture the bees and beetles that visit the flowers. The dive is followed by a swift pursuit with rapid and agile changes of direction. Less frequently, foraging flights are made directly upwards towards insects flying overhead. After capturing the prey item, the bird returns to a perch with an undulating flight, changing perches after about 50% of forays. During a five-hour period of observation, foraging flights made by this species covered distances ranging from 1 m to 12 m, and were mostly 4.5-9 m; the flights were generally of short duration, lasting 1.3-5.6 seconds, with an average of 3.2 seconds. The frequency of forays was calculated at 21.8 per hour,

a considerably higher rate of foraging flights than that recorded for the Swallow-winged Puffbird, the only aerial insectivore among the buconids.

As other jacamars tend to sit lower down in vegetation, they perhaps exhibit a greater frequency of upward flights than does the Paradise Jacamar. Further, the activity rates appear to be higher among the smaller galbulids, such as the Green-tailed Jacamar, with foraging flights perhaps twice as frequent, at around 40 per hour, although the distance and duration of flights are possibly less.

Perches selected by jacamars tend to be in rather open positions, such as bare or dead branches offering good all-round vision. The Rufous-tailed Jacamar has been reported as stationing itself above rotting fruit on the forest floor, apparently taking advantage of the numerous butterflies and dipteran flies attracted to this food source. In addition, three Purplish Jacamars encountered in eastern Ecuador were reported as all being perched on the nests of bees (Apidae), although whether they were foraging on the bees was not clear. Equally, it is conceivable that these reported nests were actually misidentified arboreal termitaria in which the jacamars were nesting, but this seems unlikely. A more plausible explanation is that jacamars occasionally position themselves near the nests of bees or social wasps (Vespidae) and harvest the regular supply of flying adults.

The usual victims of foraging forays are soft-bodied species of butterfly and moth (Lepidoptera), dragonflies (Odonata), wasps, bees and flying ants (Hymenoptera), flies (Diptera), beetles (Coleoptera), and various bugs (Hemiptera) including homopterans such as cicadas (Cicadidae). It should be noted that, while large and spectacular prey are sometimes caught, the vast

majority of food items are tiny insects. Only flying individuals of prey animals are pursued, the same species being entirely ignored when they are perched on nearby vegetation. There is a single anomalous record of a female Rufous-tailed Jacamar emerging from a half-built burrow with a grub in her bill that she proceeded to eat. The only regular exception to the rule concerns the Great Jacamar, which often makes wing-whirring dashes to snatch prey from foliage, rather than catching aerial insects. The foraging behaviour of this galbulid is more akin to that of puffbirds, trogons and motmots.

Of several hundred pursuits by Rufous-tailed Jacamars observed in Costa Rica, about 40% resulted in the insect's escape. This often happens because the bird grasps a butterfly's wings, rather than any substantial part of the insect's body. Indeed, one of the commonest forms of damage to the wings recorded on living butterflies in Costa Rica was apparently the unique snips made by jacamars, resembling the marks left by a forceps-like instrument. After a successful foray, the jacamar beats the prey item against a branch or other hard perch to kill it, and to break off the wings or more resistant chitinous parts, before swallowing the food, although such treatment is not necessary for small soft-bodied dipterans. Favoured perches of jacamars can thus be identified by the brilliant carpet of butterfly wings littering the ground below. Even though the wings of large-winged prey are usually knocked off before consumption, butterflies are sometimes swallowed, or carried to the nestlings, with the wings still attached. The amount of beating delivered to each food item is generally in direct proportion to the size and toughness of the individual prey, but it is often less than that carried out by other insectivores. Indeed, galbulids regularly consume social wasps without beating them at all, which suggests that the jacamars may have some immunity to the stings of vespids. Moreover, in five hours of observation of foraging Paradise Jacamars, the wiping of wasps back and forth against a branch to de venom them, a practice frequently undertaken by bee-eaters, was observed only once.

So far as is known, all jacamar species regularly regurgitate pellets containing the indigestible chitinous parts of insects. Analysis of these pellets can sometimes help to determine the kinds of prey animals being eaten by these birds.

The proportions of different prey types selected by jacamars vary among species, and apparently even within species accord-

ing to site and season. In Mato Grosso, in south-central Brazil, the diet of breeding Rufous-tailed Jacamars, as calculated by pellet analysis and the contents of nestlings' gizzards, reportedly comprised 86% Hymenoptera, 10% Coleoptera, 2% Odonata, 1-2% Lepidoptera, and tiny proportions of Hemiptera and Orthoptera. A study of the same species in Central America, however, revealed that Odonata and Lepidoptera predominated in the diet. How might these differences arise? From observations in Costa Rica, Sherry reported that Lepidoptera and Odonata were frequently recorded in the diet of breeding birds, but were less commonly taken outside that season, and it has been postulated that large-bodied insects are favoured during the breeding period because they are easy to transport to nestlings. Other fieldworkers repeatedly recount that small insects are certainly eaten immediately, rather than being carried to the brood. When nestlings are only four days old, they have been seen to be given dragonfly bodies as long as the chicks themselves. This preference for provisioning large items is not surprising when one realizes that prey items are brought one at a time to nestlings, a strategy unlike that of passerines, which often return from forays with the beak crammed full of items. Nevertheless, it should be borne in mind that dietary information derived from nest watches will probably exaggerate the proportion of butterflies and dragonflies in the diet, as such items, being large, are more easily identifiable.

Although this notion of a preference for larger insects when breeding is contradicted by the Brazilian data, and also by the fact that large quantities of euglossine bees have been found at some burrows in Central America, it could be that at least some of the items identified in those instances involved food regurgitated by adults rather than fed to nestlings. It is also possible that Lepidoptera, because of their more digestible body parts, are less frequently identified in pellet remains, although their wing scales might be conspicuous. While differences in study methods could therefore underlie apparent differences in diet, variation in dietary preference doubtless reflects differences in prey abundance between separate sites, as well as between seasons and between habitats. For example, stomachs of Yellow-billed Jacamars from near Manaus, in Brazil, examined by M. Cohn-Haft, usually contained no winged termites (Isoptera), but at times some were completely packed with them. This sug-

Jacamars catch insects in aerial sallies launched from an exposed perch. They feed almost exclusively on flying insects and will ignore suitable prey types that are present on nearby vegetation or on the ground. The feeding ecology of the Rufous-tailed Jacamar has been well studied in several parts of its range. This individual has captured a large dragonfly and beaten it against a branch to render it immobile and also to remove its wings before swallowing it. Along with butterflies and moths, dragonflies make up the bulk of this species' diet in Central America, especially during the breeding season.

[*Galbula ruficauda melanogenia*, Corcovado National Park, Costa Rica. Photo: Doug Wechsler/VIREO]

Jacamars feed on a wide variety of insects, most of which are apparently small, soft-bodied species. Typical prey items include butterflies and moths (Lepidoptera), bees, wasps and flying ants (Hymenoptera), dragonflies (Odonata), beetles (Coleoptera), flies (Diptera), and winged termites (Isoptera). Results of feeding studies may vary depending on the techniques employed by researchers. For example, a small prey item, like that caught by this Rufous-tailed Jacamar, might be eaten immediately rather than transported to the nest, and would thus be missed during a nest watch. Similarly, soft-bodied prey types that are easily digested whole might well be underestimated in studies based on pellet analysis.

gests that, when a hatch occurs, the resultant abundant food source is harvested enthusiastically.

Lepidoptera species are not randomly selected. Jacamars appear to target butterflies which have a bulky abdomen, such as skippers (Hesperiidae), and they are capable of capturing very large Neotropical butterflies, such as those in the genera *Morpho*, *Caligo* and *Papilio*. The relationship between abdomen size of butterflies and the dietary preferences of jacamars is, however, somewhat circular, as palatable butterflies tend to have much larger flight muscles than do unpalatable species, a characteristic that enables them to escape from predators more efficiently. In other words, their relative body size is perhaps a result of predation pressure rather than a cause of it.

A more intractable relationship concerns the avoidance of noxious prey. Many butterflies contain toxins or other repellent substances, usually derived from host plants, which render them unpalatable. Research has shown that galbulids are adept at quickly recognizing a surprisingly large number of unpalatable species, presumably through experience of their foul flavour coupled with their characteristic vivid markings. In Costa Rica, the Rufous-tailed Jacamar has been recorded as catching and then rejecting many unpalatable butterflies, including, among others, *Battus polydamas*, *Catagramma buguba*, *Eueides lybia*, *Nessaea aglaura* and *Perrhybris pyrha*. Most frequently, these species are able to escape after brief detention in the jacamar's bill, reaping the benefit of their noxious nature, and they are thereafter usually ignored by this galbulid. The relative safety experienced by these insects is increased the more distinctive they are, and most of them have therefore evolved aposematic coloration; in other words, they have acquired extremely bright and distinctive patterns which help jacamars to identify these lepidopterans before attacking them. These distinctive patterns are mimicked in their turn by palatable butterflies in response to the selective pressure of jacamar foraging behaviour: those individuals most resembling aposematically coloured species receive the same benefits as do the latter, resulting, after many generations, in identical lookalikes. In general, palatable butterflies fly rapidly and erratically, while those with aposematic patterning fly more slowly and directly. This situation probably develops partly as a signalling system by which jacamars recognize noxious prey, although non-noxious mimics tend to fly like their models rather than like their relatives, but also partly through relaxed predation pressure on such butterflies. In effect, jacamars in Costa Rica targeted almost exclusively those butterflies that were the most cryptic and the most difficult to catch. As one of the few animal groups to specialize in the hunting of butterflies in flight, the Galbulidae are quite possibly the most powerful factor driving the evolution of these fantastically accurate mimicry complexes so often observed in Neotropical butterflies.

Much interesting research into this system has been conducted by P. Chai in Costa Rica, involving both wild and captive Rufous-tailed Jacamars. The birds generally attacked palatable butterflies rapidly, especially when they were hungry. Unpalatable species tended to be ignored unless the jacamars were deprived of food for a few hours, after which time their reluctance to take noxious prey diminished. One palatable species, *Consul fabius*, has an upperwing pattern that almost exactly mimics the coloration of the noxious *Heliconius ismenius*, and an underwing pattern that closely resembles a dead leaf. Its appearance in flight is determined by its upperwings, and these are consequently designed to deter jacamars by masquerading as the wings of a poisonous insect. At the same time, as *Consul fabius* is totally safe from jacamars when perched, but is then vulnerable to countless other watchful insectivores, adaptive forces have operated to maximize crypsis rather than aposematic coloration when the insect is resting.

Analysis of the stomach contents of the White-eared Jacamar, a species with a relatively short, robust, dagger-like bill, has revealed that it feeds primarily on wasps and bees. This is quite surprising in view of its bill morphology, which was assumed by Burton to denote a preference for large or hard-bodied prey. The Great Jacamar is much more sluggish than its relatives, tending to remain motionless on its mid-level perch in forest for several minutes at a time, and then making a short

sally, more often than not ending in a move to a different perch. As this large galbulid tends to glean prey that is perched on leaves, rather than taking flying insects, it has a slightly broader, shorter bill than that possessed by most other jacamars. This is thought to be a secondary character, as in all other details of its feeding-apparatus morphology this species closely resembles other galbulids (see Morphological Aspects). The Great Jacamar is one of very few galbulids known to consume non-insect prey, having been recorded taking spiders and even small reptiles, such as lizards, on occasion.

Different members of the family have responded to competition with other jacamar species by occupying ecologically separate foraging niches that allow them to live in sympatry. In general, predominantly bright green species, such as the Rufous-tailed Jacamar, hunt at low levels on forest edges and, to a lesser extent, within forest. The Paradise Jacamar and the Brown Jacamar, meanwhile, exploit the space above the canopy, perching on emergent boughs and dead branches at the tops of trees. Between these strata lies the mid-storey, and this is occupied by species such as the Great Jacamar. In some places, this niche separation allows several species of jacamar to co-exist in the same forest (see Habitat).

## Breeding

The study of breeding systems of Neotropical birds remains in its infancy for most groups, and the jacamars are no exception. Much of what is known of the breeding behaviour of the Galbulidae is due to the patient endeavour and careful observation of Skutch, who spent many hours sitting concealed near nests of the Rufous-tailed Jacamar, recording the visits of adults and the development of their progeny.

Jacamars usually breed as socially monogamous pairs, although some species apparently breed in co-operative groups of three to five individuals, and perhaps more. While *Galbula* species are generally monogamous, there is an unusual report of one female and two male Green-tailed Jacamars co-operating to build

Owing to toxins obtained from their food plants, many butterflies are unpalatable to birds. Rufous-tailed Jacamars, and perhaps other galbulids as well, recognize noxious species and modify their prey choice accordingly. They have been seen seizing and then quickly rejecting several species of toxic butterfly, which often escape with only minor injuries and subsequently are ignored by the birds. Noxious species tend to be brightly coloured and to fly more slowly and less erratically than do tasty species. Palatable mimics enjoy the same lack of attention from jacamars that is afforded to toxic species.

a nest, suggesting that the mating system of these birds can occasionally be more complex. The Three-toed Jacamar is more habitually gregarious and may well form small breeding colonies, with up to 20 holes having been recorded in some earth banks. This species builds multiple-use burrows, catering for both roosting and breeding, and single individuals regularly participate in the digging of several burrows, although interpretation of this is complicated by the fact that nest-tunnels often have multiple entrances. Moreover, some burrows are constructed by more than two individuals, up to seven having been recorded in one case, although this might have involved a roosting cavity, and non-parent group-members apparently help to feed fledglings. In another group-living species, the Purus Jacamar, six individuals excavated a presumed nest-cavity in an arboreal termitary in Peru, but it was not discovered how many contributed to parental care. These two species, along with the White-eared Jacamar, are the most social members of the family, and further study is required to clarify the nature of their breeding systems. Certainly, if Three-toed Jacamars were indeed proved to breed colonially and cooperatively, with helpers at the nest, another remarkable behavioural link would be established with the bee-eaters, several species of which, such as the much-studied White-fronted Bee-eater (*Merops bullockoides*), have this social system.

The breeding season of galbulids is variable throughout the Neotropics, presumably according to patterns of rainfall and prey abundance. While it might be predicted that the timing of nesting should be synchronized with the onset of rains, and thus the emergence of many flying insects, this is not always the case. The Three-toed Jacamar appears to breed in south-east Brazil during the wettest period, whereas the Yellow-billed Jacamar is reported to breed in the dry season in the Guianas. Nest-building by Rufous-tailed Jacamars in Costa Rica often starts in February, in the middle of the dry season, although the rains usually arrive at the time when the nestlings are developing.

Courtship among jacamars involves bouts of singing and courtship feeding by the male, which frequently catches insects for his mate, diligently knocking off their wings before presenting them to her. During nest-building, Rufous-tailed Jacamars have been observed to perch side by side, the male bobbing his head up, down and sideways, swinging his tail up and down, and giving low squealing notes while the female trills. The two also perch alongside each other while fanning the tail and bowing together, in the manner of woodpeckers.

Jacamars breed in cavities which they dig into soft substrate. The nests of twelve species have been described. Those of seven species are known only from termitaria and those of three others only from earth banks, while the remaining two species are known to use both sites. No descriptions exist of the nests of the other six species of Galbulidae. Given the paucity of information available, it seems likely that most species will eventually be found to utilize both forms of nest-site. In all probability, however, the Paradise Jacamar nests exclusively in arboreal termitaria, as it is rarely seen below the canopy, and the Three-toed Jacamar only in earth banks, because few termitaria are large enough to accommodate colonies.

Those galbulids which excavate nest-holes in soil select vertical banks of varying size, from 30 cm to several metres in height, and usually of sand, clay or some other soft substance. In forest habitat these banks are normally situated alongside rivers, although, with the advent of trails and roads, they are often provided by the associated cuttings. More rarely, nests are sited in steep slopes or angled landslips, rather than in precipitous banks. In level forest where banks are unavailable, the Rufous-tailed Jacamar has been recorded nesting in soil lifted by the roots of a large fallen tree, provided that the attached earth is sufficiently deep. One advantage of such a site is that the gap created by the treefall is a favoured foraging habitat. Jacamars appear not to locate burrows according to the presence of concealing vegetation but, instead, to place more importance on the presence nearby of a handy perch and on an unobstructed flightpath to and from the hole. A few recorded nest-holes, including those of the Coppery-chested and the Rufous-tailed Jacamars, have been partially concealed behind overhanging vegetation, such as roots at the top of a bank. The Great Jacamar has been reported by native Amazonians to nest occasionally in rotting tree stumps, a habit which, although not unlikely, does require confirmation.

The use of arboreal and terrestrial termitaria has frequently been reported for several species of kingfisher, parrot and puffbird, among others. In level forest where banks are scarce, and also in the canopy, termitaria presumably provide a vital nest-site for jacamars, too. More surprisingly, the Rufous-tailed Jacamar has been recorded nesting in a termitarium even when a soil bank stood only a short distance away; in this case, the bank was dry and hard, and it is possible that, in such circumstances, termitaria are preferred because of their relative brit-

tleness and ease of excavation. For some time an opposite view prevailed, its premise being that termitaria are often extremely hard and galbulid bills quite fragile, so that jacamars were in fact less likely to excavate their own nests in termitaries and more likely to utilize the cavities made by other animals. The dimensions of termitarium cavities occupied by galbulids were nevertheless suspiciously similar to jacamar holes in other sites. More recently, several species, such as the Purus, Green-tailed and Paradise Jacamars, have been directly observed as they excavated holes in termitaria, thereby establishing incontrovertibly that they are capable of performing this feat. Indeed, the Yellow-billed Jacamar, a small species with a fine bill, was watched in Surinam by G. F. Mees while it was "hacking" a hole in an arboreal termitarium. This description suggests that the bill is deceptively strong.

Nest-digging individuals use the bill to loosen soil or sand, or termitarium walls, a process during which their mandibles often become dirty while the plumage remains remarkably clean. Most debris is then removed by kicking with the small feet, which are modified into a shovel shape (see Morphological Aspects) perhaps for this very purpose, but the birds sometimes emerge from burrows with lumps of earth held between the mandibles. There is some indication that the mandibles may become damaged in the process of nest-construction. In museum collections of Three-toed Jacamars, along with a small mist-netted sample, significantly more females than males had broken bill tips, suggesting both that excavation might be undertaken more commonly by the female and that this might result in fracture of the mandible tips. It is difficult to confirm this hypothesis without empirical observations, and, moreover, gunshot is a frequent cause of bill damage in specimens. Conversely, Wetmore reported that Rufous-tailed Jacamars, despite their digging activities, exhibited a surprising lack of bill damage.

In one case, a Three-toed Jacamar was recorded with a very worn left foot, leading Sick to speculate that the species is predominantly left-footed when nest-building. More recent observations have suggested, however, that the feet are used alternately by this jacamar when clearing debris from the nest. While there is little further information on this topic, Skutch, in an account of a female Rufous-tailed Jacamar's nest-building behaviour, mentions that, in kicking earth backwards with her feet, she threw out "twin jets". This appears to imply that the feet were used simultaneously.

Both the male and the female contribute in digging, the little available information suggesting that the female performs the bulk of this task, at least in the early stages. In Central America, a female Rufous-tailed Jacamar performed almost all the digging at first, remaining in the nest-chamber for several minutes at a time; the male stood sentinel nearby, calling frequently and catching insects occasionally. After a day the male began short bouts of digging, each less than a minute in duration, and eventually he spent almost as much time in excavation work as did the female. Digging was undertaken almost throughout the day, during which time the female rarely caught food for herself. The male made up for his lower contribution to building by providing her with insects. When he caught these, he called to his mate from outside the burrow, whereupon she emerged to be fed. At first the birds came out of the hole tail first, but after a while the burrow was widened so that they could turn around inside it and emerge head first.

When completed, nest-cavities are generally long and narrow. Those of Rufous-tailed Jacamars are 29-50 cm long, 4-6 cm broad and 3.5-4.5 cm high, while a cavity of the smaller Pale-headed Jacamar measured 80 cm in length, 4 cm across and 3 cm in height. Cavities tend to be shorter when made amongst up-turned roots and in termitaria, although no significant difference in dimensions has been shown. One entrance burrow made by a Rufous-tailed Jacamar in a small arboreal termitary, however, was only 6 cm long, with a full cavity length, including the nest-chamber, of 14 cm, while others, in larger terrestrial termitaria, have been up to 31 cm in length. Their dimensions are doubtless determined by the size and shape of the termitary. The longest galbulid burrow ever recorded is that of a Three-toed Jacamar, measured at 146 cm.

Burrows of the Rufous-tailed Jacamar, unless deflected by an obstruction, are usually straight, such that the nest-chamber is at least partially visible. Other burrows are reported to be curved upwards so that the chamber is invisible, as was the case with one cavity made by Coppery-chested Jacamars. It is likely that all species build both straight and curved burrows, depending on circumstances. When roots or other obstructions are met, the angle deviates, often sideways or downwards, to bypass the obstacle. In the view of some authors, jacamar burrows, or at least those of the Rufous-tailed Jacamar, are easily distinguishable from other cavities on account of the rectangular shape of the entrance, with vertical sides. There seems, however, to be no real consensus on this, and the entrances of other burrows of the same species have been described as elliptical. A few species of jacamar regularly have two or more access, or escape, routes to the nest-chamber, presumably as a defence against predation.

The time taken to complete a burrow appears to be highly variable, a fact that would seem likely to relate at least in part to the density of the substrate into which the burrow is excavated. In an example already given, a pair of Rufous-tailed Jacamars appeared almost to finish the task in three days. In contrast, a pair of Three-toed Jacamars took nearly two months to complete a burrow in a bank. One nest of the Green-tailed Jacamar was excavated by three individuals, two males and one female, each taking turns of about five minutes' duration to dig into an arboreal termitarium, usually in the afternoon; individuals not engaged in excavation usually sat close to the nest, catching insects, but not moving very far away. The burrow advanced by around 2-3 cm a day, even though work lasted for up to eight hours daily, and the entire job took about four weeks to complete. At the outset, the group worked for a total of about one hour each day, but this gradually increased to up to eight hours, while individual bouts increased from a couple of minutes to 15 minutes. The assistance of the extra male was presumably highly important. This event, incidentally, represents the only record for any *Galbula* species of more than one male at a nest.

Located at the end of the burrow, the nest-chamber is unlined, but it quickly becomes covered with the glittering chitinous parts of insects regurgitated by the incubating parents. By the time of hatching, the chamber is liberally befouled with excrement and insect parts, a situation common to many burrow-nest-

Foraging Green-tailed Jacamars perch on exposed sites in shrubby edges of tall forest, moving the head rapidly as they scan the lower and middle levels of the foliage for insects. Their diet consists mainly of Hymenoptera, Lepidoptera, Diptera, Coleoptera and Odonata. The smaller jacamars tend to be the more active foragers. Thus, Green-tailed Jacamars, of 18-22 cm, may attempt up to 40 aerial sallies per hour, whereas Paradise Jacamars (*Galbula dea*), which measure about 25-34 cm, attempt an average of only 22 sallies per hour.

ing birds. Jacamars sometimes clean out the nest-hole and reuse it in consecutive years.

Egg-laying by jacamars tends to take place at some time between ten days and six weeks after the completion of the burrow. The interval between the deposition of each egg is apparently two to four days. The eggs themselves are shiny, almost spherical and usually pure white, in common with those of many other hole-nesting birds, as they require no mottling or camouflage to conceal them from predators. Rarely, Rufous-tailed Jacamar eggs are lightly freckled with reddish or cinnamon spots.

The clutch generally comprises between two and four eggs, although apparent full clutches of one egg have been reported. The Rufous-tailed Jacamar follows the common pattern among birds of laying increasingly larger clutches with increasing latitude. In Guatemala the most common clutch is of four eggs, and in Rio de Janeiro province, in Brazil, this species has been recorded laying two clutches a year, each of four eggs. Closer to the equator, four out of eleven nests in Costa Rica contained two eggs, six held three and the eleventh held four; three or four eggs are reported in Venezuela, and in Trinidad and Tobago three is the commonest clutch size, with two or four more rare. At lower latitudes still, Amazonian populations, of the subspecies *rufoviridis*, are thought to lay only one egg per clutch. Replacement clutches are usually laid in the event of abandonment.

Studies of wild-living Rufous-tailed Jacamars indicate that the incubation period is quite variable, lasting between 19 and 23 days, and occasionally up to 26 days in adverse conditions. Eggs of the same species in captivity, however, have been recorded as hatching after only 18 days. This difference in the period of incubation suggests that embryo development is determined by such factors as temperature, as might be expected.

Incubation is undertaken by both sexes and is sometimes initiated before completion of the clutch. In the case of the Rufous-tailed Jacamar, the best-known member of the family, the female tends to incubate at night. The male sometimes arrives outside the burrow before sunrise and calls, whereupon the female emerges. In observations of this behaviour in Central America, the male then waited for a short period, during which he caught a few insects, having perhaps 20 minutes of daylight in which to feed; he then took over incubation at 05:30-06:00 hours, apparently later on overcast days. In some pairs, the female leaves the nest without waiting for the male to arrive. Notwithstanding the female's patience or otherwise, the two adults then proceed to incubate throughout the day in alternating bouts. At a nest watched in Guatemala, each stint tended to last for 2-2.5 hours, while for a pair in Costa Rica the duration of individual bouts of incubation was somewhat shorter, between 84 and 113 minutes. The male usually undertakes a longer bout during the late afternoon, following which the female begins her overnight session, entering the burrow a little after sunset. At each change-over there may be some calling and displaying, but the eggs are rarely left unattended for a period of more than five minutes. Incubation is normally carried out for about 95% of daylight hours, and is continuous during the hours of darkness.

Unlike the nestlings of most Piciformes, which are generally naked on hatching, those of the Rufous-tailed Jacamar hatch with a copious covering of long, whitish down. Many other non-piciform hole-nesting species, such as the parrots, the owls (Strigidae) and the swifts (Apodidae), also have very pale downy chicks, rather than the mottled camouflaged chicks of ground-nesting birds; this is presumably a result of reduced predation risk, and an adaptation that allows the adults to see the nestlings more clearly in the darkness of the cavity. Long down filaments on the chin and throat make nestling jacamars appear bearded. In common with members of the order Piciformes, however, galbulid nestlings have a strange appearance, at least initially, because the lower mandible projects distinctly beyond the upper one. Nestlings of the Rufous-tailed Jacamar hatch with the eyes closed, these forming dark protuberances on the sides of the head until they open, after about six days. At the same stage the pin-feathers emerge, with tufts of down at their tips. By the twelfth day after hatching the feathering is quite well developed, and the nestlings can already be sexed by the colour of their throat feathers. Whereas the outer and inner toes

are directed forwards when the chick hatches, on nestlings over six days old they point backwards, as on adults. Nestling jacamars often have pale yellowish legs with a prominent soft oval callus on the "heel" or tarsus. This heel pad, a feature also of young bee-eaters, kingfishers, woodpeckers, toucans and barbets, probably serves to cushion the chicks against the rough, unlined nest-chamber. Skutch reports that the pads of Rufous-tailed Jacamars are nearly smooth.

Although the chamber appears woefully unhygienic, with no attempt made by the adults to dispose of waste material, the chicks remain remarkably clean. This is partly because they usually stand erect, and do not let their plumage touch the floor or walls of the nest-chamber. Nevertheless, sufficient residue of animal matter and faeces is present to allow maggots to proliferate inside the nest-chamber. In one case, a brood of Rufous-tailed Jacamars had to vacate the nest after it was colonized by large numbers of ants, apparently attracted to the rotting faecal matter and insect parts. This exposure led to the death of the chicks. The loud vocalizations of nestling Rufous-tailed Jacamars suggest that they are not usually preyed on by animals that hunt acoustically.

When nestling Rufous-tailed Jacamars are taken from the nest, parents returning with food in the bill perch nearby and call in alarm, but they tend not to mob or to perform distraction displays. Adults, at least females, when brooding chicks, sometimes allow themselves to be touched by humans, rather than fleeing.

The majority of food items collected for the nestlings are apparently caught within 50 m of the nest, particularly those brought in by the male. Studies of Rufous-tailed Jacamars have provided some evidence to suggest that females forage farther afield, and return to nestlings with larger prey items, than do males. Skutch watched one pair of these birds for 25 hours during the six days before the two chicks fledged. He found that, of a total of 122 deliveries, the adult male provided 88 and the female 34. He concluded that "from every aspect, the male was the more industrious provider", always feeding the chicks first before dawn and tending to stay closer to the nest to forage. The total intake was 2.4 feeds per chick per hour. Skutch's observations at a nest containing four young Pale-headed Jacamars were briefer, but, around the third week after hatching, 13 visits were made by the adults in 1.5 hours; this equates to a similar hourly feeding rate of 2.2 deliveries per chick. When the nestlings are very young, the adults take food to the nest-chamber itself. After several days, however, the chicks tend to advance towards the burrow entrance until, finally, they perch sufficiently close to it that their parents need only insert a small portion of the body to deliver food items.

Rufous-tailed Jacamar nestlings apparently fledge after 20 to 26 days. They promptly acquire a plumage similar to that of adults, but are recognizable by the fact that they have a short bill. In the few cases studied, fledging has not been synchronous, with young birds often emerging a few hours, or even days, apart. Variations in the duration of the fledging period are probably determined largely by food availability. One pair in Costa Rica nested in the same burrow for two years in succession; the chicks in the first year were well developed when they fledged, at 21-22 days, whereas those in the second year fledged at 25-26 days yet were poorly developed. The second breeding attempt was made late in the season, and the abundance of butterflies and dragonflies at that time was seemingly rather low. At least in the case of young Rufous-tailed and Pale-headed Jacamars, the act of leaving the nest is accompanied by a great deal of loud vocalizing by adults and offspring alike. Young Rufous-tailed Jacamars sometimes leave the burrow before they can properly fly, although this is probably not a common occurrence. Adults and young of some species tend to roost together in the burrow after fledging, this period of communal roosting by family-members lasting for up to eight weeks. This has been shown to be so with Pale-headed Jacamars, but is apparently not the case with Rufous-tailed Jacamars, which roost separately.

One pair of Yellow-billed Jacamars in French Guiana was found to be double-brooded, excavating a new cavity for the second clutch only a short distance from the first nest. A pair of Rufous-tailed Jacamars in Costa Rica also raised two clutches,

Much of what is known about the breeding biology of galbulids comes from studies of Rufous-tailed Jacamars. Their breeding season varies widely with latitude, beginning as early as February in Central America as opposed to November or December in Brazil and Bolivia. Courting males sing to females and frequently bring them food.

Paired birds may sit side by side near their uncompleted nest, the male bobbing his head in all directions, pumping his tail up and down, and emitting low squeals while the female produces a trill.

Pair members will also perch next to each other while performing a mutual display of head bowing and tail fanning. Both sexes help build the nest, which consists of a tunnel dug into a vertical bank, an arboreal or terrestrial termitarium, or the dirt-laden roots of an overturned tree.

The clutch of 2-4 eggs is incubated for about three weeks by both sexes, the female taking the lead at night; the young leave the nest when they are

between three and four weeks old, and often two broods will be raised per year. Most of the *Galbula* species are thought to be socially monogamous, although several other species, most notably the Three-toed Jacamar (*Jacamaralcyon tridactyla*), the Purus Jacamar (*Galbalcyrhynchus purusianus*) and perhaps the White-eared Jacamar (*Galbalcyrhynchus leucotis*), are suspected of breeding co-operatively in groups of four to six birds.

the second nest built about 150 m from the first. It seems reasonable to conclude that most galbulid species can be double-brooded, although this appears to be exceptional in the case of the relatively well-studied Rufous-tailed Jacamar.

## Movements

All jacamars appear to be wholly sedentary. The only reported study involving uniquely marked individuals concerned two Rufous-tailed Jacamars, one of each sex. Observations showed that one of these, the female, remained a breeding resident on approximately the same territory until at least four years after initial capture. Similarly, the marked male was still present in the same location one year later.

Despite this apparently strict site-fidelity, however, long-term studies at certain localities have proven that individual jacamars may wander. These are perhaps young birds in search of territories, or those displaced by habitat loss. For example, Skutch writing of his residence at Los Cusingos, in Costa Rica, records that "at long intervals, I hear the stirring calls of a solitary jacamar, apparently a wandering male seeking a mate that he cannot find. Without one, he does not stay".

## Relationship with Man

Despite the ambivalence that most jacamars show towards people, humans have in general proved to be rather fond of the jacamar. The Galbulidae have endeared themselves to man on account of several behavioural and morphological traits, among which can be listed their apparently trusting nature, their spryness and their gaudy coloration. In stark contrast to their apparently ponderous and slow-witted allies, the puffbirds, jacamars have frequently been the subject of praise. According to Skutch, jacamars possess "all the physical features that win so much admiration for hummingbirds – metallic brilliance of plumage, richness and variety of colour, abundant vitality, gracefully dashing movements". He describes them as "electrified with a high voltage".

Often equated with overgrown hummingbirds, the jacamars are again likened to that group by R. French, because of their "excitable temperament and intense vitality". This vitality is an often repeated theme: even the jacamar's voice "helps create the impression of a bird keyed up to the highest pitch of excitement". Likewise, the Rufous-tailed Jacamar has been described as an "aery, gemlike bird with bright brown eyes and rapier bill". Sherry remarked that this species was one of the reasons why birdwatchers go to the Neotropics. It must be added that, in general, it is the members of the genus *Galbula* upon which these distinctions fall. Those in the genus *Brachygalba* are more modest creatures, in truth rather dull in colour. As an adjunct to their colourful activity, the jacamars are often unwary of people, allowing a close approach, especially when nesting. While this confidence is considered charming by many, it also renders the birds vulnerable to hunting.

The resemblance of the Galbulidae to hummingbirds, even if somewhat superficial, has led to the same name being applied to both groups in various portions of their range. Examples include *beija-flor* ("flower-kisser") or *chupa-flor* ("flower-sucker") in Brazil, *gorrión* in Guatemala, and *tucuso* in Venezuela. This terminology overlooks the fact that hummingbirds feed on nectar, whereas jacamars are, with a single exception, entirely insectivorous; this is the kind of mistake that native Indians, who coined the name "jacamares", usually do not make. The Great Jacamar, of course, looks nothing like a hummingbird, and it often shares local names with the motmots, such as *Juró* in Panama. In much of Amazonian Brazil, jacamars share the name *ariramba* with the kingfishers; to distinguish the former from the latter, jacamars are also given the name *bico-da-agulha*, or "needle-bill". Other colloquial names reflect the cavity-nesting behaviour of the family, as in the local name *cavadeira*, meaning "digger", for the Three-toed Jacamar in Brazil.

Charles Kingsley's account of his first meeting with a Rufous-tailed Jacamar in the shady forests of Trinidad admirably

conveys the beauty of these birds. Although he unfortunately mistakes a *Morpho* butterfly for a moth, and treats the male jacamar as a female, his words aptly capture the dazzling intensity of these creatures which have thrilled so many naturalists and visitors to the Neotropics:

"And what was that second, larger flash of golden green which dashed at the moth, and back to yonder branch not ten feet off? A Jacamar – kingfisher as they miscall her here, sitting fearless of man, with the moth in her long beak. Her throat is snowy white, her underparts rich red brown. Her breast, and all her upper plumage and long tail, glitter with golden green. There is light enough in this darkness it seems."

Whether jacamars are regarded by local natives as a worthwhile supplement to their diet is not really known, but it would seem unlikely that these birds represent a valued food. The flesh of jacamars is reported to have a strong, distasteful odour, likened to that of trogons.

## Status and Conservation

The majority of jacamar species occupy broad ranges in forested lowlands. Their preference for a rapidly disappearing habitat in areas where that habitat is most easily destroyed leaves them vulnerable to population declines. For many galbulids, this alarming situation is alleviated by two main factors: the occupation of an extensive range, and the predilection for forest edge. The first of those results in a resilience to habitat loss on the basis that it is difficult for humans to eradicate all the appropriate forest over a very wide area of a species' distribution. The second allows jacamars to survive, and even to thrive, in fairly broken, fragmented and disturbed habitat. All the same, even the commonest species, the Rufous-tailed Jacamar, has been reported to have disappeared from certain sites as a result of uncontrolled habitat loss and poaching, as happened in some forests in Costa Rica in the 1940's.

The response of different species to habitat destruction varies according to their ecological requirements. Research carried out by J. M. Thiollay in French Guiana revealed that the abundance of birds in the forest interior tended to decrease in response to selective logging; among these, the Yellow-billed Jacamar decreased dramatically and the Great Jacamar disappeared altogether. Meanwhile, species inhabiting the forest edge or the canopy, including the Paradise Jacamar, actually increased as a result of selective logging, although this apparent effect may have been partially an artefact of their easier detection in broken habitats.

Two species of galbulid occupy greatly restricted ranges, and both are considered globally threatened according to IUCN criteria. One is the Coppery-chested Jacamar, a scarce inhabitant of middle altitudes and forested valleys in the eastern Andes from southernmost Colombia to northernmost Peru. This species, the only jacamar restricted to the subtropical zone, is listed as Vulnerable by BirdLife International. It has been recorded at elevations ranging from 600 m to 1700 m, and is apparently most common between 1000 m and 1300 m. It has been recorded only once in Colombia since its discovery there in 1970, and the largest population undoubtedly occurs in Ecuador. At Río Bombuscaro, in the province of Zamora-Chinchipec, it is reported to be fairly common on the basis of the presence of four to six resident pairs along a section of trail 2-3 km long. This area lies within the Podocarpus National Park, which is currently the only measure providing any protection for the species. Although the Coppery-chested Jacamar has been found at several other sites and may prove to be secure, it seems to be very thinly and patchily distributed. As it is generally confiding, hunting could be a problem in some recently settled areas. Moreover, this jacamar appears to be dependent on fairly intact lower montane forest, a habitat type seriously threatened by agricultural settlement, cattle grazing, and clearance for coffee and tea cultivation. Extensive protected areas are required

Considered to have been common in the nineteenth century, the Three-toed Jacamar has declined substantially in distribution and numbers and is no longer common anywhere. At present, an estimated 250-1000 individuals occur in small patches of dry, lowland Atlantic Forest in south-eastern Brazil. They may persist in some areas of degraded habitat if native understorey has been retained, but habitat loss and subsequent range restriction continue to render the birds vulnerable to local extinction and to the negative effects of inbreeding. Currently listed as Endangered by BirdLife International, the Three-toed Jacamar is in dire need of effective conservation measures.

Photo: Luiz Claudio Marigo]

in this zone. Podocarpus National Park has itself in recent times been under threat from mining activities and colonization by humans, and requires focused conservation action on behalf of this species and a diverse array of threatened Andean fauna for which the area is vitally important.

The other globally threatened galbulid is the unusual Three-toed Jacamar, which is considered Endangered. It is an endemic species of the Atlantic Forest in south-eastern Brazil, although the forest which it prefers is not the moist evergreen rainforest associated with this region. It appears to favour drier scrubby woodlots, often surrounded by cultivation, and it occurs even in eucalyptus (*Eucalyptus*) woodland so long as natural understorey remains. In either habitat it requires earth banks in which to nest and roost. From the accounts of J. T. Reinhardt, one can deduce that this species was very common in Rio de Janeiro state and Minas Gerais in the nineteenth century. Since that time it seems to have undergone an inexplicable decline, having apparently disappeared from Espírito Santo, Paraná and São Paulo, and since the mid-1970's reports of its presence have come only from eastern Minas Gerais and Rio de Janeiro. In these two states this jacamar is extremely local, but is common at a few sites, although it may be somewhat under-recorded as its preferred degraded habitat is understandably unattractive to ornithologists. Fieldwork in Minas Gerais in the late 1990's confirmed early records of the species' occurrence in the region, and established its continued presence in some fragments of habitat severely disturbed by humans. Habitat loss and the collapse of roosting and nesting cavities through subsidence, especially during the rainy season, are major threats. Detailed studies of remaining populations of the Three-toed Jacamar, and the establishment of reserves in representative habitat fragments, are strongly recommended. In addition, the artificial provision and maintenance of earth banks would perhaps benefit the species, and such measures could profitably be undertaken as an experimental conservation strategy in suitable areas.

Although no other galbulids are currently considered threatened, or even near-threatened, it could be argued with some justification that two species need to be re-evaluated with regard to their conservation status. Both could be deemed to be scarce and potentially threatened with extinction. The White-throated Jacamar frequents lowland riparian habitats near the junction of

Brazil, Bolivia and Peru. It is rarely recorded, is apparently local and is quite specialized in its habitat requirements. In common with several other species, it appears to be reliant on successional habitats along Amazonian rivers. Comprehensive surveys are required to establish its exact distribution and status throughout its range, as also are effective measures to control habitat loss along the relevant Amazonian tributaries. There is an uncertain historical record of this jacamar from Jaén, in the Peruvian department of Cajamarca, far from its currently known range, suggesting that this species should be searched for in the catchment of the Río Marañón. It occurs in Tambopata Reserve, in Peru, an important area that requires effective protection.

The Dusky-backed Jacamar of Colombia and Panama appears to be relatively scarce. Its known range should be thoroughly surveyed at the earliest opportunity, in order to establish the species' true status and to assess its population trends. At the same time, it would be wise to seek suitable locations for establishing additional protected areas, with the aim of safeguarding this poorly known jacamar.

In summary, the widespread use of edge habitats by jacamars has meant that some species may have benefited substantially as a result of the destructive actions of humans. Increased fragmentation of forest in Amazonia has presumably opened up many areas to colonization by these species, and their populations may well have risen as a result. This relationship is reversed, of course, for those species which prefer intact forest, and all jacamars tend to be most common in areas where human populations are sparse. Moreover, in the face of wholesale development, deforestation and disturbance, jacamars generally disappear. It is significant that only one species, the Rufous-tailed Jacamar, is known to frequent the wooded fringes of certain towns and cities.

# Genus *GALBALCYRHYNCHUS*

Des Murs, 1845

## 1. White-eared Jacamar

### *Galbalcyrrhynchus leucotis*

**French:** Jacamar oreillard **German:** Kastanienglanzvogel **Spanish:** Jacamará Orejiblanco  
**Other common names:** Chestnut Jacamar (when lumped with *G. purusianus*)

**Taxonomy.** *Galbalcyrrhynchus leucotis* Des Murs, 1845, "Santa Fé de Bogotá", Colombia; presumably = Amazon lowlands.

Forms a superspecies with *G. purusianus*. Sometimes considered conspecific, but no intermediate forms documented despite their co-existence on R Ucayali, in Peru; studies along potential zone of contact would help clarify their relationship. Monotypic.

**Distribution.** E of Andes in S Colombia (S from Meta), Ecuador and NE Peru (S to R Ucayali), and W Brazil along R Solimões (E to below mouth of R Purús at Caviana, opposite Manacapurú).

**Descriptive notes.** 18-21 cm; 44-50 g. Chunky jacamar, recalling kingfisher (Alcedinidae), looking broad-winged and short-tailed in flight. Plumage is entirely reddish-chestnut, forehead, crown, wings and tail glossed bronzy or greenish-black, with conspicuous white ear-coverts; robust bill 4.8-5.6 cm (4.1-4.5 cm from nostril), light pinkish with dark tip, sometimes looking white depending on light conditions; iris bright red; bare eyering and loreal region pinkish-red; feet relatively large, pinkish-red. Immature generally paler, some fine darkish streaks on abdomen, bill shorter. Voice: Presumed song a prolonged rising trill resembling

that of a woodcreeper (Dendrocolaptidae); also occasional loud "kyew" or "cue" call, sometimes in series; vocalizations given by single bird or by small groups in concert.

**Habitat.** Lowland humid primary forest (*terra firme* and *várzea*) and secondary forest, mainly along borders near clearings, rivers and streams, at up to 500 m.

**Food and Feeding.** Insects, apparently Hymenoptera and Lepidoptera predominating; sturdiness of bill suggests that it may favour larger or harder prey than that taken by most jacamars. Forages at medium height and up to canopy, sometimes lower along edges. Perches solitarily, in pairs or small groups (up to 8), on exposed branches; darts out to feed on flying insects, often returns to same perch.

**Breeding.** Birds in breeding condition reported in Jun in Colombia; nest Jul in NE Peru. One nest in NE Peru was situated in arboreal termitarium 3 m above ground; 2 birds seen entering and leaving repeatedly over 2 days. No further information available.

**Movements.** Sedentary.

**Status and Conservation.** Not globally threatened. Generally common and conspicuous throughout range, e.g. particularly numerous around Limoncocha and Imuyacocha (Ecuador). No immediate threats documented, despite the ongoing destruction of lowland forest; preference for successional and edge habitats suggests good survival prospects. Occurs in several protected areas, such as Amacayacu National Park, in Colombia, and Cuyabeno Reserve, in Ecuador.

**Bibliography.** Best *et al.* (1997), Butler (1979), Canaday & Jost (1999), Chapman (1917, 1926), Clements & Shany (2001), Cory (1919), Cracraft (1985), Forrester (1993), Haffer (1974), Hill & Greeney (2000), Hilty & Brown (1986), Meyer de Schauensee (1949, 1952, 1982), Nicéforo & Olivares (1967), Olrog (1968), Ortiz & Carrión (1991), Parker *et al.* (1982), Ridgely & Greenfield (2001), Ridgely *et al.* (1998), Rodner *et al.* (2000), Sick (1993), Sneath (1914), Stotz *et al.* (1996), Taczanowski (1886).

## 2. Purus Jacamar

### *Galbalcyrrhynchus purusianus*

**French:** Jacamar roux **German:** Purúsglanzvogel **Spanish:** Jacamará del Purús  
**Other common names:** Chestnut Jacamar (when lumped with *G. leucotis*)

**Taxonomy.** *Galbalcyrrhynchus purusianus* Goeldi, 1904, upper Rio Purús, Brazil.

Forms a superspecies with *G. leucotis*. Sometimes considered conspecific (and was initially presumed to represent female of that form), although no intermediate forms documented despite the fact that both occur on R Ucayali, in Peru; studies along potential zone of contact would help clarify their relationship. Monotypic.

**Distribution.** E Peru (Madre de Dios, Puno, upper R Ucayali) to W Brazil (upper R Jurú and R Purús) and N Bolivia (Beni, Pando).

**Descriptive notes.** 20 cm; 50 g. Forehead, crown, wings and tail dark bronzy or greenish-black; plumage otherwise chestnut; large bill 5.2-5.5 cm (4.4-4.7 cm from nostril), light pinkish, tipped dark; iris bright red; bare eyering and loreal region pinkish-red; feet relatively large, pinkish-red. Differs from very similar *G. leucotis* in lacking white ear-coverts. Immature paler, bill smaller. Voice. Call a series of loud "pee-ur" whistles and a sharp "pee".

**Habitat.** Inhabits borders of lowland primary and secondary *terra firme* and *várzea* forest, often near rivers, oxbow lakes, swamps with

*Cecropia* and palms. By R Manu, in Peru, frequents middle successional stages (mixed canopy, *Ficus/Cedrela* and transitional forest). Rarely in forest interior. In Beni, in Bolivia, has been observed perching on roadside electricity wires in settled areas.

**Food and Feeding.** Insects, usually wasps and bees (Hymenoptera) and termites (Isoptera); of 21 prey items recorded at Cocha Cashu, Peru, all were Hymenoptera. Also reported to catch fish in Peru, although this probably the result of confusion with kingfishers (Alcedinidae). Large bill does, however, suggest that some large prey may be taken. Groups of 1-6 forage from mid-level to canopy. Insects caught by sallying from a perch. Hymenoptera beaten thoroughly on perch before consumption.

**Breeding.** Hole-excavation observed in Oct in Peru. Probably co-operative breeder; groups of 4-6 sometimes sing and display together. In Peru, 6 individuals observed excavating a single burrow in a termitarium 4-7 m above ground, burrow volume 43 litres; cavity was occupied during the day, thus almost certainly a nest, although breeding not confirmed and possibility that hole functioned as a roost-site not ruled out. No further information available.

**Movements.** Sedentary.

**Status and Conservation.** Not globally threatened. Locally fairly common, but generally scarce in Peru. Occurs in Manu Biosphere Reserve, Peru. Apparently tolerates disturbed and partially modified habitats, and no specific threats are known.

**Bibliography.** Brightsmith (1999), Clements & Shany (2001), Cory (1919), Forrester (1993), Gyldestolpe (1945a, 1945b), Haffer (1974), Meyer de Schauensee (1982), Olrog (1968), Parker *et al.* (1982), Pinto (1938b), Remsen & T aylor (1989), Robinson (1997), Robinson & Terborgh (1997), Ruschi (1979), Sick (1993), Sneath (1914), Stotz *et al.* (1996), Terborgh *et al.* (1984), T aylor (1958).

# Genus *BRACHYGALBA* Bonaparte, 1854

## 3. Dusky-backed Jacamar

### *Brachygalba salmoni*

**French:** Jacamar sombre **German:** Salmonglanzvogel **Spanish:** Jacamará Dorsioscuro  
**Other common names:** Salmon's Jacamar

**Taxonomy.** *Brachygalba salmoni* P. L. Sclater and Salvin, 1879, Río Nechí, Antioquia, Colombia. Forms a superspecies with *B. goeringi*, *B. lugubris* and *B. albogularis*. Isolated population in N Colombia at Carmen, in Bolívar, described as race *carmenensis* on the basis of slight differences in plumage coloration and bill shape, but these appear to fall within range of individual variation elsewhere in Colombia and Panama. Monotypic.

**Distribution.** E Panama (Darién) and NW Colombia (N Antioquia, S Córdoba, N Bolívar).

**Descriptive notes.** 16.5-18 cm; male 18.5 g, female 16 g. Male has upperparts, chest, flanks and underwing coverts dark greenish-black, somewhat glossy on chest, bluer in worn plumage; crown and, particularly, forehead dull brown, slightly glossed greenish; primaries blackish; checks and malar sooty-blackish, throat buffy-white or white, belly and centre of breast cinnamon; undertail-coverts cinnamon, longest bronze-green; bill 3.6-4.9 cm, slender and sometimes slightly decurved, black; iris red; feet black. Female similar but throat buff, iris dark reddish-brown. Immature

mon-buff, shorter bill, grey iris. Voice. Call a plaintive, upwardly inflected "sweet" or "feet", frequently repeated, sometimes expanded to "pe-peat", "pe-pe-pe-peat" or a longer series; probably has more complex song like *B. goeringi*.

**Habitat.** Shrubby edges, treefalls, trails and clearings of humid primary and secondary forest with tall trees, and along fairly open streambanks, in lowlands and hills up to 700 m.

**Food and Feeding.** Flying insects, including Hymenoptera (Apidae, Vespidae), Isoptera, Lepidoptera (including moths) and Coleoptera. Usually perches in pairs or small family groups on exposed horizontal branches, often in canopy, sometimes on low bushes, generally at greater heights than *Galbula ruficauda*; sallies short distances (usually less than a few m), sometimes medium or long distances, to catch insects in air. Often returns to same perch after capture.

**Breeding.** Birds in breeding condition in Jan-Feb in Colombia. No information on breeding behaviour; probably nests in earth bank.

**Movements.** Sedentary.

**Status and Conservation.** Not globally threatened. Restricted-range species: present in Darién Lowlands EBA and in Nechí Lowlands EBA. Reckoned to be relatively scarce in general, but locally common. In Panama, generally uncommon in Darién (rare at Cerro Pirre). Occurs in Los Katíos National Park, Colombia. Tolerates, or perhaps even prefers, a degree of habitat disturbance whereby clearings and regrowth are created. Isolated population in Bolívar, N Colombia, possibly vulnerable to habitat destruction. Surveys required in order to establish population size and trends.

**Bibliography.** Anon. (1998b), Bangs & Barbour (1922), Cory (1919), Cracraft (1985), Haffer (1962, 1974, 1975), Hilty & Brown (1986), Meyer de Schauensee (1949, 1950, 1982), Nicéforo & Olivares (1967), Olrog (1968), Orjuela (1985), Ridgely & Gwynne (1989), Ridgway (1914), Robbins *et al.* (1985), Rodner *et al.* (2000), Stotz *et al.* (1996), Wetmore (1968a).

## 4. Pale-headed Jacamar

### *Brachygalba goeringi*

**French:** Jacamar à tête pâle **German:** Fahlhacken-Glanzvogel **Spanish:** Jacamará Acollarado

**Taxonomy.** *Brachygalba goeringi* P. L. Sclater and Salvin, 1869, near Marurá, north of Lake Valencia, at foot of Guiguc Mountains, Venezuela.

Forms a superspecies with *B. salmoni*, *B. lugubris* and *B. albogularis*. Monotypic.

**Distribution.** NE Colombia (Arauca, Casanare) and NW Venezuela (Lara E to Aragua, N Guárico, Barinas, Apure).

**Descriptive notes.** 16.5–18 cm; 16–18 g. Male has crown and upper mantle ashy-brown, rest of upperparts, tail and wings dark brown with greenish sheen, becoming bluish-black in worn plumage; pale supercilium more rufescent-brown at rear; throat buffy-white, breastband ash-brown, flanks dark brown, chestnut band across upper belly, rest of underparts white; bill 4.5–5.1 cm long (3.4–4.5 cm from nostril), slender, black; iris reddish brown; feet black. Female like male, perhaps with more extensive chestnut on belly. Immature has shorter bill, grey crown and greyish-brown nape, whiter throat, supercilium and side of head,

dusky patch on cheeks and ear-coverts, brighter upperparts more strongly glossed green and fringed and tipped with ferruginous, feathers of pectoral band and flanks tipped buff or white. **Voice.** Thin, high “weet”, sometimes in series, accelerating in pace and ascending in tone, ending in a sharp trill, this sequence sometimes given repeatedly when excited, resulting in undulating series of sharp crescendos, twitters and high thin trills, during which the body is often turned rapidly from side to side and the tail flicked up and down; also a low twittering; nestlings generally silent, but can give similar, though weaker, calls.

**Habitat.** Edges of deciduous, secondary and gallery forest, typically in *llanos*; also light open woodland, thickets, clearings and drier savanna, occurring up to 1100 m but usually considerably lower.

**Food and Feeding.** Mostly Lepidoptera and Odonata. During c. 5 hours of nest watches in Venezuela, about half of food items brought to nestlings were adult Odonata 4–5 cm long with wings detached; next most prevalent were small or medium-sized Lepidoptera, mostly skippers (Hesperiidae), usually delivered with wings attached; much rarer items were small Diptera and probably Homoptera; adults possibly consumed different items at the feeding grounds. Among butterflies, Heliconiinae are generally ignored, presumably because of their distastefulness, as are morphos (Morphinae), presumably because of their large size. Usually perches in pairs or small family groups on exposed branches emerging from canopy, or on lower shrubs, overhanging branches and roots along streambanks. Makes acrobatic darting and looping sallies from a perch to catch flying insects. In Venezuela, tends to occupy higher foraging niche than sympatric *Galbula ruficauda*, feeding almost entirely from treetops rather than the lower storey.

**Breeding.** Apr–May in Venezuela. One nest dug into a clay bank, burrow 90 cm above ground, 80 cm long with nest-chamber at end; 4 nestlings; after fledging, adults and offspring roosted in nest for several weeks. No information on incubation and nestling periods.

**Movements.** Sedentary.

**Status and Conservation.** Not globally threatened. Common throughout its range, although apparently local in NE Colombia. No specific threats documented so far, despite overall habitat loss in certain areas as a result of deforestation.

**Bibliography.** Blake (1961), Cory (1919), Haffer (1974), Hilty & Brown (1986), Meyer de Schauensee (1949, 1982), Meyer de Schauensee & Phelps (1978), Nicéforo & Olivares (1967), Olrog (1968), Rodner *et al.* (2000), Skutch (1968), Stotz *et al.* (1996), Underdown (1929).

## 5. Brown Jacamar

### *Brachygalba lugubris*

**French:** Jacamar brun **German:** Braunbrust-Glanzvogel **Spanish:** Jacamará Pardo  
**Other common names:** Todd's Jacamar (*phaeonota*)

**Taxonomy.** *Galbula lugubris* Swainson, 1838, Kanuku Mountains, Guyana.

Forms a superspecies with *B. salmوني*, *B. goeringi* and *B. albogularis*. No contact or intergradation between races is known, and potential zones of overlap merit investigation to elucidate taxonomic relationships. Race *phaeonota*, known only from the type specimen, was described as a separate species, but considered probably a form of present species; further research necessary to confirm its taxonomic placement or, indeed, its validity. Races *melanosterna* and *naumburgi* previously treated as together constituting a separate species, and their taxonomic status may require reassessment. Seven subspecies recognized.

**Subspecies and Distribution.**

- B. l. fulviventris* P. L. Slater, 1891 - E of Andes in C Colombia (Buenavista, Villavicencio).
- B. l. obscuriceps* J. T. Zimmer & Phelps, Sr., 1947 - S Venezuela (upper Orinoco region, R Ocamo) and NW Brazil (upper R Padauri, R Negro).
- B. l. lugubris* (Swainson, 1838) - E & S Venezuela through the Guianas to NE Brazil.
- B. l. caquetae* Chapman, 1917 - S Colombia E of Andes (S from Caquetá) to S E Ecuador and N Peru.
- B. l. phaeonota* Todd, 1943 - W Brazil, at Tonantins (on R Solimões).
- B. l. naumburgi* Chapman, 1931 - NE Brazil (Maranhão, Piauí).
- B. l. melanosterna* P. L. Slater, 1855 - E Bolivia (Santa Cruz) and C & S Brazil (Pará S to Rondônia, Mato Grosso, Goiás, W Minas Gerais, W São Paulo).

**Descriptive notes.** 14–18 cm; 17–23 g. Upperparts, including crown, sooty-brown, lower back darker, glossed greenish-black; diffuse pale supercilium; wings and tail blackish with slight blue sheen, absent on primaries; chin and throat whitish, breast and flanks rufescent-brown, lower breast and belly whitish or occasionally buffy, undertail-coverts rufescent-brown; bill 4.5 cm long (3.4–4.2 cm from nostril), slender, straight, generally black; iris dark brown; bare eyering blackish-brown; feet black, base of tarsi sometimes yellowish. Immature not described. Races differ from nominate in tone and intensity of colour on

upperparts and breast. S races generally with yellowish bill base, paler eyes, yellow eyering; *fulviventris* has browner upperparts and breast, buffy belly; *obscuriceps* has blackish crown, dark brown upperparts and breast, rufescent-brownish or buffy rest of underparts; *caquetae* has crown tipped pale ochraceous-buff, nape, mantle and breast more rufescent, lower back to upertail-coverts more blackish; *phaeonota* is more uniform, darker, less rufescent on upperparts, throat, breast, flanks and undertail-coverts, isolating dirty white belly, the feathers of chin and upper throat with

whitish shaft streaks and rufescent tips; *naumburgi* is dark brown above, black wings and tail glossed greenish, blackish below with white throat and belly; *melanosterna* similar to previous, but proximal half or whole of lower mandible pale yellow, eyes pale blue. **Voice.** High, insect-like descending “tick tick tick ti ti ti ti tit t t t t”, terminating in stuttering trill; call a very high, sharp whistle, “hilew”, rather different from *Galbula* calls, or lower “chewee”.

**Habitat.** Canopy, edges and shrubby clearings of primary and secondary *terra firme*, *várzea* and gallery forest, rarely cloudforest, also open savanna woodland, most often on riverbanks with scattered trees and shrubs; usually in lowlands to 900 m, but records extend to 1500 m in Venezuela.

**Food and Feeding.** Diet includes Hymenoptera (e.g. 12-mm Apidae, Vespidae, Chrysididae), Coleoptera (e.g. 7-mm Staphylinidae, Curculionidae), Homoptera (e.g. cicadas), Diptera (e.g. Tabanidae) and Lepidoptera. Perches in pairs or small parties on exposed branches in upper canopy, less commonly down almost to ground level; often beside or over water. Sallies from perch for flying insects.

**Breeding.** Family with 3 juveniles in late Mar and birds in breeding condition in late May in Colombia. No further information available; presumably breeds in arboreal termitarium or in burrow dug into bank.

**Movements.** Sedentary.

**Status and Conservation.** Not globally threatened. Fairly common locally throughout much of range, including Surinam, French Guiana, and W Brazil (Rondônia); was previously considered abundant, at least seasonally, in S Brazil. Generally uncommon in E Ecuador, but numerous at Limoncacha; uncommon in N Peru. Occurs in Imataca Forest Reserve and El Dorado, Venezuela, in Amacayacu National Park, Colombia, and in Chapada dos Guimarães National Park, Brazil. Although sensitive to wholesale deforestation, its habitat requirements suggest that selective logging would not be a threat. Race *phaeonota*, known only from type locality, requires further study to clarify its conservation status.

**Bibliography.** Cadena *et al.* (2000), Chapman (1917, 1926, 1931), Cory (1919), Fry (1970b), Griscom & Greenway (1941), Haverschmidt & Mees (1994), Hellmayr (1929), Hilty & Brown (1986), Meyer de Schauensee (1949, 1982), Meyer de Schauensee & Phelps (1978), Naumburg (1930), Nicéforo & Olivares (1967), Parker *et al.* (1982), Phelps & Phelps (1958), Pinto (1938b), Remsen & Traylor (1989), Ridgely & Greenfield (2001), Sargeant (1994), Schubart *et al.* (1965), Slater & Salvin (1879), Sick (1993), Snethlage (1914), Snyder (1966), Stotz, Fitzpatrick *et al.* (1996), Stotz, Lanyon *et al.* (1997), Tostain *et al.* (1992), Willard *et al.* (1991), Willis (1992), Willis & Oniki (1990), Zimmer, J.T. & Phelps (1947), Zimmer, K.J. & Hilty (1997), Zimmer, K.J. *et al.* (1997).

## 6. White-throated Jacamar

### *Brachygalba albogularis*

**French:** Jacamar à gorge blanche **Spanish:** Jacamará Gorgiblanco  
**German:** Weißkehl-Glanzvogel

**Taxonomy.** *Galbula albogularis* Spix, 1824, Pará = Rio Javari, Brazil.

Forms a superspecies with *B. salmوني*, *B. goeringi* and *B. lugubris*. Monotypic.

**Distribution.** E Peru (Loreto, Madre de Dios, possibly Cajamarca), W Brazil (R Solimões, R Javari, upper R Purús) and N Bolivia (Pando, La Paz).

**Descriptive notes.** 15–16 cm. Male has throat, supercilium and side of head conspicuously white; upperparts dark brown or dull black, glossed greenish-blue; primaries and tail black, tail quite short and square; breast and belly dark brown or blackish, glossed greenish-blue, elongated chestnut patch on middle of belly; undertail-coverts blackish; bill 4.5 cm long (3.8 cm from nostril), slender, pale yellow; iris pale blue; bare facial skin yellow; feet black. Female similar, with perhaps more extensive chestnut on belly. Immature not described. **Voice.** Call a plaintive upslurred “psueet” or “kuweei”, given infrequently.

**Habitat.** Edges of lowland primary forest, usually in successional habitat along rivers, e.g. young forest with *Cecropia* trees, river islands and “Zabolo” habitat.

**Food and Feeding.** Diet poorly known, but Lepidoptera (including *Eurema*, *Eunica*) and Hymenoptera (e.g. Vespidae) recorded. Perches quietly on exposed branches at canopy level, often shaded by large leaves. Sallies from a perch, generally 1–17 m up, to catch flying insects; foraging flights of 2–30 m reported.

**Breeding.** No specific information available; nest presumably in burrow in earth bank or termitarium, as in other jacamars.

**Movements.** Presumably sedentary.

**Status and Conservation.** Not globally threatened. Known from only few scattered localities. Appears to be rare, patchily distributed, and specialized in habitat requirements, although this may be a reflection more of uneven sampling effort and this species’ generally inconspicuous nature rather than of its true status. Regular at Tambopata Reserve, in Peru. No immediate threats are recorded, although it is probably sensitive to destruction of riverine habitat. As very little is known about the species’ ecology, distribution or status, much fieldwork is required to investigate these aspects.

**Bibliography.** Allen (1995), Angehr & Auca (1997), Bronaugh (1984), Clements & Shany (2001), Cory (1919), Cracraft (1985), Donahue (1994), Forrester (1993), Foster *et al.* (1994), Griscom & Greenway (1941), Guilherme (2000, 2001), Haffer (1974), Meyer de Schauensee (1982), Olrog (1968), Parker & Remsen (1987), Parker *et al.* (1982), Pinto (1938b), Remsen & Parker (1984b), Remsen & Traylor (1989), Sick (1993), Snethlage (1914), Stotz *et al.* (1996), Whittaker & Oren (1999).

## Genus JACAMARALCYON Lesson, 1830

## 7. Three-toed Jacamar

### *Jacamaralcyon tridactyla*

**French:** Jacamar tridactyle **German:** Dreizehen-Glanzvogel **Spanish:** Jacamará Tridáctilo

**Taxonomy.** *Galbula tridactyla* Vieillot, 1817, São Paulo, Brazil.

Close to *Brachygalba*, particularly *B. lugubris*, but isolated by foot morphology, elongated head feathers and gregarious behaviour. Monotypic.

**Distribution.** SE Brazil (Minas Gerais, Espírito Santo, Rio de Janeiro, São Paulo, Paraná).

**Descriptive notes.** 17-20 cm; male 17.4-18.8 g, female 17.8-19.3 g. Head chestnut-brown, more blackish-brown on throat, thin golden-buff stripes on forehead, lores and throat; elongated head feathers often ruffled; back and graduated tail uniform blackish, glossed with green; central breast and belly white, sides of abdomen clear grey, undertail-coverts greyish; bill c. 4.7 cm long (3.6-3.9 cm from nostril), pointed, all black; iris dark brown, often spotted or wholly yellowish-brown or red (apparently an age-related feature); tarsus and feet blackish-grey, only 3 toes, soles yellowish. Differs from superficially similar *Brachygalba*

*lugubris* in elongated head feathers, 3-toed foot. Immature has less evident golden stripes on head, short tail, shorter bill with white base. VOICE. Song a sequence of short, relatively weak whistles; complex group song up to 20 seconds long, various shrill ascending whistles, apparently given by 2-6 individuals simultaneously; call a sharp rasping "churr", from perch or in flight.

**Habitat.** Semi-deciduous or gallery forest, mainly small isolated fragments only a few ha in extent, at edges or in degraded areas with bushes and scattered tall trees, usually near or along water-courses, roads and tracks where earth banks present; at 240-1100 m. Often in sites tangled with vines, or highly degraded and heavily disturbed by people, near urban areas. Sometimes tolerates eucalyptus (*Eucalyptus*) woodland where natural understorey remains, but tends to avoid intact evergreen forest.

**Food and Feeding.** Mainly Hymenoptera, Lepidoptera, Diptera and other small insects, including dragonflies (Odonata), termites (Isoptera), Homoptera, Hemiptera, and beetles (Coleoptera). One study showed Hymenoptera, particularly wasps, to make up the bulk of the diet; another revealed a preference for small cryptic Lepidoptera, as well as Diptera and Hymenoptera. Diet composition appears to vary seasonally with rainfall and insect abundance; capture of cicadas (Cicadidae) and flying termites, for example, is most frequent in Sept-Dec (early wet season), when these insects abound. Small groups of 2-10 individuals perch 8-15 m up, sometimes down almost to ground level, on tall trees (e.g. *Cecropia*, *Inga*, *Piptadenia*, *Eucalyptus*) or on vines, bamboo, tall grasses, wires and fences, darting into the open to catch flying prey, often close to foliage, returning more often than not to same perching area; sometimes foraging from the same perch or group of perches for at least 30 minutes. Of 173 sallies, 42 (24%) resulted in successful capture.

**Breeding.** Sept-Feb, at time of highest rainfall. Possibly colonial, up to 20 holes recorded in same bank; observations suggest a degree of co-operation, with groups of 5 or more. Burrow c. 6.5 cm wide at entrance, 84-146 cm long, excavated in earth bank, completion reportedly taking up to 2 months; individuals often build several holes simultaneously, with 2-7 birds/cavity. Clutch 2 eggs; incubation by at least a pair, possibly helped by others, period 19-20 days; chicks fledge after 28-30 days, thereafter visit nest-burrow for roosting, sometimes accompanied by adults; other group-members appear to help feed fledglings.

**Movements.** Sedentary.

**Status and Conservation.** ENDANGERED. Restricted-range species; present in Atlantic Forest Lowlands EBA. Historically very common. Has declined dramatically in range and numbers; recent reports only from C & S Minas Gerais and from Rio de Janeiro (R Paraíba Valley), where it is very local, but common at a few sites. Not recorded in Espírito Santo since 1940; no reports from São Paulo since mid 1970's, and no reliable records from Paraná since 1961. Estimated world population below 1000 individuals. It appears to prefer degraded woodland and tolerates a fair degree of human disturbance, but its absence from many apparently suitable sites suggests a habitat specialization that remains poorly understood. Habitat loss and collapse of roosting and nesting cavities as a result of subsidence, especially during the rainy season, are major threats. Detailed studies on remaining population and strict protection of representative fragments of habitat are recommended. In Minas Gerais, occurs in the highly disturbed Fernão Dias State Park, as well as in Caratinga Biological Station and in UFMG Ecological Station. Occurs also in several privately protected woodlots.

**Bibliography.** Bernardes *et al.* (1990), Bomfim & Reis (1996), Collar & Andrew (1988), Collar, Crosby & Stattersfield (1994), Collar, Gonzaga *et al.* (1992), Collar, Wege & Long (1997), Cory (1919), Cracraft (1985), Ferreira de Vasconcelos *et al.* (1999), Forrester (1993), Knox & Walters (1994), Lyons (1999), Machado & Lamas (1996), Machado *et al.* (1995), Melo-Júnior (1996, 1998, 2000, 2001b, 2001c), Meyer de Schauensee (1982), Olog (1968), Schubart *et al.* (1965), Sick (1993, 1997), Silveira & Nobre (1998), Stattersfield & Capper (2000), Tobias *et al.* (1993), Wege & Long (1995), Willis & Oniki (1993).

## Genus *GALBULA* Brisson, 1760

### 8. Yellow-billed Jacamar

#### *Galbula albirostris*

**French:** Jacamar à bec jaune **German:** Gelbschnabel-Glanzvogel **Spanish:** Jacamará Piquigualdo

**Taxonomy.** *Galbula albirostris* Latham, 1790, South America = Cayenne.

Forms a superspecies with *G. cyanicollis*; the two are sometimes considered conspecific, but no intergradation has been observed in zone of potential sympatry in R Ucayali Valley, NE Peru, and their populations are otherwise separated by R Amazon almost throughout its length. Race *chalocephala* possibly a distinct species, as morphological differences from nominate race considerable and apparently constant, with no intergrades known; further studies needed in zone of potential overlap in Venezuela (upper R Orinoco) to clarify its taxonomic status. Two subspecies recognized.

**Subspecies and Distribution.**

*G. a. albirostris* Latham, 1790 - E Colombia (Mitú, Vaupés), S & E Venezuela (S of R Orinoco), the Guianas and N Brazil (N of Amazon).

*G. a. chalocephala* Deville, 1849 - SE Colombia E of Andes (S of Meta), E Ecuador and W Brazil (upper R Negro) S to NE Peru (S to upper R Ucayali); possibly also S Venezuela (upper R Orinoco).

**Descriptive notes.** 18-21 cm; 16-24 g. Male has metallic purplish or coppery gloss on crown; rest of upperparts, including sides of head and neck, shining emerald-green; primaries dull black; tail relatively short and moderately rounded, outer rectrices brown, more cinnamon towards bases; chin buff, throat white, entire rest of underparts pale cinnamon-rufous; bill 3.5-4.3 cm long (2.8-3.4 cm from nostril), slender, pale yellow, upper mandible tipped dusky or blackish; iris dark brown; bare eyering and loreal region yellow; feet yellow, black claws. Female has rufous-buff throat, as well as slightly paler underparts. Immature

undescribed. Race *chalocephala* is slightly larger (bill 3.1-3.8 cm from nostril), all or most of upper mandible dusky or black, upperparts metallic bronzy green, crown more bronzy purple, chin darker, lower underparts richer darker cinnamon-rufous. VOICE. Song a high-pitched "peea pee-pee-te-t-e'e'e'e'e'e", terminating in long rattling trill; calls a sharp "peek" and "trra", sometimes in rapid series, given by single bird or several together.

**Habitat.** In contrast to other jacamars, inhabits mainly interior of primary and mature secondary *terra firme*, *várzea* and *igapó* forest, most frequently at small clearings, treefall gaps, occasionally at edge. Also vine-tangled woodland, less commonly in gallery forest or sandy coastal forest. Usually below 900 m, but recorded to 1300 m in Venezuela. Generally frequents lower level to mid-level, 1-10 m above ground.

**Food and Feeding.** Insects, including Coleoptera (e.g. Cassididae), Hemiptera, Homoptera (e.g. Cicadidae), Diptera, and Hymenoptera including e.g. ants (Formicidae; Ponerinae), bees (Apidae), and wasps (Vespidae) 10-15 mm long. Stomachs sometimes contain large numbers of winged termites (Isoptera). Possibly also takes Lepidoptera and Odonata. Sits on open perches, typically in pairs, sallies forth from time to time to catch passing insects. Often joins mixed-species foraging flocks.

**Breeding.** Breeds during dry season in the Guianas, i.e. Jun-Sept in Surinam, Jul-Nov in French Guiana; at least occasionally double-brooded, as pair in French Guiana laid first clutch end Jul, followed by a second clutch in a new cavity in early Nov. Four reported nests were all excavated in arboreal *termitaria* 1.5-3 m above ground, these apparently often attached to the spiny bark of mature *Astrocaryum sciophilum* in French Guiana; nest possibly sometimes in earth bank, as with congeners, although so far this has not been confirmed. Clutch 2 eggs; no information on incubation and fledging periods.

**Movements.** Sedentary.

**Status and Conservation.** Not globally threatened. Uncommon in E Colombia and E Ecuador, but generally fairly common in E Peru, Amazonian Brazil, S Venezuela and the Guianas. No immediate threats are known but, since this species is more restricted to forest interior (and usually that of mature forest), it is presumably sensitive to deforestation and other types of habitat destruction. Indeed, a population in French Guiana declined dramatically in response to selective logging. Occurs in several protected areas throughout its range, e.g. Imataca Forest Reserve and El Dorado, in Venezuela, Amacayacu National Park and Tinigua National Park, in Colombia, and Cuyabeno Reserve, in Ecuador.

**Bibliography.** Bangs & Penard (1918), Blake (1962), Cadena *et al.* (2000), Chapman (1917, 1926), Cohn-Haft *et al.* (1997), Cory (1919), Davis (1986), Griscom & Greenway (1941), Haverschmidt & Mees (1994), Hilty & Brown (1986), Meyer de Schauensee (1949, 1982), Meyer de Schauensee & Phelps (1978), Nieforo & Olivares (1967), Olog (1968), Parker *et al.* (1982), Peres & Whittaker (1991), Phelps & Phelps (1958), Pinto (1938b), Reynaud (1998), Ridgely & Greenfield (2001), Sargeant (1994), Schubart *et al.* (1965), Sick (1993), Sneath (1914), Snyder (1966), Stotz *et al.* (1996), Thiollay (1992), Thiollay & Jullien (1998), Tostain *et al.* (1992), Willard *et al.* (1991), Zimmer (1930), Zimmer & Hilty (1997).

### 9. Blue-necked Jacamar

#### *Galbula cyanicollis*

**French:** Jacamar à joues bleues **German:** Blauhals-Glanzvogel **Spanish:** Jacamará Cariazul  
**Other common names:** Blue-cheeked/Purple-necked Jacamar

**Taxonomy.** *Galbula cyanicollis* Cassin, 1851, Pará, Brazil.

Forms a superspecies with *G. albirostris*; sometimes considered conspecific, but no intergradation observed in zone of potential sympatry in R Ucayali Valley, NE Peru, and their populations are otherwise separated by R Amazon almost throughout its length. Considerable geographical variation in plumage characters; upper Amazonian subpopulation possibly a separate race, or even distinct species. Monotypic.

**Distribution.** E Peru (S to lower R Ucayali) and Brazil S of Amazon (E to Maranhão, S to Rondônia and N Mato Grosso).

**Descriptive notes.** 19-22 cm; 21-26 g. Male has crown often bluish, cheeks and malar steel-blue in E (apparently varying clinally to green with only traces of blue in W birds); upperparts shining green; tail relatively short and moderately rounded, with inner pair of rectrices shining green, and remainder green-fringed rufous; underparts uniform chestnut; bill 3.9-5 cm long (3.4-4.1 cm from nostril), upper mandible usually black but considerable individual variation from all black to, rarely, all yellow, lower mandible yellow; iris dark brown; bare eyering and loreal region yellow; feet yellow. Differs from *G. albirostris* in slightly larger size, bluer head, chestnut chin and throat. Female has slightly duller underparts. Immature not described. VOICE. No information available, although likely to be similar to that of *G. albirostris*.

**Habitat.** Lower strata in interior of lowland evergreen forest, occasionally at edges; often in *várzea* forest and, indeed, where these are flooded cyclically (as in tidal areas near Belém, Brazil), seems to appear within the forest only when it is flooded. Also occurs locally in gallery forest in Brazilian *cerrado*. To 900 m.

**Food and Feeding.** Recorded prey Coleoptera, Hymenoptera (e.g. Ichneumonidae 15 mm long, Apidae, Formicidae) and Diptera (e.g. Brachycera). Possibly also takes Lepidoptera and Odonata. Sallies from a perch to take flying insects.

**Breeding.** Birds with enlarged gonads or egg in oviduct in Sept; 2 active nests found in Jun and Oct in Brazil. Nest in arboreal termitarium 1-2 m above ground. Clutch 2 eggs; no information on incubation and fledging periods.

**Movements.** Sedentary.

**Status and Conservation.** Not globally threatened. Generally common throughout range. Occurs within several protected areas, e.g., Tapajós National Park, in Brazil. Owing to its greater reliance on intact forest understorey, this species, as *G. albirostris*, is likely to be more susceptible to deforestation than are most other jacamars.

**Bibliography.** Clements & Shany (2001), Cory (1919), Forrester (1993), Griseom & Greenway (1941), Gyldestolpe (1945a), Haffer (1974), Haverschmidt (1960), Ihering & Ihering (1907), Meyer de Schauensee (1982), Naumburg (1930), Oren & Parker (1997), Parker *et al.* (1982), Pinto (1935, 1938b), Ruschi (1979), Schubart *et al.* (1965), Sick (1993), da Silva (1996), da Silva *et al.* (1990), Sneath (1914), Stotz *et al.* (1996), Zimmer *et al.* (1997).

## 10. Rufous-tailed Jacamar

### *Galbula ruficauda*

**French:** Jacamar à queue rousse **German:** Rotschwanz-Glanzvogel **Spanish:** Jacamará Colirrufo  
**Other common names:** Black-chinned Jacamar (*melanogenia*); Rufous-and-green/Spot-tailed Jacamar (*rufoviridis*)

**Taxonomy.** *Galbula ruficauda* Cuvier, 1816. Guyana.

Forms a superspecies with *G. galbula*, *G. pastazae*, *G. tombacea* and *G. cyanescens*. Race *rufoviridis* (with *heterogyna*) geographically separated from other races by *G. galbula*, *G. tombacea* and *G. cyanescens*, and long regarded as a full species; given its phenotypic similarity to other forms of present species, however, probably best treated as conspecific, pending further research. Race *melanogenia* previously considered a separate species, but this treatment confounded by limited hybridization with nominate race around Gulf of Urabá, NW Colombia; Ecuadorian and Colombian individuals tend towards smaller size and darker coloration, but differences considered insufficient for recognition of additional geographical races. Races *heterogyna*, *pallens* and *brevirostris* may form parts of clinal variation, as differences in coloration are minor. Six subspecies currently recognized.

**Subspecies and Distribution.**

*G. r. melanogenia* P. L. Slater, 1853 - E Mexico (Veracruz, Oaxaca, Chiapas) S to W Andes of Colombia and Ecuador.

*G. r. pallens* Bangs, 1898 - extreme N Colombia (Santa Marta, lower Magdalena Valley) and extreme NW Venezuela (Zulia).

*G. r. brevirostris* Cory, 1913 - N Colombia (Norte de Santander) and NW Venezuela (around head of L. Maracaibo).

*G. r. ruficauda* Cuvier, 1816 - C Colombia (Magdalena Valley N of Cauca, Arauca, Casanare), Venezuela (except NW & S), Trinidad and Tobago, Guyana (and very scarce E to coastal French Guiana), and N Brazil (upper R Branco, in Roraima).

*G. r. rufoviridis* Cabanis, 1851 - much of Brazil S of Amazon and E of R Madeira, and N Bolivia (Pando, La Paz); records from Paraguay and Argentina unconfirmed.

*G. r. heterogyna* Todd, 1932 - E Bolivia (Beni, Cochabamba, Santa Cruz) and SC Brazil (W Mato Grosso).

**Descriptive notes.** 19-25 cm; 18-28 g. Male has upperparts, including face and wing-coverts, and broad breastband shining metallic coppery green; primaries blackish; relatively long tail graduated, central pair of rectrices longest and metallic green, remainder cinnamon-rufous; chin very pale buffy, throat white (sometimes speckled green); some birds on Tobago have head glittering green with bluish gloss, back golden reddish-green, central pair of rectrices golden-orange with green shaft, pectoral band glittering reddish; belly, undertail-coverts and underwing-coverts rufous-chestnut; bill 4-5.7 cm long (3.9-5.0 cm from nostril), slender, sharp, black; iris brown; bare eyering and loreal region greyish; feet yellowish-brown to greyish-flesh, black claws. Female has chin and throat cinnamon-buff, belly and underwing-coverts dark cinnamon-buff, slightly duller and paler than male. Immature has shorter bill initially tipped buff, shorter tail, duller more bronzy upperparts, broader and less clean-cut pectoral band. Race *melanogenia* has varying amount of black on chin, central 2 pairs of rectrices green; *pallens* similar but has rufous areas paler, especially in female, and narrower chestband, longer bill; *brevirostris* also paler, but with shorter bill; *rufoviridis* brighter green, has white chin, central 2 pairs of rectrices green, remainder rufous, terminal portions of outer rectrices green on outer web; *heterogyna* similar to previous but paler. **VOICE.** Standard song an accelerated sequence

of notes with terminal trill; prolonged song of male varies in tempo, with melodious and buzzy sections of drawn-out peeps interspersed with twittering, chuckling or ascending trills and low "bee-bee-bee"; frequently repeated call a brisk, thin, penetrating "peep" or "pee", usually terminating abruptly, sometimes repeated 3-10 times in succession, by both sexes; also a very rapid trill.

**Habitat.** Wide variety of habitats, including shady borders of humid, deciduous and semi-arid formations, *terra firme*, gallery and second-growth forest, banks of creeks and streams, marshes, bamboo patches, plantations, thickets, *llanos* and savannas with scattered trees; in lowlands, locally to 900 m, rarely to 1350 m. Also interior of scrubby deciduous cactus-rich woodland along Caribbean coasts of Venezuela and Colombia, and dry *cerrado* and *caatinga* woodland in Brazil. N race *melanogenia* more strictly associated with humid habitats, preferring forested streams. Perches at lower and middle levels, frequently in shaded edge habitats, also at clearings inside forest but rarely within forest itself.

**Food and Feeding.** Variety of Lepidoptera, Odonata, Hymenoptera, Isoptera, Hemiptera, Orthoptera, and Coleoptera (e.g. Geotrupidae, *Bolboceras*). In Mato Grosso, Brazil, 86% of prey items were Hymenoptera, including Ichneumonidae (e.g. *Metopi*), Chalcididae, Eucharitidae, Pteromalidae, Scoliidae, Bethyidae, Formicidae (e.g. *Camponotus*, *Odontomachus*, *Messor*), Pompilidae (e.g. *Cryptochilus*), Vespidae (e.g. Eumeninae, *Apoica*, *Polybia ruficeps*, *P. fastidiosuscula*, *P. quadricincta*, *Epipona tatusa*, *Agelaia vicina*, *A. multipicta*), Sphecidae (e.g. *Liris*, *Pison*, *Trypoxylon*, *Cerceris/Eucerceris*, *Bembicini*), Apoidea (e.g. Halictidae, *Hemisia*); 10% were beetles, including Staphylinidae, Coprinidae, Elateridae, Bruchidae, Curculionidae and Scolytinae; small minority were Lepidoptera, Odonata and Hemiptera. In a study in Central America, however, Lepidoptera and Odonata made up a large proportion of the diet, at least in breeding season. During 120 hours of field observation in Costa Rica, 109 Lepidoptera were captured, including 28 Papilionidae, 49 Hesperidae and 32 moths; butterflies included very large forms such as *Morpho*, *Papilio* and *Caligo*, smaller varieties such as Charaxinae, Satyrinae, Brassolinae, most Nymphalinae and even a few Heliconiinae; many noxious butterfly species, including Heliconiinae, were either pecked and rejected or entirely ignored. Perches singly or in pairs 1-3 m above ground, occasionally up to 10 m in low canopies, on partially exposed slender horizontal branches, from which makes aerial sallies. After capture, prey is taken to a perch and usually beaten several times against a branch to stun it, and knock off its wings, before swallowing. Observations in Goiás, Brazil, indicated that the social wasps *Polybia ignobilis*, *P. quadricincta*, *P. fastidiosuscula*, *Epipona tatusa* and *Agelaia multipicta* were consumed in flight. Sometimes associates loosely with mixed-species foraging flocks.

**Breeding.** May-Jun in Mexico; Feb-Jul in Guatemala, Honduras, Costa Rica, Panama, Trinidad and Tobago; Apr-Jun in Venezuela; usually Jan-Apr, rarely Oct, in Colombia; Nov-Dec in Bolivia; Sept-Dec in Brazil (Minas Gerais); often double-brooded. Male regularly feeds female during courtship. Burrow excavated by both sexes, usually 20-50 cm deep but sometimes shorter, with terminal nest-cavity, in sand bank, steep bare slope, uplifted roots of fallen tree, or arboreal or terrestrial termitarium, usually 0-3 m above ground. Clutch 2-4 eggs, perhaps sometimes only 1 in Amazonia; both sexes incubate, female at night, period 19-23 days; chick hatches with copious covering of long, whitish down, lower mandible projecting beyond upper, outer and inner toes directed forwards; fledging period 19-26 days (18 days recorded in captivity), shorter in Venezuela than in Costa Rica.

**Movements.** Usually highly sedentary; possibly some short-distance dispersal.

**Status and Conservation.** Not globally threatened. Generally common and widespread. Fairly common in Mexico (Oaxaca), uncommon in Belize; common to abundant along Caribbean slope from Honduras to N Colombia, uncommon in SW Colombia (Nariño) and NW Ecuador. Nominate race was judged extremely common on Tobago in 1930's, fairly common there in 1990's, and abundant in much of Venezuela, but rare in French Guiana (possibly only a recent colonist). Race *heterogyna* is common along R Beni, in N Bolivia. Race *rufoviridis* generally common or very common in Brazil, even in highly degraded areas. While deforestation and habitat loss are the major threats, most races readily tolerate man-made habitats, in some regions being common along roadsides and in cocoa plantations. Declines reported in Costa Rica and Panama due to hunting, habitat loss and human interference, partly because of stricter habitat preferences of *melanogenia*. Recorded in many protected areas throughout its range, e.g. Carara Biological Reserve and Corcovado National Park, in Costa Rica, Guatopo National Park and Henri Pittier National Park, in Venezuela, Tayrona National Park, in Colombia, and Brasília National Park, in Brazil.

## 14. Bluish-fronted Jacamar

*Galbula cyanescens*

French: Jacamar à couronne bleue

Spanish: Jacamará Coroniazul

German: Blaustirn-Glanzvogel

Other common names: Blue-fronted Jacamar

**Taxonomy.** *Galbula cyanescens* Deville, 1849, Sarayacu, River Ucayali, Peru.

Forms a superspecies with *G. ruficauda*, *G. galbula*, *G. pastazae* and *G. tombacea*; most closely related to the last two. Monotypic.

**Distribution.** S of Amazon in E Peru, W Brazil (E to R Madeira) and N Bolivia (S to N La Paz).

**Descriptive notes.** 20-23 cm; 22-26 g. Male has entire crown metallic green to bluish; upperparts metallic green, glossed bluish, sometimes coppery; primaries blackish; tail rufous, 2 central pairs of rectrices green, outer 2 pairs with small green patches near tips; chin and upper throat blackish, often freckled whitish; throat and chest green, rest of underparts, including underwing-coverts and undertail, rufous; bill 4.4-5.5 cm long, slender, black; iris dark brown; bare eyering and loreal region greyish; feet greyish-brown. Differs from very similar *G. tombacea* in having green to bluish crown, smaller or non-existent white chin spot.

Female as male, but with ochraceous lower breast and belly. Immature undescribed. **VOICE.** Long series of high-pitched "kree" or "kree-ip" notes; full song an excited series of notes that accelerate to a trill, slow again to individual notes, then accelerate to a final flourish, "kip kip-kip-kipkipkrkrkr-kree-kree-kree-kip-kip-kikikrrrrrueuw".

**Habitat.** Edges of humid primary forest, gallery forest and second growth, often in streamside and lakeside vegetation, at up to 1000 m. By R Manu, in Peru, was found generally to avoid early successional stages, populations being most dense in mid-stages with mixed canopy and *Ficus/Cedrela* forest, becoming less dense again towards mature forest.

**Food and Feeding.** No specific taxa recorded as food, but diet thought to be similar to that of *G. ruficauda*. Perches on exposed branches at mid-levels, often 12-20 m up, but also in scrub layer; sallies to catch flying insects. Sometimes joins mixed-species flocks.

**Breeding.** No information available.

**Movements.** Sedentary.

**Status and Conservation.** Not globally threatened. Although poorly known, apparently common throughout its range. In Peru, density of up to 13 pairs/100 ha recorded by R Manu. Occurs in Manu National Park and Tambopata Reserve, in Peru, and in Madidi National Park, Bolivia. No specific threats recorded.

**Bibliography.** Allen (1995), Angehr & Auca (1997), Bronaugh (1984), Clements & Shany (2001), Cory (1919), Cracraft (1985), Davis (1986), Donahue (1994), Forrester (1993), Foster *et al.* (1994), Gyldestolpe (1945a), Ihering & Ihering (1907), Meyer de Schauensee (1982), Munn (1985), Olrog (1968), Parker & Bailey (1991), Parker & Remsen (1987), Parker *et al.* (1982), Pinto (1938b), Remsen & Traylor (1989), Robinson & Terborgh (1997), Ruschi (1979), Sick (1993), Sneath (1914), Stotz *et al.* (1996), Terborgh *et al.* (1984), Traylor (1958), Zimmer (1930).

## 15. Purplish Jacamar

*Galbula chalcothorax*

French: Jacamar violacé

German: Purpurglanzvogel

Spanish: Jacamará Violáceo

**Taxonomy.** *Galbula chalcothorax* P. L. Slater, 1855, Quijos, Ecuador.

Forms a superspecies with *G. leucogastra*. Sometimes regarded as conspecific, but geographical isolation and apparently stable morphological differences support treatment as separate species. Monotypic.

**Distribution.** SE Colombia (Putumayo, Vaupés, Guainía), E Ecuador, E Peru and W Brazil (R Jurua).

**Descriptive notes.** 20-23 cm; 24.5-26.5 g. Male has crown and sides of head blackish-green with bluish sheen; upperparts, including tail, and breast metallic reddish-purple or coppery red; chin black, throat white, belly blackish with feathers tipped white, especially on lower flanks and towards vent; underside of tail dusky, outer rectrices tipped and fringed whitish on inner web; underwing-coverts black; bill 4.4-8 cm long (3.2-3.7 cm from nostril), slender, all black; iris dark brown; bare eyering and loreal region greyish-black; feet black. Differs from *G. leucogastra* in distinctly larger size, particularly wing length; generally

shows more purplish tones. Female as male, but throat and belly yellowish-fulvous or buff. Immature undescribed. **VOICE.** Song is rising series of inflected notes, often in pairs, "weeee weeee wi-deee wi-deee wi-deee wi-deee", sometimes accelerating into trill; call "weeee", similar to that of Dusky-capped Flycatcher (*Myiarchus tuberculifer*).

**Habitat.** Edges, clearings, treefalls and canopy of primary and secondary *terra firme* forest, also sand-belt woodland, and often along rivers or streams; mainly below 500 m, but in Ecuador locally up to 1000 m.

**Food and Feeding.** No information on diet, but presumably similar to that of *G. ruficauda*. 3 specimens taken in E Ecuador were apparently all on bees' nests, but whether they were foraging on bees is not made clear. Singles, pairs or groups of 3-4 perch from low to high levels (2-10 m), sometimes on exposed canopy branches, more often in shrub layer. Sallies for flying insects. Sometimes associates with mixed-species flocks.

**Breeding.** No information available.

**Movements.** Sedentary.

**Status and Conservation.** Not globally threatened. Poorly known and generally uncommon. Fairly common in Ecuador along R Napo, and occurs in Cuyabeno Reserve; scarce in E Colombia, where reported from Tinigua National Park, in Meta, and Amacayacu National Park, in SE Amazonas; rare in E Peru. It is probably threatened to some extent by forest degradation and habitat loss. Further ecological studies are needed to determine its habitat requirements, status and distribution. **Bibliography.** Balchín & Toyne (1998), Best *et al.* (1997), Butler (1979), Cadena *et al.* (2000), Chapman (1926), Clements & Shany (2001), Cory (1919), Cracraft (1985), Forrester (1993), Goodfellow (1902), Gyldestolpe (1945a), Hilty & Brown (1986), Meyer de Schauensee (1982), Olrog (1968), Parker *et al.* (1982), Pearson (1975b), Ridgely & Greenfield (2001), Ridgely *et al.* (1998), Rodner *et al.* (2000), Ruschi (1979), Schulenberg & Awbrey (1997), Sneath (1914), Stotz *et al.* (1996).

## 16. Bronzy Jacamar

*Galbula leucogastra*

French: Jacamar à ventre blanc

German: Bronzeglanzvogel

Spanish: Jacamará Bronceado

**Taxonomy.** *Galbula leucogastra* Vieillot, 1817, South America = Cayenne.

Forms a superspecies with *G. chalcothorax*. Sometimes regarded as conspecific, but geographical isolation and apparently stable morphological differences support treatment as separate species. Thought to have hybridized with *G. galbula* in Surinam. Birds from R Tapajós, Brazil, described as race *viridissima* on basis of greener plumage, but this character is difficult to assess, and colour apparently falls within range of individual variation shown elsewhere in species' range. Monotypic.

**Distribution.** S Venezuela (S Bolívar, Amazonas), the Guianas and Brazil (from upper R Negro and R Purús E to R Madeira and R Tapajós) S to Rondônia, Mato Grosso and N Bolivia (Pando).

**Descriptive notes.** 19-22 cm; 15-18 g. A relatively small, dark jacamar. Male has crown and sides of head metallic dark greenish-blue; rest of upperparts and entire breast metallic bronzy green, sometimes with slight purplish gloss; primaries blackish; graduated tail bronze-green on upper surface, especially central pair of rectrices; chin black; throat, belly, underwing-coverts and undertail-coverts with extensive white, underside of tail dusky, outer rectrices edged and tipped white; bill 3.9-4.6 cm long (3.3-3.3 cm from nostril), slender, black; iris dark brown; bare eyering and loreal region black; feet black. Differs from *G. chalcothorax* in distinctly smaller size, particularly wing length; generally shows brighter rufous tones. Female has throat and belly buff or ochraceous, eyering and loreal region blackish-grey. Immature unknown.

**VOICE.** Song high, ascending and accelerating whistling notes, apparently similar to *G. albirostris* but ending with trill, rather than rattle; also distinctive very high-pitched, rhythmic sequence, "eww-hihi heww-heehee heww", this also described as rising series of triplets, "weeee, weep-pip-weeeeee, weep-pip-weeeeee, weep-pip-weeeeee"; calls sharp and clipped.

**Habitat.** Edges and clearings of primary and secondary *terra firme* forest, white-sand *campinarana* in Amazonia, wooded savannas and (at least in coastal French Guiana) marshes scattered with woodlots, regularly along streams and rivers in lowlands; locally to 900 m. Occurs locally in gallery forest, dry forest and *cerrado* in Brazil, where it occupies light undergrowth and open lower canopies.

**Food and Feeding.** Only reported food items are Neuroptera (Mantispidae), Hymenoptera (Apidae, *Melipona*; also Chrysidae, Ichneumonidae), Diptera (Syrphidae, Asilidae), Hemiptera, Homoptera (Fulgoroidea). Perhaps takes fewer Lepidoptera or Odonata than do other *Galbula* species. Perches in pairs, groups of 3 or 4, but frequently singly, from low to high levels (usually 2-10 m), on exposed canopy branches or the upper shrub layer. Sallies for flying insects, as other jacamars. Sometimes associates with mixed-species canopy flocks.

**Breeding.** 2 nests found, both in arboreal termitarium; in Surinam in Jul, 6 m above ground, very short entrance, nest-chamber measuring 8 cm by 8 cm, 1 nestling, fed by both adults; other in French Guiana, early May, 15 m above ground. No further data available.

**Movements.** Sedentary.

**Status and Conservation.** Not globally threatened. Appears to be uncommon throughout its range. Not uncommon in Surinam, very rare in French Guiana; in Brazil, rare N of Manaus, uncommon further south. No immediate threats are recorded, but may suffer to some extent from overall habitat loss. Several protected areas, however, exist within its range, e.g. Tapajós National Park, Brazil.

**Bibliography.** Bangs & Penard (1918), Cohn-Haft *et al.* (1997), Cory (1919), Forrester (1993), Fry (1970b), Griscom & Greenway (1941), Haverschmidt (1958, 1960), Haverschmidt & Mees (1994), Hindwood (1959), Meyer de Schauensee (1982), Meyer de Schauensee & Phelps (1978), Olrog (1968), Oren & Parker (1997), Parker & Remsen (1987), Phelps & Phelps (1958), Pinto (1938b), Remsen & Traylor (1989), Rodner *et al.* (2000), Sick (1993), da Silva (1996), Sneath (1914), Snyder (1966), Stotz *et al.* (1996), Tostain *et al.* (1992), Willard *et al.* (1991), Willis & Oniki (1990), Zimmer & Hilty (1997), Zimmer *et al.* (1997).

## 17. Paradise Jacamar

*Galbula dea*

French: Jacamar à longue queue

German: Paradiesglanzvogel

Spanish: Jacamará Colilargo

**Taxonomy.** *Alcedo Dea* Linnaeus, 1758, Surinam.

Previously placed in a separate genus *Urogalba*, but this now subsumed by *Galbula*. Races described largely on the basis of differences in size and plumage tone, but these may represent only clinal variation. Four subspecies recognized.

**Subspecies and Distribution.**

*G. d. dea* (Linnaeus, 1758) - S Venezuela (upper R Orinoco), the Guianas, and Brazil N of Amazon (E of R Negro).

*G. d. brunneiceps* (Todd, 1943) - SE Colombia (E Guainía, Vaupés, S to Amazonas), E Ecuador, E Peru, and W Brazil (W of R Negro and, S of Amazon, between R Madeira and R Tapajós).

*G. d. phainopepla* (Todd, 1943) - W Brazil S of Amazon (W of R Madeira).

*G. d. amazonum* (P. L. Slater, 1855) - NC Brazil (W to R Tapajós, S to N Mato Grosso) and N Bolivia (Pando, Beni, N La Paz).

**Descriptive notes.** 25.5-34 cm; 25-32.5 g. Slender, elongated jacamar with plumage appearing all black at a distance. Crown dark brown; rest of upperparts, including tail, glossy black with slight bluish sheen; wings metallic bluish-black, bronze-green sheen on coverts and inner remiges; rectrices

tipped brownish-white, uppertail-coverts, tail and tertials bronzy to greenish, black chin less extensive, white throat more extensive; *phainopepla* is similar to previous but generally smaller and brighter, uppertail-coverts and tail more greenish, wing-coverts and tertials washed more bronzy. Voice. Usually fairly quiet; song a well-spaced “peep peep peep peep peep peep pee pee pe”, usually descending, becoming slightly faster and weaker towards end; call a single “pip”, or “glewweh” like a distant woodpecker (Dendrocolaptidae) or hawk (Accipitridae); also a low “ghib-ghib-rehha”.

**Habitat.** Humid primary and secondary *terra firme*, *várzea*, savanna forest, locally also dry forest and gallery forest along rivers and streams; usually below 500 m, but locally to 1100 m. Generally at canopy level, descending to lower levels at borders (very rarely in interior). Most often recorded at treefalls, clearings or edges.

**Food and Feeding.** Recorded prey items include Lepidoptera (e.g. Rhopalocera), Odonata (e.g. Libellulidae), Diptera (e.g. Tabanidae), Hymenoptera (e.g. Vespidae, Apidae; these usually the vast majority of food items), and Coleoptera (e.g. Curculionidae). Stomach contents have included spiders. Perches in singles, pairs or groups of 3 or 4. Sallies from exposed perch on outer or upper branches, sometimes as low as 1 m but usually in canopy, foraging height thus dependent on vegetation structure. Catches insects in air, often after direct stooping dive and agile chase, but sometimes after vertical upward flight; returns to a perch with undulating flight, changing perches after c. 50% of forays. In 5 hours of observation, flights occurred at rate of 21.8 per hour, ranged in distance from 1 m to 12 m (mostly 4.5-9 m), and were generally of short duration, 1.3-5.6 seconds (mean 3.2 seconds). It is unclear whether spiders are taken aerially, from webs, or from branches. Sometimes joins mixed-species flocks in canopy.

**Breeding.** Pair excavating nest-burrow in arboreal termitarium in May in Colombia; pairs regularly seen near high arboreal termitaria in dead trees in Surinam and French Guiana. No further information available.

**Movements.** Sedentary.

**Status and Conservation.** Not globally threatened. Generally common, but often overlooked because of its canopy-dwelling habits. Very common in sand-belt forest of Guainía and Vaupés, in Colombia; common along waterways in Guyana, where has been observed in the botanical garden of Georgetown; quite common in Surinam, French Guiana and S Venezuela, and generally common throughout Amazonia. Rare and local in E Ecuador; locally common in E Peru. No immediate threats are known, but general habitat destruction presumably continues to reduce populations. Numbers may increase in response to selective logging, as recorded in French Guiana, although this possibly a result of easier opportunity of detection. Recorded in many protected areas, e.g. Imataca Forest Reserve and El Dorado, in Venezuela, Amacayacu National Park, in Colombia, Tambopata Reserve, in Peru, and Tapajós National Park, in Brazil.

**Bibliography.** Allen (1995), Bangs & Penard (1918), Brace *et al.* (1997), Burton (1976), Cohn-Haft *et al.* (1997), Cory (1919), Descourtiz (1983), Donahue (1994), Fry (1970b), Griscom & Greenway (1941), Gyldenstolpe (1945a, 1945b), Haverschmidt & Mees (1994), Hilty & Brown (1986), Meyer de Schauensee (1982), Meyer de Schauensee & Phelps (1978), Olrog (1968), Oren & Parker (1997), Parker *et al.* (1982), Peres & Whittaker (1991), Phelps & Phelps (1958), Pinto (1938b), Remsen & Traylor (1989), Sargeant (1994), Sick (1993), Snyder (1966), Stotz *et al.* (1996), Thiollay (1992), Thiollay & Jullien (1998), Tostain *et al.* (1992), Willard *et al.* (1991), Zimmer & Hilty (1997), Zimmer *et al.* (1997).

## Genus JACAMEROPS Lesson, 1830

### 18. Great Jacamar

#### *Jacamerops aureus*

**French:** Grand Jacamar

**German:** Riesenglanzvogel

**Spanish:** Jacamará Grande

very long and narrow, particularly central pair (14-18 cm); chin blackish with brown spot, conspicuous white throat and upper breast to sides of neck, rest of underparts blackish; underwing-coverts white; bill 4.9-6.8 cm long, needle-like, black; iris dark brown; feet black, soles yellowish-brown. Immature not described. Race *brunneiceps* has longer wings, shorter tail, longer bill, crown slightly paler brown, upperparts with more bronzy greenish sheen, less bluish, wing-coverts glossed bronzy green, brown spot on chin smaller; *amazonum* larger, has slightly longer wings, longer bill, shorter tail, crown light brown with feathers

**Taxonomy.** *Alcedo aurea* P. L. S. Müller, 1776, Berbice, Guyana.

Was formerly considered sufficiently distinct to be placed in a monotypic subfamily Jacameropinae, although this no longer considered warranted. Specific scientific name frequently spelt as *aurea*, but this incorrect as genus name is masculine. Slight variations in tone and intensity of upperpart and underpart coloration in different parts of range, but considerable overlap mitigates against naming of further geographical races. Four subspecies recognized.

**Subspecies and Distribution.**

*J. a. penardi* Bangs & Barbour, 1922 - Costa Rica (Caribbean slope), S to W Colombia (E to E Andes) and NW Ecuador (Esmeraldas).

*J. a. aureus* (P. L. S. Müller, 1776) - Colombia E of Andes, S Venezuela and the Guianas.

*J. a. isidori* Deville, 1849 - E Ecuador, E Peru, W Brazil (E to R Purús) and N Bolivia (Beni, N La Paz).

*J. a. ridgwayi* Todd, 1943 - lower Amazonian Brazil (E of R Negro on N bank, E of R Tapajós on S bank) S to Mato Grosso.

**Descriptive notes.** 25-30 cm; 57-76 g. By far the most bulky jacamar. Male has chin, sides of face and entire upperparts iridescent green, glossed with bluish on chin, forehead, crown and tail, with golden, purplish or coppery on mantle; primaries blackish; tail rather long, broad and rounded, central pair of rectrices brighter coppery bluish-green; lower throat gleaming white, rest of underparts chestnut-rufous, underside of tail dusky or blue-black; bill 4.6-5.5 cm, relatively short, stout and decurved, all black; iris dark brown or chestnut-brown; bare eyering and lores grey; feet dark horn or green-grey, claws black. Female

similar, but lacks white patch on throat. Immature similar to adult female, but duller and less iridescent above with little or no coppery sheen, paler and duller below, rectrices narrowly tipped dull bronze. Race *penardi* has greener upperparts; *isidori* has paler underparts; *ridgwayi* has upperparts more purplish, chin, forehead and crown more greenish than blue, underparts darker and more amber-brown than previous race. Voice. Often silent; song, usually given at long intervals, a prolonged penetrating, high-pitched, hawk-like “kle-eeeeuuu”, the preliminary clipped note abruptly shifting to long falling whistle; pairs counter-call with various soft buzzing, grating or cat-like mewling notes, sometimes doubled.

**Habitat.** Unbroken humid forest and well-shaded forest borders, often along streams and rivers (including *várzea* and *igapó* forest), less commonly at forest edges and in tall open second growth; also locally in gallery forest on Brazilian *cerrado*. Usually below 700 m, locally to 1100 m.

**Food and Feeding.** Various Hymenoptera of families Scoliidæ, Vespidae (*Pachodynerus*), Apidae, Ichneumonidae and Formicidae, also Hemiptera, Homoptera, Lepidoptera, Odonata, also Coleoptera of families Buprestidae (*Chrysobothris*), Cetonidae, Chrysomelidae, Scarabeidae, Cerambycidae (*Trachyderes succinctus*). At least in Costa Rica, spiders and small lizards also taken. More sluggish than other jacamars, therefore easily overlooked; often very confiding. Perches in pairs or solitarily on slender branches or horizontal vines from mid-levels to lower canopy, usually at 4-10 m, lower at edges or gaps. Sallies to catch flying insects; tends not to return to same perch. Also gleans insects, spiders and small lizards from foliage in flight. Beats most prey against perch before swallowing. Rarely, if ever, joins mixed flocks.

**Breeding.** Breeds in Mar-Jun in Costa Rica, in Apr-May in W Colombia (Chocó), in Jan in Brazil (R Negro), in Oct in Peru; timing probably related to variations in wet season. Nest in arboreal termitarium 3-15 m above ground; also reported in rotting tree trunk. No information on clutch size, nor on incubation and fledging periods.

**Movements.** Sedentary.

**Status and Conservation.** Not globally threatened. Generally considered rare or uncommon, although it may often be overlooked owing to its unobtrusive canopy-dwelling nature; recorded much more frequently when voice is known. Rare to very uncommon, and apparently decreasing, in Costa Rica. Uncommon and apparently local in Panama, Colombia and Ecuador; in Panama, widespread but uncommon around Canal area, Darién and Cerro Pirre. Widespread in Guyana; not very numerous in Surinam. Apparently rare in E Peru; common in Rondônia, Brazil. Presumably adversely affected by deforestation; indeed, reported to decline substantially after selective logging in French Guiana. No immediate threats are known. Occurs in several protected areas throughout range, e.g. Imataca Forest Reserve and El Dorado, in Venezuela, Tambopata Reserve, in Peru, Tapajós National Park, in Brazil, and Madidi National Park, in Bolivia. Further studies needed to estimate population numbers.

**Bibliography.** Allen (1995), Blake (1962), Cadena *et al.* (2000), Chapman (1926), Descourtiz (1983), Donahue (1994), Foster *et al.* (1994), Haffer (1975), Haverschmidt & Mees (1994), Hilty & Brown (1986), Levey & Stiles (1994), Meyer de Schauensee (1949, 1950, 1952, 1982), Meyer de Schauensee & Phelps (1978), Nicéforo & Olivares (1967), Oren & Parker (1997), Ortiz & Carrión (1991), Parker & Bailey (1991), Parker *et al.* (1993), Peres & Whittaker (1991), Remsen & Traylor (1989), Ridgely & Greenfield (2001), Ridgely & Gwynne (1989), Salaman *et al.* (1999), Sargeant (1994), Schuhart *et al.* (1965), Sick (1993), da Silva (1996), Slud (1960, 1964), Snyder (1966), Stiles & Levey (1994), Stiles & Skutch (1989), Stotz *et al.* (1996), Terborgh *et al.* (1984), Thiollay (1992), Thiollay & Jullien (1998), Tostain *et al.* (1992), Traylor (1958), Wetmore (1968a), Willard *et al.* (1991), Zimmer & Hilty (1997).

Class AVES  
Order GALBULIFORMES  
Family BUCCONIDAE (PUFFBIRDS)

- Small to medium-sized perching birds with large head, short rounded wings, stocky body, small feet, and narrow tail; plumage soft, and drab to contrasting.
- 13-29 cm.

- Neotropical.
- Wooded, mostly lowland habitats.
- 12 genera, 35 species, 72 taxa.
- No species threatened; none extinct since 1600.

### Systematics

The puffbirds have been treated in modern works as comprising, variously, 30 to 36 species, these divided among as few as seven to as many as 13 genera. Somewhat surprisingly for a group that remains relatively little known, no new species of Bucconidae have been discovered since 1925, and only four taxa that stand as full species were named after 1900. In fact, fully two-thirds of the recognized species have been known for at least 150 years, and most of the others for nearly as long. Despite this lengthy history of the majority of puffbird species, most have proven to be difficult subjects of field study, and even basic data on nesting, feeding and vocalizations are still lacking for several of them.

Several fossil species and genera were for a time placed within the Bucconidae, some having been moved there from other families in which they were originally described. The fossil *Neanis [Hebe] schucherti* was once thought to represent the earliest passeriform, in the family Rhinocryptidae, but was later recognized as a member of the Eocene "puffbird" group. Another, *Uintornis*, was first thought to be a woodpecker (Picidae), and then a cuckoo (Cuculidae), and yet another, *Botaurides*, was originally named as a heron (Ardeidae). These fossils, while closest to the Bucconidae, nevertheless differ from the modern family in a suite of characters, including a shorter mandibular symphysis, a broader manus, and several details of the distal end of the tarsometatarsus. These differences led A. Feduccia and L. D. Martin, in 1976, to place them in a new family, Primobucconidae; since then, the modern Bucconidae have been considered unrepresented in the fossil record. The Primobucconidae was said to be the dominant group of small arboreal birds in the Lower and Middle Eocene of North America, having radiated into several species and genera; at least one species was also identified from the Eocene of Britain. More recently, however, the taxa that were brought together in the Primobucconidae have been shown to belong to at least three different families, so that, after the removal of several taxa from the Primobucconidae, only one remains in that family. In a paper published in 1998, G. Mayr showed that an Eocene fossil from the famous Messel quarry in Germany has numerous similarities with the Primobucconidae, and primobucconid-like birds certainly occur both at Messel and at Quercy, in France. Small non-passerines with various degrees of zygodactyly were clearly the dominant perching birds in the Eocene of the Northern Hemisphere.

Early systematists often placed the puffbirds together with the barbets (Capitonidae), sometimes even in the same genus, and although Buffon considered the New World barbets and the puffbirds

to be related, using the name "Tamatia" for both, he believed that the Old World barbets were unrelated. In the middle of the nineteenth century, J. Cabanis and F. Heine treated the Bucconidae and the Capitonidae as separate families, and most subsequent researchers have considered these two groups to be fairly distantly related. Nevertheless, not long after Cabanis and Heine's work was published, H. Burmeister and even H. Schlegel treated the puffbirds and the barbets together, differentiating them principally on the basis of the number of rectrices which they possess. In 1850, C. L. Bonaparte recognized the barbets and the puffbirds as separate families, but confusingly reversed the family and generic names from those in subsequent usage. Numerous other early classifications united some or all of the zygodactylous groups, such as the Cuculiformes, the Piciformes, the Coraciiformes and the Trogoniformes, in various combinations, primarily or solely on

The puffbirds comprise a well-defined monophyletic assemblage, most species having a bulky head, large eyes, a robust bill, a bristly face and loose plumage. Nevertheless, agreement on generic limits within the Bucconidae has proven rather difficult. The Spotted Puffbird belongs to a controversial genus, *Nystactes*, which is usually merged with *Bucco*. The most distinctive trait of the two *Nystactes* species is their strongly bifid, or cleft, bill tip. Both species also have a black bill and an unbarred tail.

[*Nystactes tamatia pulmentum*, Amacayacu National Park, Colombia.

The Chestnut-capped Puffbird belongs to one of five monospecific genera in the Bucconidae. Placed in the "bucconine" group by Ridgway, it exhibits the ancestral puffbird plumage pattern that includes a broad breastband, strong facial markings and a pale hindcollar that contrasts with the rest of the upperparts. It is generally considered to be monotypic, although some authors treat birds from the Río Caura region of southern Venezuela as a separate race, *caurensis*. Like the genus *Nystactes*, *Argicus* is often merged with *Bucco*.

the basis of the toe arrangement, despite the major differences between some of the groups in the form of zygodactyly involved.

Almost all authorities, beginning with H. G. Möhring in 1752, have agreed upon the sister-taxon relationship between Galbulidae (jacamars) and Bucconidae, though a few notable exceptions exist. C. L. Nitzsch, in his influential study of pterylography published in 1840, concluded that the Galbulidae possess an aftershaft, while the Bucconidae lack this, and subsequent workers accepted this uncritically as a major difference between the two groups. In 1956, however, C. G. Sibley showed that the Bucconidae do in fact have a vestigial aftershaft that is homologous to the small aftershaft of the Galbulidae.

An overwhelming number of morphological and biochemical characters link the Galbulidae and the Bucconidae, and no serious doubts have been raised as to the monophyly of the clade formed by these sister taxa, traditionally classified as the suborder Galbulae, within Piciformes. The two groups are similar in virtually all of the many osteological and myological aspects studied by J. Steinbacher, as well as in their syringeal and hyoid morphology. Characters that have been taken to be synapomorphies, or at least useful taxonomic characters shared by the two families, include the form of the tongue; the strongly desmognathous palate; the lack of ectepicondylar processes on the humeri; the conditions of the anterior iliac blades, the furcula, the sternal plate and the posterolateral processes; the possession of two carotids; the long, globose caeca; the naked, bilobed uropygial gland; the similar type of zygodactyly; and apparently derived conditions of trochlea IV. Some characters traditionally cited as diagnosing the Galbulae are not well established, and at least one, the forked spina externa, has been found to be variable and widespread. Externally, the two families share forward-directed setae surrounding the bill; eyelashes; similar pterylography; non-oscine wing-coverts; and the same number and moult patterns of remiges and rectrices. Several biochemical studies have supported their relationship as sister taxa: first, electrophoretic studies of egg-white proteins; then an allozyme study of the Piciformes and Coraciiformes; and DNA-DNA hybridization analyses.

Nevertheless, the status of the Bucconidae and the Galbulidae as separate families has rarely been questioned, although H. Seebohm merged them in 1895, as did S. D. Ripley 50 years

later. This near-consensus may be due to the fact that jacamars and puffbirds differ in several obvious external characters. Bucconids have a shorter, more curved, hooked, heavier bill, often with a bifid tip; reduced or non-existent plumage gloss; and a general chunky, large-headed shape. Internally, the two families differ in the form of the spinal cord, with Bucconidae bearing that of Piciformes and many other groups, while the type shown by Galbulidae is as that of Coraciiformes, among other groups. Moreover, bucconids differ from jacamars in having a rounded gonys; a vomer; a high keel on the palatine; six ribs; minor differences in most muscle groups and skeletal elements; several minor differences in pterylography; a posteriorly scutellate tarsus; and full, lax, earth-toned plumage.

The relationships of the Galbulae, which as a unit has enjoyed nearly universal acceptance, have nevertheless been the subject of considerable controversy. After a plethora of alternative placements, the Galbulae have in recent years most often been placed as a suborder within the order Piciformes, following A. Wetmore's classification. By far the most thorough study of the morphology of both jacamars and puffbirds was that of J. Steinbacher, published in 1937. After making comprehensive comparisons of their musculature, osteology, internal anatomy, and other aspects with those of the Capitonidae and the Picidae, Steinbacher's overwhelming conclusion was that jacamars and puffbirds are closely related, but also that jacamars are somewhat closer to barbets in many respects than are puffbirds. Steinbacher did not seriously question the tenet that all were piciforms, although, unfortunately, his comparisons with coraciiforms were extremely limited. The case for inclusion of the Galbulae in the Piciformes has been defended mainly by J. L. Cracraft and R. J. Raikow, using phylogenetic analyses of morphological characters, but it remains supported by only a few characters, mainly zygodactyly, the validity and homology of which were strongly disputed by S. L. Olson. In P. J. K. Burton's detailed study of puffbird morphology, which appeared in 1984, the view that the Bucconidae are better placed with the Coraciiformes was supported. Furthermore, it has recently been shown that one of the many characters in which the Galbulae differ strikingly from the remaining families of Wetmore's Piciformes is the lack of villi, the projections on the basalmost downy barbules of the breast feathers. Also, the Galbulae pos-

The two members of the genus *Hypnelus* may be conspecific, as they hybridize near Lake Maracaibo. The two forms are strongly differentiated from each other in plumage, however, the Two-banded Puffbird having two black breastbands and a pale throat, and the Russet-throated Puffbird (*Hypnelus ruficollis*) having a single black breastband and a rusty throat. Hybridization appears to be limited, for most specimens can be clearly assigned to one form or the other. Unless future studies in the contact zone suggest otherwise, the two taxa are probably best treated as separate species.

[*Hypnelus bicinctus bicinctus*, Caño Colorado, Monagas, Venezuela.

sess the primitive state for an electrophoretic marker that is derived in the remaining members of Wetmore's Piciformes; C. G. Sibley and J. E. Ahlquist have found, in multiple biochemical data sets, that relationships of the Galbulae with the rest of the Piciformes are weak at best; and in an electrophoretic study the Galbulae were sister to a motmot of the genus *Momot*, a coraciiform, followed by a picine. Sibley has long advocated treatment of the Galbulae as a separate order, Galbuliformes, and on the currently available evidence this seems to be the safest course to steer.

All buconids are rather similar in basic shape, structure and general appearance, with the notable exception of the surprisingly martin-like Swallow-winged Puffbird (*Chelidoptera tenebrosa*). Even this aberrant form, however, would seem to be undeniably a puffbird, with quite typical buconid internal morphology. Within the past century, no doubts have been expressed about the monophyly of the family Bucconidae. There are several clear-cut genera, which can scarcely be treated in any other manner: the nunbirds in the genus *Monasa*; the White-faced Nunbird (*Hapaloptila castanea*) in its own monospecific genus; the Swallow-winged Puffbird in *Chelidoptera*; the nunlets in *Nonnula*; the Lanceolated Monklet (*Micromonacha lanceolata*) in another monospecific genus; and the "soft-feathered" puffbirds in the genus *Malacoptila*. The remainder of the family, however, poses more difficulty in generic allocation. P. L. Sclater, in 1882, placed all the rest in the genus *Bucco*. However, too much variation exists among the 15 species involved to justify keeping all within a single genus. About three decades later, R. Ridgway included them in a subfamily Bucconinae, while recognizing differences at the generic level. More recently, G. W. Cottrell, in 1968, reverted to the inclusive genus *Bucco*, on the grounds that all but one member had a cleft-tipped bill.

The distribution within the proposed subfamily Bucconinae of the bifid bill tip nevertheless requires further comment, as recent observations differ from those of Cottrell, whose work has prompted some authors to return to Sclater's expanded genus *Bucco*. While Cottrell considered that, in the Bucconinae, all but one species, the Chestnut-capped Puffbird (*Argicus macrodactylus*), show the bifid bill tip, this feature has been found to be very pronounced in members of the genera *Hypnelus* and *Nystactes*, less so in *Notharchus*, but reduced to a slightly broadened but essentially non-bifid tip in *Nystalus* and the Collared Puffbird (*Bucco capensis*). Moreover, the bill of the Chestnut-

capped Puffbird has a pointed, definitively non-bifid tip. It should be noted that juveniles do not show a bifid tip at first, and there is some variability among adults of bifid-tipped species, this being almost certainly related to wear and replacement of the ramphotheca. The presence of the bifid bill tip seems correlated with other characters that define natural groups within the Bucconinae, and these groups should be recognized at least as subgenera, if not as full genera.

The most perplexing problem at the generic level involves the Collared Puffbird, which in bill shape and colour, as well as plumage pattern, is closer to species of *Nystalus* than to other members of an expanded genus *Bucco*. Since it is the type species of the genus and family, however, it cannot be removed from the genus *Bucco*. Resurrection of generic names in former widespread usage, until they were all placed in *Bucco* by J. L. Peters, provides an interim solution to the problem, pending further study. Thus, the genus *Argicus* can be used for the Chestnut-capped Puffbird, and the genus *Nystactes* for the Spotted Puffbird (*Nystactes tamatia*) and the Sooty-capped Puffbird (*Nystactes noanamae*). This is congruent with the bill-tip morphology and other external characters: *Bucco* and *Nystalus* have a non-bifid or very slightly bifid tip of the bill, a brightly coloured bill, and a barred tail; *Argicus* has an autapomorphic or unique plumage pattern and a fine bill tip; and *Nystactes* has a strongly bifid, all-black bill, and some distinctive plumage features. In 1936, H. von Boetticher suggested that the cleft tip of the bill, which is unique to the Bucconinae, is used as a vice, but evidence in support of this notion remains elusive.

In Ridgway's classification, the Bucconinae were distinguished from the other members of the family principally by the heavy, straight, hook-tipped bill, in most cases with a slightly to strongly bifid tip. The remaining species, all of which he grouped in Malacoptilinae, on the other hand, typically have a somewhat curved bill but lack a strong terminal hook or any suggestion of the bifid tip. While the plumage within the Bucconinae is highly variable, in general the component taxa have more contrasting colours and ornate patterns, such as a broad black breastband, a pale hindcollar, spotted upperparts, whitish underparts, and a strong facial pattern. Conversely, the Malacoptilinae exhibit mainly dark, relatively uniform plumage, with one or a few, often semi-concealed patches of contrasting colour about the face or wing that are probably used in display; in addition, they often have lengthened throat feathers. Members of the genus

*Malacoptila* (meaning "soft feather") have mainly pale-streaked or pale-spotted brown upperparts with a patch of contrasting colour on the breast. The smaller nunlets in *Nonnula* comprise a fairly uniform genus having mostly drab, entirely unstreaked or unspotted plumage with subtle colour patterns of brown, rufous and grey; they also have a fairly long, thin, curved bill, usually with silvery sides, and conspicuous eye-rings which are sometimes formed by brightly coloured bare skin. The nunbirds in the genus *Monasa* are strikingly different in behaviour from all other puffbirds; and morphologically, too, they form a readily diagnosed group, all having a relatively shorter, brightly coloured bill, black to dark grey plumage relieved only, if at all, by small white patches, and a longer, broad tail. Two aberrant monotypic genera are *Micromonacha*, a tiny, short-tailed, uniquely patterned bird with solidly dark upperparts, streaked underparts, and a complex undertail pattern; and *Hapaloptila*, a large, mainly bright chestnut Andean species that combines certain external features of both *Malacoptila* and *Monasa*, while its bill is "inflated" and scarcely curved, being almost hooked, and its wings are relatively long, hence the former name of "Slenderwing". The most aberrant puffbird of all, however, is clearly *Chelidoptera*, which, as its common name of Swallow-winged Puffbird implies, is highly adapted for aerial activity. It has relatively long wings, a shorter, narrow bill, sleek, tight plumage, and a short and broad tail, and Burton noted that it has an unusually large heart. Despite its apparent distinctness, it is not placed in a separate subfamily; its adaptations to a more aerial lifestyle seem to have involved primarily superficial characteristics.

Over half of the 35 species of puffbird are monotypic. By contrast, most of the wide-ranging species exhibit complex geographical variation. These are the White-necked Puffbird (*Notharchus macrorhynchos*), the White-whiskered Puffbird (*Malacoptila panamensis*), the Spotted Puffbird, the White-fronted Nunbird (*Monasa morphoeus*) and the Rusty-breasted Nunlet (*Nonnula rubecula*). In all these cases, there is long-standing disagreement as to the number and distribution of valid subspecies, and further study is needed. The subspecific nomenclature of two other bucconids seems to be especially unsettled. For the Rufous-capped Nunlet (*Nonnula ruficapilla*), the possibility of undescribed races has been mentioned in the literature; and, for the Black-streaked Puffbird (*Malacoptila fulvogularis*), at least four subspecies have been described, all of which seem likely to represent individual, seasonal and age-related variation. Further, in the case of the Spotted Puffbird, three subspecies pre-

viously considered valid probably represent intergrading, variable populations.

The possibility of an undescribed species of *Nystalus* in Brazil, based on a sight record, has been mentioned in recent literature, by C. A. Peres and A. Whittaker in 1991, but the description provided fits that of Striolated Puffbird (*Nystalus striolatus*). Another taxonomic puzzle concerns a species named by A. de W. Bertoni, in 1901, as *Microtrogon galbuloides*. Unfortunately, the describer of this did not even indicate whether a specimen was preserved; it has merely been presumed, from the inadequate description, to represent a puffbird, which on geographical grounds could be only the Rusty-breasted Nunlet, but it may not be a bucconid at all. In any case, Bertoni's collection has evidently now disintegrated, so we shall probably never know for certain the identity of this bird.

There are several cases among the Bucconidae in which the specific status of a given taxon is in question or has been disputed. These include the Semicollared Puffbird (*Malacoptila semicincta*), which has sometimes been regarded as a subspecies of the White-chested Puffbird (*Malacoptila fusca*); most authors, however, consider the several constant differences between the two, and the lack of intergradation between them, sufficient to establish the former as a full species. A less clear-cut case is that of the White-necked Puffbird, which has normally been attributed the isolated southern Brazilian population, *swainsoni*, as a subspecies. The latter is fairly distinctive, and was said by Sibley in 1996 to differ vocally, although comparative studies are needed. In addition, as the geographically nearest races of *macrorhynchos* differ greatly from *swainsoni*, and there is no possibility of overlap or intergradation, it seems better to treat the southern form as a distinct species, the Buff-bellied Puffbird (*Notharchus swainsoni*). At the same time, however, it should be noted that the nominate race of the White-necked Puffbird in the Guianan region is also distinctive in appearance and possibly in song; thus, further study of the situation is required. Another species-level problem involves the Spot-bellied Puffbird (*Nystalus maculatus*) and its southern subspecies *striatipectus*. Their specific distinctness has recently been convincingly espoused by J. M. C. da Silva, who recommended that *striatipectus* be treated as a separate species, for which the name Streak-bellied Puffbird would be appropriate. This proposal was based largely on the phylogenetic species concept; there are also several additional constant differences between adults of the two taxa, with no intermediates recorded. However, the vocalizations of the two forms

*Malacoptila* puffbirds have lengthened throat feathers and lax plumage, the latter being reflected in their generic name. Most of the species are quite heavily streaked or spotted on the breast and back, a notable exception being the Rufous-necked Puffbird, which has the streaking confined to the head. White-chested Puffbirds exhibit the streaking typical of the genus but get their common name from a white breast patch that often is not visible in the field.

are similar, and it will be necessary to evaluate this case under the biological species concept before accepting the proposed split. A further example where uncertainty prevails concerns the Pied Puffbird (*Notharchus tectus*). This is comprised of two groups of races, one trans-Andean and one cis-Andean, which may prove to be separate species.

Two dissimilar-looking taxa that have been considered conspecific, on the basis of hybridization between them, are the Two-banded Puffbird (*Hypnelus bicinctus*) and the Russet-throated Puffbird (*Hypnelus ruficollis*). As the great majority of specimens are clearly of one form or the other, suggesting that hybridization is fairly limited, it is probably best to follow Peters in treating them as separate species, pending a thorough study that will elucidate the nature of their contact zones. Uncertainty also clouds the taxonomy of the Rusty-breasted Nunlet, which is highly variable regionally over a wide range; a revision of its disjunct component subspecies, some of which may merit the status of full species, is needed. On the other hand, the Grey-checked Nunlet (*Nonnula frontalis*) and the Rufous-capped Nunlet are quite similar, and have sometimes been treated as conspecific. Finally, the White-fronted Nunbird, currently treated as a single polytypic species, was earlier divided into several different species; intermediates between some of the component taxa exist, however, whence their relegation to the status of subspecies, although there are obvious differences between the disjunct northern group of races and the Amazonian and south-east Brazilian races, and further study is needed.

### Morphological Aspects

The origin of the family name Bucconidae has been disputed. It has been thought to refer to the large bill, but it could also incorporate the meaning of "charlatan" or "tonto", the latter alluding to the perceived stupidity of these birds (see Relationship with Man).

All puffbirds have a relatively large head and large eyes, and a swollen-based, fairly heavy, curved and/or hooked bill. There are well-developed rictal bristles continuous with numerous setae surrounding the bill base, the anterior ones of which are for-

wardly directed, and the nostrils have a large operculum. The wings are relatively short to very short, and rounded; and the tail is short to medium-length, narrow, and graduated, though broader and longer in some *Monasa* species.

Osteologically, the quadrate has a short, broad, pointed orbital process; the medial condyle is extremely deep, ending in a rounded tubercle, with the lateral and posterior condyles merged. The postorbital process is long, curved and broad; a retroarticular process or medial brace is lacking; and there is a strong postorbital ligament. There are 14 cervical and four dorsal vertebrae, two distinct cervical ribs, and four true ribs. The visceral anatomy of the family is characterized by a capacious oesophagus, a thick-walled muscular gizzard, no gall bladder, and a short intestine with long globose caeca. Bucconids have fairly small zygodactylous feet, on which the first and fourth digits are permanently reversed. The body temperature is low to average for higher non-passerines. Interestingly, the White-eared Puffbird (*Nystalus chacuru*) has been reported to undergo periods of torpor within its burrow during cold weather.

Several species have elongate throat feathers, which may form conspicuous display features. Puffbirds have been called drab-plumaged, but most have at least one major plumage feature, such as a large white throat spot, a black chestband, or rufous on the throat or crown, that enlivens their appearance. Some have a complex plumage pattern, and several are strikingly pied and fairly glossy, or are sharply patterned in chestnut, black, brown and white. Additionally, the irides, the orbital skin and/or the bill are often brightly coloured. The plumage, bill and feet of some species of *Nystalus* may become stained during the nesting season by the soil of their burrows.

A number of species have spotting or scaling on the upperparts at all ages, which, together with the fluffy plumage, tends to give them a look of immaturity. Age-related plumage variation is, in fact, minimal in most bucconids, and some species are difficult to age except by bill characters. There are no bucconids in which the plumage pattern of the juveniles is truly different from that of the adults. Typically, juveniles have reduced, duller markings than adults; the areas which are white on adults are tinged with buff or fringed with dark on juveniles, while the dark areas are more fringed or spotted with pale col-

The five members of the genus *Notharchus* exhibit an impressive array of plumages with a basic theme of black and white. The strikingly plumaged White-necked Puffbird is among the largest of the bucconids and has one of the widest ranges, occurring from southern Mexico south to northern Bolivia. Geographical variation in this species is complex and not well understood, with three races currently recognized, and two other proposed ones rejected. The northern race, *hyperhynchus*, differs from the nominate in having much more white on the forehead and hindcollar and a larger bill; indeed, it may be a separate species.

[*Notharchus macrorhynchus*, *hyperhynchus*, near Esmeralda, Amazonas, Venezuela. Photo: Bruno Walther]

Washed with rufous and barred all over except on the throat, the Barred Puffbird resembles the female Fasciated Antshrike (*Cymbilaimus lineatus*), and the two are sometimes sympatric. It is the only bucconid thought to have colour morphs, darker rufous birds originally being listed as race "fulvidus".

Puffbirds are well known for seeming lethargic, sitting motionless for long periods before making a rapid dash to snatch a prey item out of the air or from the foliage.

The generic name *Nystalus* means "drowsy", reflecting the seemingly languid habits of the family.

[*Nystalus radiatus*,

our. In those species which have bright bare-part colours, these colours are typically duller on juveniles. Variability in iris colour among presumed adults is great for some species, and studies are needed to determine what the significance of this may be.

Sexual dichromatism is almost absent among the members of this family. It occurs only in two species of *Malacoptila*, and in one of these, the Moustached Puffbird (*Malacoptila mystacalis*), the difference in appearance between males and females is minor. It has frequently been noted that female puffbirds of several species are slightly larger than the males, although this has not been tested statistically.

Only one species is thought to exhibit true colour morphs. This is the Barred Puffbird (*Nystalus radiatus*), which occurs in both light and dark rufous morphs.

In the only major moult study for the family, published in 1968, J. Haffer found that primary moult follows a simple descendant, centrifugal sequence, while moult of the secondaries and rectrices is irregular. For the nunbirds, the body moult has been reported to occur during the post-nuptial period, and to be protracted.

The flight of puffbirds is generally very fast and direct, on rapidly beating wings (see General Habits, Food and Feeding). The wings of at least one species, the White-necked Puffbird, produce a low whirring noise in flight.

It is worth mentioning the apparent physical resilience of these birds. Some puffbirds have been found to be, for birds of their size, unusually difficult to kill by thoracic compression or by shooting, individuals often reviving subsequent to apparent death. This may be attributed, at least partly, to their notably strong ribs as compared with those of jacamars of similar size. Indeed, several bucconid species have acquired colloquial names which reflect their ability to withstand being hit by stones flung by catapult or slingshot (see Relationship with Man).

As a final point of interest, preparers of specimens have noted that many puffbird species are malodorous. Indeed, representatives of all genera except *Hapaloptila* were reported as such in a recent survey. Since at least G. Shaw's writings, in 1815, it has been known that puffbirds are not especially edible, and perhaps their oft-remarked confiding and imperturbable nature (see General Habits), which has frequently allowed members of a pair or group to be shot sequentially (see Relationship with Man), is related to this circumstance. On the other hand, their unpleasant odour could simply be a result of the type of prey that they ingest, which would have a side benefit of making them undesirable as prey themselves.

## Habitat

The Bucconidae are found exclusively in the Neotropics, from southern Mexico to northern Argentina. Within this region, they are absent from islands except for a very few on the continental shelf. They reach their greatest abundance and diversity in northern South America, especially in Amazonia.

Puffbirds are almost entirely arboreal except, in the case of some species, when nesting. All are therefore strongly associated with wooded habitats, and, indeed, most are intimately linked with humid tropical lowland forest. No fewer than 70% of puffbirds, a total of 25 species, occur in Brazil, and almost as many, 23, are present in the Amazon Basin. Very few puffbirds,

Measuring 13-16 cm in length, and weighing only 15-20 g, the nunlets are diminutive puffbirds. Their plumage is a sombre mix of browns, reds and greys and has no streaking or spotting. They have a relatively long, thin bill and either a white or a reddish eye-ring, the latter colour usually formed by bare skin. The Brown Nunlet has a pale rufous loreal spot and is uniformly plain brownish on the crown and upperparts; the rufous colour on its underparts decreases in richness from the throat to the belly. It is a restricted-range species that inhabits the understorey of humid lowland forest in the Upper Amazon-Napo Lowlands Endemic Bird Area in Ecuador, Colombia and Peru.

[*Nonnulla brunnea*,

VIREO]

Sexual dichromatism is rare in puffbirds, occurring only in two *Malacoptila* species. In one, the Moustached Puffbird (*Malacoptila mystacalis*), the sexes are so similar in appearance that plumage dichromatism is generally ignored in field guides. In contrast, the sexes are noticeably different in the White-whiskered Puffbird: males have a rufous tone to the plumage, especially about the face and chest, whereas females are greyer overall and tend to be more heavily streaked on the underparts. With four accepted races, the species is widely distributed from south-east Mexico to Ecuador and Colombia. It is much less common in the northern half of its range than farther south.

[*Malacoptila panamensis* poliopis, near Alto Tambo, Ecuador. Photo: Steven Holt/VIREO]

however, are deep-forest species; the Black-breasted Puffbird (*Notharchus pectoralis*), the Collared Puffbird, the Black-streaked Puffbird and the Brown Nunlet (*Nonnula brunnea*) are perhaps the closest to being so. Most of the *Bucconidae* are birds of forest edge, tree-fall gaps and streamsides, where tangles of vegetation form at different levels up to the canopy. In such places, the birds find both the narrow horizontal perches that they require and the mix of green-leaf and dead-leaf large invertebrates that make up most of their diet. A few species appear to be associated, though not exclusively, with bamboo stands, and a few others with lake and river margins. While most are birds of lowland tropical forest and edge, several have adapted to drier, more open woodland, and at least one reaches moderate altitudes in the Andes.

This apparent habitat preference may to some extent, however, be a matter of constraint. It has been observed that *Malacoptila* puffbirds are much less common in forest east of the Andes than is the White-whiskered Puffbird in forest west of those mountains; east of the Andes, the Rufous-necked Puffbird (*Malacoptila rufa*) and the Semicollared Puffbird are more birds of forest edge, sandy woodland and swamp margins. In Honduras, by contrast, the White-whiskered Puffbird is an inhabitant of deep forest. It may be that this difference, if real, is due to a higher diversity of avian species in Amazonian forest than in Central American forest, such that *Malacoptila* species are at a disadvantage when competing for resources inside forest in the Amazon and Orinoco Basins.

Pressure limiting the puffbirds to the edge habitats may come from birds of other families, as well as from the *Monasa* nunbirds. Nunbirds are large and numerous, and may well help to exclude other Amazonian buconids from the middle storeys of forest. Indeed, some nunbirds also do this to others of their genus. The White-fronted Nunbird is the dominant species, occupying *terra firme* forest and edge, while the Yellow-billed Nunbird (*Monasa flavirostris*) is associated with bamboo and second-growth borders, and the Black-fronted Nunbird (*Monasa nigrifrons*) is a bird of the seasonally and permanently flooded forest habitats known respectively as *várzea* and *igapó*. So clear is this habitat division between Black-fronted and White-fronted Nunbirds that the two species were once seen a few metres apart, following an ant swarm as it moved from *várzea* alongside a stream into *terra firme*. Although these two species partition habitat widely thus

in Amazonia, they have mutually exclusive ranges in south-eastern Brazil, a matter which is deserving of ecological study.

A slightly different pattern of habitat specialization is found among the members of the genus *Nonnula*. In Amazonia, the Rusty-breasted Nunlet occupies *terra firme* forest, but it also penetrates *várzea*, while in northern Amazonian Brazil the sympatric Chestnut-headed Nunlet (*Nonnula amaurocephala*) occurs in *igapó* forest, and south of the Amazon the Rufous-capped Nunlet is over much of its range a bird of riverine bamboo thickets. The River Amazon itself is the dividing line between two quite differently plumaged congeners, the White-chested and Rufous-necked Puffbirds, as it also is between the Black Nunbird (*Monasa atra*) and the Black-fronted Nunbird. In Colombia, altitudinal replacement is seen in the case of two closely related species, the White-whiskered Puffbird and the Moustached Puffbird: the former occurs in the lowlands, the latter in the lower Andes.

Several buconids have seemingly inexplicable discontinuities of range that are not obviously correlated with habitat or competitive exclusion. Prime examples are the Brown-banded Puffbird (*Notharchus ordii*) of northern and southern Amazonia, so far not recorded from central Amazonia; the Striolated Puffbird, found in western and extreme eastern Amazonia, but nowhere in between; and the Crescent-chested Puffbird (*Malacoptila striata*), which has two widely separated populations, one near the mouth of the Amazon and the other in south-eastern Brazil.

It is worth emphasizing that the Rufous-capped Nunlet is not always an inhabitant of bamboo, and that the White-whiskered Puffbird is in some places a deep-forest bird. These facts indicate that habitat selection is relative and plastic, depending on a variety of factors, including competition from other members of the family. The habitat used by some species also varies over the course of the day. A. F. Skutch noted that White-whiskered Puffbirds come out of the forest to forage in adjoining shady pastures or other clearings, this occurring most often in the dim light of early morning or late afternoon, and in periods of wet or overcast weather.

Moreover, it is not entirely proven that so many puffbirds are genuine edge species. While the patterns revealed to date doubtless reflect real circumstances, they are unlikely to be the complete patterns. Puffbirds, because of their remarkable stillness and silence (see General Habits), are observed relatively

For all practical purposes, puffbirds make their living in trees and are closely tied to wooded habitats. Several species excavate nesting burrows below ground, but even these forage from elevated perches and thus are never far from trees. Despite their arboreal habits, however, few puffbirds are denizens of deep, unbroken forest. Rather, they seem to favour forest edges, tree-fall gaps and other clearings. Whether this apparent preference for edge habitats is based on forest structure or on some other factor remains to be determined.

For example, in some *Malacoptila* puffbirds, the affinity for edge habitat seems to be positively correlated with the diversity of other bird species in the forest interior, raising the possibility that interspecific competition constrains puffbirds to edges. Moreover, because puffbirds are so lethargic, their apparent proclivity for open habitat may be due to the fact that they are easier to observe there than in denser habitats.

Whatever habitat they occupy, puffbirds typically perch on horizontal branches while they scan for potential food items. Most species, including the Pied Puffbird, often use exposed perches. In contrast, a few species, including the Moustached Puffbird, prefer more concealed perches in dense tangles near the ground beneath the canopy of humid forest.

The majority of puffbirds occupy humid lowland forest, with few species occurring at elevations above 1200 m.

A notable exception is the White-faced Nunbird, which lives at higher elevations than any other buconid. This species is found most often on steep slopes along the edge of wet foothill forest above 1500 m, and it ascends as high as 2900 m into the cloudforest zone. This distinctively marked species, with its solid grey cap, large bill encircled by white feathers, bright chestnut underparts and long tail, is uncommon to rare throughout its range from western Colombia and Ecuador south to north-west Peru.

[*Hapaloptila castanea*, Pichincha, Ecuador. Photo: Steven Holt/VIREO]

rarely; whether one is caught sight of or not is seemingly only a matter of chance. If, therefore, almost all the observations are made in the understorey and edges of forest, it is possible that this may in part be because birds in the canopy are simply invisible. There is at least a modest chance that some buconid "edge specialists" also spend parts of their daily or annual cycle in the canopy, and so go largely undetected. Skutch thought that this might be true of White-whiskered Puffbirds. Furthermore, M. A. Carriker found that the White-necked Puffbird was fairly common in Costa Rica only because of the way in which the edges of a clearing filled up with birds in response to a sudden abundance of wood-boring insects in the trees that had been left to rot. Did this reveal the species to be an edge specialist, or had numbers of White-necked Puffbirds simply been drawn from other forest micro-habitats, perhaps the canopy, in which they were less visible?

One micro-habitat that may be important for many species of puffbird is standing or running water. White-whiskered Puffbirds have been found to occupy territories focused on streams, with ridges often serving as border areas. These birds tend to avoid flat summit areas altogether; indeed, one female which did take up residence in such a flat, dry area at the headwaters of a stream failed to procure a mate during her year's occupancy. This suggests that streams are crucial for reproductive capacity in this species, presumably because they promote an increase in understorey foliage and, hence, a greater biomass of appropriate food. Some 50% of all puffbird species show a preference for vegetation close to water. This is hardly surprising when one considers that these are possibly the closest ecological equivalents to the Old World forest kingfishers (Alcedinidae). In fact, they are sometimes even referred to as "kingfishers" by local people.

A handful of buconid species have radiated into foothill and submontane forest areas. These include one species of *Nystalus*, three of *Malacoptila*, and two species in monotypic genera, the Lanceolated Monklet and, notably, the White-faced Nunbird. The last occurs from 750 m, though mostly from 1500 m, up to an altitude of 2900 m, ascending higher than any other puffbird. A small number of the *Buconidae*, including all but one of the four *Nystalus* species and both of the *Hypnelus* puffbirds, have specialized in occupying drier, more open woodland habitats. Some of these, along with the anomalous Swal-

low-winged Puffbird, are the species most likely to be seen in man-modified habitats, such as the sides of railway tracks. White-eared Puffbirds often perch on telegraph wires and fences, and occur in suburban areas where trees preserve park-like conditions.

### General Habits

Puffbirds get their English name from their frequent and peculiar habit of fluffing out the plumage and drawing in the large head, so that, perched on a branch, they appear almost ball-like and not much like birds at all. This behaviour may serve to disguise them from avian predators, since sitting, as they do, in exposed positions, waiting for prey to move, must have its risks. Certainly, the explanation for the obdurate stillness of puffbirds would seem to be the need not to be seen by either predator or prey. Nevertheless, foraging puffbirds commonly do not fluff their feathers.

This stillness is also a notable puffbird trait, for these birds allow an extremely close approach before flushing. The birds might fluff up their feathers and still-perch while waiting for improved hunting conditions, possibly connected with slight torpor for energy conservation. Skutch argued that puffbirds, although sitting motionless for long periods, are ever alert, and that their behaviour at the nest (see Breeding) shows what remarkably keen-sighted, wary creatures they are. Their visual powers are testified to by the astonishing ability that they show when picking prey from leaves (see Food and Feeding).

Nunbirds and nunlets tend to sit in a rather upright stance. Other puffbirds may slouch more, although still with the tail held vertically. The short legs mean that the body appears to be resting on the perch; they probably also limit these birds' mobility, although the nunbirds are capable of suddenly switching around on a branch. Usually, the only movement made by a buconid when perched involves deliberate slow turning of the head as it watches for prey.

The one other movement commonly shown by a perched buconid involves the tail. This tends to happen only as the bird prepares for flight, whether forced or voluntary. A White-whiskered Puffbird will nervously lift its short, narrow tail, and jerk it, motmot-like, in slow sideways movements, first to the right and

A handful of puffbirds, including three of the four species of *Nystalus*, are found in drier woodland, brushy grassland and savanna, and they will also regularly use disturbed habitats. The White-eared Puffbird carries this penchant to an extreme: not only does it favour wooded edges and second growth, it also occupies coffee plantations, tree-lined streets in towns, and railroad rights-of-way, where it often can be seen perched conspicuously on a telephone wire, fence wire or fencepost.

[*Nystalus chacuru uncirostris*, Apurímac, Peru.  
Photo: Günter Ziesler]

then to the left, or rotate it, before it takes wing. Two-banded Puffbirds also have this habit, swinging the tail through an arc in a series of three or four abrupt jerks, beginning out on one side and "clicking" around to the other, and then back again. At least four species of *Nonnula* and two other *Malacoptila* puffbirds show similar such movements of the tail. Nunbirds appear instead to rotate or flick the tail backwards, allowing it slowly to become reset in the vertical. In all cases, this tail-moving behaviour seems to express alarm, excitement and/or flight intention. There is also an observation of a Rusty-breasted Nunlet sitting quietly in front of observers, and repeatedly flicking one or both wings high above the back in the manner of some small flycatchers (Tyrannidae).

The flight of puffbirds is very fast and direct, on rapidly beating wings. Most flights are made either as foraging attacks or in order to change from one perch to another, but they are equally brief and darting. The more slender *Monasa* nunbirds, however, fly with a few quick wingbeats followed by a short sail, sometimes circling gracefully and unhurriedly; when returning from a sally, they glide upwards to a perch. In the air, the wings of the White-fronted Nunbird appear rather short and rounded, and the tail looks long, broad-feathered and full; in short flights through the canopy, this species is often suggestive of a jay (Corvidae). Nunbirds sometimes engage playfully in short sallying flights, ostensibly with no intention of catching prey. The most graceful bucconid in the air, however, is undoubtedly the Swallow-winged Puffbird, which is the only member of the family that has evolved to catch most, if not all, of its prey in flight. It can shape its wings for rapid upward attack, and then set them forward with open slotting in the manner of a vulture or hawk (Accipitridae) in order to stall and circle slowly, with elegant aerobatic manoeuvres; from this, it can then change again to hovering, or to a swooping, slightly undulating flight to another piece of airspace, before drifting back down to a high perch.

Perhaps not surprisingly for a family that is relatively poorly known, the roosting habits and comfort behaviour of puffbirds appear hardly ever to have been recorded. The more sociable members of the family sleep side by side on branches. When resting, these birds sink on to the branch and bring the nictitating membranes over the eyes. The Bucconidae scratch the head by the direct method, bringing the foot forward and up under the wing, but observations of preening have rarely been recorded. White-fronted Nunbirds take dust baths, and have been seen

flopped down in the grass in a sunny spot with the wings spread out, obviously sunning.

Little is known of the parasites of the Bucconidae, but several species have been found to harbour blood parasites of the genus *Haemoproteus*. A parasitic nematode of the genus *Procyrnea* (Habronematidae) has been reported from the Swallow-winged Puffbird, and a mallophagan louse *Picicola* (Philopteridae) has been found on the Crescent-chested Puffbird, the latter representing the first known non-passerine host of this mallophagan subgenus. Several Amazonian species of bucconid showed evidence of arboviruses; indeed, the presence of these insect-borne viruses was detected in 18% of all individuals sampled.

Although puffbirds sometimes remain immobile when in danger, they generally react in a more positive manner. When a puffbird becomes anxious, as when hearing the alarm call of another bird, it sleeks its plumage, presumably in readiness for rapid take-off, while at the same time angling itself forwards until the body, head and tail are more or less all in line. Often, the bird stares ahead at the source of danger, adopting an intense binocular expression that, to one observer, gave the impression of fierceness or myopia. One White-eared Puffbird reacted to an observer by pressing itself against its low branch, facing the intruder head-on, and gazing almost cross-eyed with intensity, appearing strangely rodent-like.

If they do take flight, alarmed puffbirds quickly fly into the shelter of palm clumps or other tangled vegetation in the understorey, and it seems, from some accounts, that many species habitually make use of screening greenery at the first sign of disturbance. When caught, they may feign death. Fieldworkers who net puffbirds find that the trapped birds are often docile, fluffing themselves up and opening the bill, while others will bite hard. One female puffbird, when dug out of a nest, closed her eyes as if dead. An interesting reaction to a passing vulture was given by another individual, which was reported to have swung beneath the perch until the perceived danger had passed.

The rather solitary puffbirds of deep-shade habitats, if they wander into more open situations than those in which they are normally found, appear to provoke mobbing behaviour from some passerines. This is possibly because of their superficial resemblance to owls of the genus *Glaucidium*. Black-breasted Puffbirds have been seen being violently attacked by Yellow-green Vireos

(*Vireo flavoviridis*), and there are observations of both Crescent-chested and White-whiskered Puffbirds being mobbed by a host of small birds. On one occasion, a White-whiskered Puffbird was seen being pursued, every time it flew, by Grey-capped Flycatchers (*Myiozetetes granadensis*) and several species of hummingbird (Trochilidae).

White-whiskered Puffbirds, while usually solitary, can also occur in small groups of up to a dozen individuals, and White-eared Puffbirds may at times be found in small groups of two to five birds. During most of the year, Pied Puffbirds move about in small parties of six or so. Even the seemingly solitary Lanceolated Monklet is sometimes met with in groups of up to three. Although these species are often encountered singly, family members may stay together for some time after the young fledge. Among the Bucconidae, there appears to be a correlation between the level of overall activity and the degree of sociability. As an example, Pied and Two-banded Puffbirds have been judged to be more active than some of their more solitary relatives. Within any species, however, activity levels may also vary depending on the presence or absence of offspring.

In the case of nunbirds in the genus *Monasa*, the persistence of young on the territory has been incorporated into the entire social system. These birds are group-territorial, with at least some of the offspring remaining on site in order to help to advertise and defend the territory in future breeding efforts. "Flocks" appear to be stable groups that are confined to particular home ranges or territories, each part of which they visit at regular intervals. Members of Black-fronted Nunbird groups have been seen transferring food to one another, although all birds in the group appeared to be adult. While holding prey such as a large insect 3-4 cm long, the "donor" gives a characteristic whistle, whereupon the recipient approaches and collects the item directly from the other's bill. This behaviour has also been recorded for White-fronted Nunbirds, where it was interpreted either as the feeding of older young or as indicative of adults coming into breeding condition.

Not surprisingly for such sedentary species, puffbirds appear, from the scant evidence available, to be territorial throughout the year. The territories of White-whiskered Puffbirds are roughly circular, centred on some major stream drainage and commonly bordered by ridges, and almost 300 m in diameter. During disputes, individuals of this species call while spreading the tail slightly and wagging it back and forth, either tilting it upwards or holding it tent-like in an inverse "V". They face each other at close range, with the body sleeked, carpal out and

wingtips slightly lowered. They often sleek the head plumage and raise the white tufts above and to each side of the base of the bill, as well as, at times, raising normally concealed whitish spots between the tufts, so that the beak is outlined in white. They then stand high on their legs, stretch the neck, and wigwag the body back and forth, sometimes indulging also in bill-grappling. Females fluff out the streaked chest feathers conspicuously. During episodes of countersinging, the bill is pointed upwards. In the case of the Spotted Puffbird, the disputants fluff out their speckled belly feathers and the orange feathers of the throat and chest, exposing the black neckstripes.

Black-breasted Puffbirds are as aggressive intraspecifically as they are indifferent interspecifically. Territorial pairs react to each other in turn by singing loudly at intervals, mainly in the daytime rather than at dawn or dusk. When giving the song, the bird stands "as upright but level-headed as a drill sergeant", sleeking its head and body feathers, showing the white nape and black chest, and then flies at a passing conspecific while uttering a series of loud grunts.

White-fronted Nunbirds advertise their territories with many vocalizations and spectacular group singing, the latter involving co-ordinated barking or "gobbling" for up to 15 minutes at a time (see Voice). The frequency of these performances appears to increase between October and December, when a resurgence in song activity occurs in many individuals. Nunbirds stream to the location of the bird initiating the calls, and the performances trigger similar ones by nunbirds in neighbouring territories. Presumably, the displays serve both to promote internal flock co-ordination and to impress and deter neighbouring flocks.

## Voice

Puffbirds are among the most silent of the birds in Neotropical forests, and only the nunbirds and *Nystalus* species could be said to produce loud calls and attractive songs. As with many forest kingfishers in Asia, a number of puffbirds tend to sing only very early and late in the day, for very short periods before dawn and after sunset. Even the more vocal species, such as the White-eared Puffbird, still give their best performances during these half-dark minutes of the day.

Even when these birds are calling, they can often appear as if they are not. The White-necked Puffbird does not open its bill, nor does its throat move, while it is vocalizing. The White-whiskered Puffbird can be equally undemonstrative. Skutch recounts

Bucconids are amongst the quietest birds in Neotropical forests, often singing only for brief periods at sunrise and sunset. Sometimes they vocalize without opening the bill, making it difficult to locate the sound, even from a short distance. Not so with this Spot-bellied Puffbird, which delivers its song with open bill. It has recently been suggested that the two races of this species may constitute two separate species, and some possible slight differences in voice have been reported, but all in all it seems that their vocalizations are rather similar. More study is required, especially in the area of probable contact in the Brazilian Pantanal.

[*Nystalus maculatus*,  
Pantanal of Brazil.

Perched on a horizontal branch as it scrutinizes its surroundings for suitable prey, this Striolated Puffbird has adopted the standard posture of a foraging bucconid. Hunting perches usually offer unobstructed views in all directions. Attacks are initiated in a swift dash from the perch, to strike at prey that may be in the air, on the ground, among foliage, or on a tree limb or trunk, the latter assaults being termed "sally-strikes". An actively hunting bird may sit so still as to appear half-asleep, then bursting into flight with rapid wingbeats in pursuit of its quarry. Successful birds often return to the same perch to consume their catch and then resume the wait for further prey.

that, at a nest of this species, he heard a rapid undulatory twittering lasting for minutes on end, which he took to be the insistent begging of a recently fledged passerine. The male puffbird was all the while in plain view, but never showed any movement of the bill. It was only on a second occasion, when the calling was heard and again the male was in view, that Skutch saw "the slightest vibration of his mandibles".

The songs of puffbirds commonly consist of series of identical or near-identical high-pitched whistles, sometimes ending in trills or in a different series of notes, and sometimes rising or falling in pitch. The six *Nonnula* nunlets all have very similar songs which seem to differ in the number of notes and their length and emphasis. The Barred Puffbird makes a very human-like wolf-whistle, whereas the White-faced Nunbird utters hoots reminiscent of *Glaucidium* owls. It is the *Monasa* nunbirds that have the most developed vocabularies, doubtless a result of their group-territorial behaviour. They have loud, relatively musical songs which are often given in choruses, becoming more complex and babbling and continuing for many minutes. A few puffbirds in other genera, however, commonly deliver their songs as a duet, if not a chorus, notable among these being the White-eared Puffbird. This species is popularly known in Brazil as the *fevereiro*, meaning February, because of the sound that results from the pair-members eliding the basic "fufu" unit of their song. It is from this sound that the species' scientific name of *chacuru* is derived. To some people the noise recalls crazed laughter, thus providing another analogy with the kingfishers, this time the kookaburras (*Dacelo*), also dry-country birds.

Careful study reveals that puffbirds, despite their long silences, do have moderately extended vocabularies. The White-whiskered Puffbird utters several sounds, all weak and thin, and usually accompanied by a movement of the tail. Its commonest note is a gentle, high "tsinnnn", but it also has a protracted, slightly descending "ssssssss", a plaintive descending "tsee", and a strong and repeated, hummingbird-like descending "tsirrrr" given with the bill wide open. One of these calls may be referable to the interminable, weak, complaining notes that have been reported to be given by parents when near nestlings. On the other hand, the sound heard by Skutch on the occasion, mentioned above, when he could not tell that the bird was calling, was an altogether different one, "a rapid, undulatory twittering, some-

times almost a sizzling", which Skutch interpreted as an expression of anxiety. At an ant swarm, when behaving aggressively towards a conspecific that is not a mate, this species will displace its rival while uttering a rattling grunt, "chwhiwh". Individual White-whiskered Puffbirds, when confronting each other, also grunt when simply alighting on a new perch. In one protracted dispute between two pairs, one male attacked the other with a rough whistled "seeieeee" rather than the usual grunt, while the other female attacked her counterpart with grunts.

The most elaborate vocabulary appears to belong to the White-fronted Nunbird, which has a considerable variety of clamorous, querulous calls. In a 1964 article, P. Slud identified ten different vocalizations. These included prolonged excited gabbles that can sound in parts like a police whistle; low whistles; rather smooth, sometimes rippled notes recalling the sound of a small pulley; a weak "ank-ank"; a short "how how"; a single "oo"; a trogon-like "chahring"; a low, nasal, quick "chfkara"; a full-voiced "kü-kü-kü-kü-kü-kü"; and musical nasal whining notes at different speeds. Later, E. O. Willis noted that this nunbird sometimes gives "chert" chirps before a foraging sally, and that it displaces competitors at perches by uttering rattling chirps and gurgles; one gave a "cha-a-a-a-a" as it displaced a conspecific. The prolonged gabbles are the song. Members of this group-territorial species converge from different directions to perch a few inches apart along a horizontal limb, where, with the neck stretched and the bill pointing upwards, the spread tail lifting and lowering, they call very loudly with the mouth wide open, excitedly and in unison, for a minute or more.

The calls of the various *Monasa* species can be so loud as to startle the observer. Some of their calls may even startle other bird species, because these nunbirds are forest "vigilantes", having well-developed alarm or anti-predator calls. Those of the Black-fronted Nunbird, for example, consist of short "too-loo-loo" gurgles, in greater alarm punctuated with a loud whistled "peer peer peer peer", which causes birds of all species to freeze. Almost exactly the same call is given by White-fronted and Black Nunbirds, in those cases sending other birds to cover. The Black-breasted Puffbird, even though it is not sociable like the *Monasa* species, also has highly developed alarm behaviour. At the appearance of a predator such as a hawk, it stands erect, puffs out its nape and body feathers, and gives a sharp, protracted, but highly ventriloquial

Bucconids feed mainly on insects, although next to nothing is known about the diet of a dozen species in the family. Various Lepidoptera, Orthoptera, Hymenoptera and Homoptera are commonly reported as prey items. Several species attend army-ant swarms or join mixed-species feeding flocks, taking advantage of food items stirred up from the ground or flushed from the vegetation as the ants or foraging flock move below and through the understorey, respectively. Spot-bellied Puffbirds often forage from low perches, attacking prey in the foliage or on the ground. They feed primarily on insects, but an individual in Brazil was observed capturing a colubrid snake.

[*Nystalus maculatus*,

"wheeer" once every two to four seconds. This has a dramatic effect even on birds at ground level, which make hysterical dashes for cover and indulge in extended tail-jerking sessions.

While in the nest, young White-whiskered Puffbirds are usually silent. As with most nestling birds, however, the real or apparent sound of wingbeats near the mouth of the burrow can cause older broods to commence a high-pitched, rapid trilling. Once out of the nest, they can be as insistent as any fledglings, giving a weak scratchy note and sibilant chattering calls. Young White-fronted Nunbirds constantly utter a piping "chiv-ree", Black Nunbirds a continual "pseuh-wooh", and Black-breasted Puffbirds a persistent "wheet". The alarm calls of the Plain-brown Woodcreeper (*Dendrocincla fuliginosa*) cause young bucconids to become silent, as do those of their parents. The young nunbird, each time it gives its begging call, flashes its pale gape at the parent.

## Food and Feeding

All members of the Bucconidae for which the food and feeding habits have been reported are chiefly insectivorous. One species, the Swallow-winged Puffbird, is probably exclusively so, since it appears to forage only in the air.

Apart from the Swallow-winged Puffbird, which makes fast upward dashes into airspace, and then more slowly undulates and circles back down to its perch, the hunting technique is standard throughout the family. The birds make flycatcher-type sallies from an open perch that offers good all-round vision, *Cecropia* often being favoured, and they target prey that is amid green foliage, on trunks and branches, on the ground or in the air. Attacks aimed at animals on substrates are commonly called "sally-strikes", which is very apt for the way in which it conveys something of the speed and directness of a puffbird's foraging flight pattern. After many minutes spent perched on some shaded or open branch, unathletic and immobile except for the occasional deliberate head movement, often giving the impression of being only half-awake and largely indifferent, the bird suddenly launches into a hurtling direct dash with rapidly beating wings, its body looking surprisingly slender. Having captured its quarry, often with a loud snap of the bill, it carries the prey, still alive, back to a perch, frequently the original one, where the item is

beaten and swallowed. The whole sequence is very similar to that of a foraging kingfisher. Indeed, if one seeks an explanation of why the latter family failed so signally to radiate in Neotropical forests, competitive exclusion by the Bucconidae must be high on the list of plausible reasons.

Some evidence of the speed of puffbird foraging flights has emerged during the detailed studies of Amazonian birds conducted by Willis, who has several times seen puffbirds outfly dendrocolaptines in pursuit of flushed prey at ant swarms. In one instance, a White-fronted Nunbird rapidly overtook a Buff-throated Woodcreeper (*Xiphorhynchus guttatus*) in a long chase after a flying insect, and in another a Black Nunbird passed a Plain-brown Woodcreeper pursuing a cicada (Cicadidae).

Although the nunbirds readily come to the ground for prey, aerial sallies to take flying prey appear to be commoner among, and more appropriate to, these more streamlined species, which have a longer, broader tail and a narrower bill. Inevitably, these sallies are likely at times to be rather longer-distance attacks. The sally-strikes that are the chief tactic of the chunkier, smaller-tailed species are relatively short-distance affairs, but they still involve ranges of 5-50 m and can sometimes be spectacular as the bird hits the foliage in pursuit of its prey; occasionally, however, the tactic is changed at the last moment from strike to hover-glean, depending on the substrate and the intended prey.

The large eyes, and their slightly binocular arrangement on the large head, evidently provide the bucconids with extremely high visual resolution, even in very poor light conditions. The very slightest movement made by a cryptic animal can be picked up by the bird: one observer saw a solitary ant cause an orthopteran to move a leg, which prompted a nunbird to attack. Several observers have noted how puffbirds can be active into the dusk, at a time when other diurnal birds have started roosting. The powerful twilight vision of the Bucconidae doubtless enables them to capture insects, such as moths and cicadas, which become active only as the light fades. Incidentally, there is a record of a Spotted Puffbird catching hawkmoths (Sphingidae) at a flowering plant, the only reported instance of a bucconid waiting at a fixed point to which prey will come.

Some puffbirds take advantage of "beaters" in the forest. They accompany monkey troops and flocks of caciques (*Cacicus*), they follow the daily foraging flocks of mixed bird species, the very numbers within which cause disturbances to other smaller ani-

This White-eared Puffbird has managed to catch a large orthopteran. This species routinely captures prey from the ground, taking lizards, larger insects, and wingless arthropods such as millipedes, centipedes and scorpions, and it even obtains such unlikely prey items as velvet worms (Peripatus) and crabs. Although the heart of its distribution is in central Brazil, the White-eared Puffbird ranges into northern Argentina a few degrees south of the tropic of Capricorn. It has one of the southernmost distributions of any bucconid and is reported to lower its body temperature and enter torpor during cool weather.

VIREO]

White-faced Nunbirds do much of their foraging in the canopy, gleaning wasps, crickets, grasshoppers, locusts and butterfly larvae from the vegetation. Recent observations of more than 200 food deliveries at the first nest known to science revealed that 78% of the prey were insects. The remainder of the food items included lizards, a frog, nestling birds, and a mouse, the latter two prey categories never having been reported previously. In another study, a stomach contained plant matter identified as either buds or fruit. Only six species of puffbirds are known to consume plant parts, and the significance of this food type in their diet is unknown.

mals, and they similarly follow the army-ant swarms which do the same thing, but to animals larger than themselves, on the forest floor and in certain trees. Nunbirds sometimes move about under canopy-travelling groups of primates and flocks of oropendolas (*Psarocolius*, *Gymnostinops*) and caciques, apparently in order to seize on prey which those birds flush downwards as they move. White-fronted Nunbirds commonly travel with large mixed-species bird flocks containing caciques, woodcreepers, woodpeckers, pihas (*Lipaugus*), mourners (*Rhytipterna*, *Laniocera*) and various trogons (Trogonidae). Rufous-necked Puffbirds have been seen closely following an understorey flock of antbirds (Thamnophilidae) and tanagers (Thraupidae), and at least five other puffbirds have been noted as doing likewise. Certainly, many species of buconid are at least occasional attenders at ant swarms, although the naturally higher-foraging species such as the White-necked and Pied Puffbirds rarely do so, as is the case with others, such as the Collared and Spotted Puffbirds, that are confined to habitats in which ant swarms are rare.

When the White-whiskered Puffbird follows swarms, it commonly perches 1-2 m up on thin branches that are about 2 cm wide, thus not so thin that they wave under the bird's weight and give away its presence. From such a perch, it makes most of its captures in sallies to the ground. The basic behaviour is probably very similar to that adopted away from ant swarms. Typically, a foraging individual sits on a branch, with the plumage fluffed out and the tail down and closed, for long periods; just before making a sally, it sleeks its feathers and leans forwards, tail in line with the body, staring in the direction of the prey. After a strike it returns to the perch, still sleeked, then fluffs itself out and assumes a vertical posture, either to wait again or, if the strike was successful, to eat its catch. If the puffbird sees a prey disappear under leaves, it may settle on the ground and swipe aside the leaves with its bill in order to make its capture, and in doing so it stands remarkably high on its legs, recalling a thrush of the genus *Turdus*.

The food of puffbirds consists of large arthropods and small reptiles and amphibians, with berries occasionally being taken by some species. Most of the diet is made up of insects, apparently chiefly Lepidoptera in the form of caterpillars and moths, and Orthoptera in the form of grasshoppers, locusts, bush-cricket

and crickets. Nunbirds seem best adapted to preying on Orthoptera of up to about 6 g in mass. In addition, a wide variety of other insects is eaten, including mantises (Mantidae), bugs (Hemiptera), roaches (Blattodea), cicadas, stick-insects (Phasmida), butterflies, dragonflies (Odonata) and so on. It seems that beetles (Coleoptera) are taken most often when certain species of them become numerous: there are records of puffbird stomachs being crammed with particular kinds of beetle when sudden abundances of the latter had occurred, whereas observations at ant swarms suggest that Coleoptera are rarely taken. It may be that beetles in the size-class that puffbirds target are too well armoured to be worth catching, or are too strictly nocturnal, and that smaller beetles become economical to catch only when there are enough of them in a given area to justify a diversion from the search for larger prey.

Apart from insects, the arthropod prey of puffbirds includes spiders, scorpions (Scorpiones), centipedes (Chilopoda), millipedes (Diplopoda), crabs and velvet worms (*Peripatus*). Among vertebrate prey consumed, lizards are most commonly reported, but both snakes and frogs are clearly regular in the diet of many buconids. The massive bill of a puffbird is deeper than it is wide, generally with a powerful gripping hook tip, and the large head allows for strong jaw muscles and a wide gape. Most species have profuse rictal bristles, which presumably protect soft parts of the head from heavily armed or otherwise noxious insects. When a prey item is captured, it is held head outwards and routinely beaten on a branch until it is not only dead, but also reasonably free of toxins and sufficiently broken up to be more easily ingested. Then, it is turned in the bill and swallowed head first. A Black Nunbird was once seen catching a huge centipede which it proceeded to crush at both ends, as if it could not be sure which end was the head. When dealing with a scorpion, a Black-breasted Puffbird chews the animal's thorax until it stops moving, and then swallows the food whole. The handling time for a prey item, such as a large grasshopper caught by a nunbird, may be as long as twelve minutes.

Swallow-winged Puffbirds, since they feed on the wing, take somewhat different prey. Bees, wasps, alate termites and flying ants appear to be the staple diet of this species. These prey items are not so large as the ones taken by other puffbirds, and many seem to be swallowed in flight. Surprisingly, this conspicuous,

relatively well-studied puffbird has not been reported to beat and process prey items on a branch after having captured them.

The importance of plant food in the diet of puffbirds is unknown. The berries of mistletoe (Loranthaceae) have been found in the stomach of a Spotted Puffbird, while the Lanceolated Monklet is known to take berries, and a White-faced Nunbird stomach was found to contain either fruit or buds. In addition, the White-eared Puffbird is reported to take vegetable matter. Most notably, one Russet-throated Puffbird had apparently been feeding exclusively on seeds, and birds of this species, when sampled emetically, were found to have consumed the fleshy fruits of one particular plant on a regular basis. It may be significant that two of the species mentioned here, the Lanceolated Monklet and the White-faced Nunbird, are in their own monotypic genera, and represent distinctive buconid lineages, and that two others, the Spotted and Russet-throated Puffbirds, live in strongly seasonal habitats.

The food brought to young in the nest appears to differ little, if at all, from that taken by adults. At a nest of White-whiskered Puffbirds, mantids, moths, caterpillars and spiders, along with small *Anolis* lizards up to 12 cm long, were brought to nestlings only two days old.

After they leave the nest, young puffbirds have the habit of flying to snatch or "hover-glean" food from the bill of a parent. This is doubtless invaluable practice for independent foraging, which may not commence until a month after fledging (see Breeding).

## Breeding

Puffbirds are probably monogamous. Most species breed, and perhaps live together throughout the year, as territorial pairs, but a few may have slightly more complex systems. Certainly, the nunbirds breed in co-operative groups, which appear to involve the offspring from previous years helping to defend the territory and feed the young. Swallow-winged Puffbirds tend to nest in loose, non-territorial groups, and non-parent visitors to nests have been witnessed.

Although the nests of many buconids have not been documented, the information that does exist indicates that puffbirds nest in cavities. From the evidence available, it appears that the genera *Notharchus*, *Bucco* and *Hypnelus* are typical, but seem-

ingly not obligate, users of arboreal termitaria, while *Nystalus*, *Monasa* and *Chelidoptera* always nest in earth tunnels; the species of *Malacoptila* and *Nonnula* are reported to use both types of site. There are also poorly documented reports of White-necked and White-whiskered Puffbirds and Rusty-breasted Nunlets nesting in holes in trees, and of White-whiskered Puffbird nests in holes in bamboo. The Russet-throated Puffbird has the apparently unique habit among the Bucconidae of taking over the mud nests of the Pale-legged Hornero (*Furnarius leucopus*), although it does this only occasionally. Sometimes, puffbirds may nest in a cavity excavated in previous years.

The timing of breeding appears, at least in the case of ground-nesting species, to coincide with the start of dry seasons. This, of course, minimizes the risk of flooding in the burrow.

A pair of Black-breasted Puffbirds, when excavating a hole in a very large black nest of the termite *Nasutitermes pilifrons*, took turns of between one minute and a quarter of an hour at the task, one bird tapping at and crunching the hard woody material while the off-duty partner stood sentinel nearby. The pair worked persistently, both morning and afternoon, for many hours a day until, after some two weeks of effort, the structure was seemingly complete. It consisted of a narrow, horizontal tunnel, about 18 cm in length and 3 cm in diameter, leading to a spacious, neatly rounded, unlined chamber in the heart of the termitary. The eggs, however, were laid only some ten days later. During the period of egg-laying, one partner stood guard in front of the nest, as occurred during the ten-day interval between the completion of the nest and the deposition of the first egg.

Similar behaviour and/or results have been recorded for other species, including the Brown-banded Puffbird and the Two-banded Puffbird. One pair of the latter dug an entrance tunnel about 8 cm across, leading backwards and upwards for nearly the entire diameter of the termite dwelling to a slightly enlarged spherical chamber about 15 cm across. There was no lining in the chamber, the egg being deposited on the debris at the bottom of the nest-cavity.

Skutch was never sure whether ground-nesting puffbirds excavated their own burrows or used pre-existing ones, and there is a report that the birds use holes dug by armadillos and pacas (*Cuniculus*). Nevertheless, two neglected old records, from 1909 and 1922, indicate that these birds do dig their own burrows, and some more recent observations confirm this fact. In 1922, J. P.

With a deep and powerfully hooked bill and strong jaw muscles, many puffbirds are capable of capturing vertebrate prey, as demonstrated by this Collared Puffbird, which has seized a small frog. This species often hunts from shaded perches in the understorey, regularly taking snakes, lizards and large insects from the forest floor. Larger prey, and those possessing weapons such as pincers or stingers, are thoroughly beaten against a branch or other hard surface before being swallowed head first. This behaviour serves not only to kill the prey item, but also to help break it up into manageable pieces and perhaps even to remove toxins.

[*Bucco capensis*,

French Guiana.

Nunbirds in the genus *Monasa* sometimes forage on the ground and from the foliage, as shown by the orthopteran and the caterpillar captured by these Black-fronted Nunbirds. This species also associates with army ants, and sometimes follows troops of monkeys to obtain prey disturbed by the primates. However, nunbirds take more prey in flight than do most other puffbirds. This is naturally related to the fact that they are more graceful in flight, sometimes gliding and circling upwards when returning to a hunting perch. In addition, they are fully capable of rapid flight, as proven by their ability to overtake woodcreepers (*Dendrocolaptidae*) during pursuit of prey at army-ant swarms. *Monasa* nunbirds are rather large bucconids that depart radically in appearance, as well as in behaviour, from all other puffbirds. They have dark, mostly unmarked plumage; ■ short, brightly coloured bill; and ■ relatively long, broad tail. The body is streamlined, and they tend to perch in a more upright posture than do typical puffbirds.

da Fonseca gave some idea of why nest construction by bucconids has so rarely been witnessed. His pair of White-eared Puffbirds was extraordinarily vigilant, the off-duty bird keeping the most careful watch and calling the digging partner out of the hole at the slightest hint of danger, both then flying away in total silence; as soon as the danger had passed, the pair returned to resume its activities, which, if uninterrupted, would last all day. In another early observation, this time involving Spot-bellied Puffbirds of the subspecies *striatipectus*, sometimes called the "Streak-bellied Puffbird", it was noted that the sharp hooked tip of the male's bill appeared to be abraded, and that this might be due to its undertaking most of the work of excavation. Digging with the bill has been confirmed for both sexes of the Crescent-chested Puffbird and both those of the White-whiskered Puffbird, although in the latter case the male takes the major role. On the other hand, Black-fronted Nunbirds were recently watched as they used their feet to dig a nest.

Ground nests are dug at an angle into flat or gently inclining ground. The smaller species of the family may construct tunnels only some 0.5 m long, whereas the larger nunbirds build burrows up to 1.5 m in length. The tunnels are straight, and terminate in a chamber which is lined with bits of leaf. At the entrance, there is a low collar or frame of leaf parts, twigs and overlying leaves which is presumably created by the birds themselves, although the behaviour has never apparently been witnessed. This frame blends with the ground, and helps to conceal the small opening in the forest floor. The Black Nunbird and its congeners make fairly large piles of leaves under which a rounded tunnel runs along the ground from one edge to the entrance of the nest-tunnel itself.

Returning to Skutch's uncertainty, one reason for it was that he never saw tailings of earth that would suggest that the birds had done their own digging, and other observers have noted the lack of such evidence even at nests of the Swallow-winged Puffbird. Such tailings do, however, appear, but it is thought that they very quickly get washed away by rain or covered by leaves; in the case of the Swallow-winged Puffbird, the earth appears to be trodden in at the lip of the entrance, forming a slight smooth dome. In any case, the birds continue to be highly vigilant at whichever site they choose. The Black-breasted Puffbirds watched by Skutch at their termitarium nest, as mentioned above, waited ten days after completing the nest before laying, one or the other member of the pair guarding the nest for much of the time. It is presumably during this period that mating occurs.

Copulation by puffbirds has rarely been witnessed. In one instance involving a pair of Black-breasted Puffbirds foraging together, the male was 0.6 m from the female when he fluffed his plumage, suddenly gave a grunting "chwah-it" three times and flew above her. She held her wings out and her tail closed and up, while he fluttered his outspread wings; the male then flew 0.6 m away again, wiped his bill rapidly, and looked about with the body rather puffed out. His mate slowly recovered to an upright posture, wiped her beak rapidly, and flew off. The male remained, fluffed himself up, and gave a loud song after a third Black-breasted Puffbird sang in the distance.

The eggs of puffbirds are white, dull to glossy, and relatively small, like those of a woodpecker. They are laid at intervals of about two days. Most puffbirds lay clutches of two to three eggs. A replacement clutch may be laid if the first is lost, but it appears that no species of bucconid rears more than one brood per year. The sexes share incubation duties. In the case of the ground-nesting White-whiskered Puffbird, the schedule is very simple. The male covers the eggs from just after midday and until dawn, and roughly an hour after he leaves the female arrives for a stint lasting five to eight hours; she, in turn, leaves the eggs uncovered for an hour or more, until the male returns for his session. The termitary-nesting Black-breasted Puffbird has a more complex incubation schedule, the mates replacing each other after much shorter periods of attendance. Since the nest-chamber of this species is less accessible to predators than is a burrow in the ground, the parents can afford to be rather less discreet in their habits.

Swallow-winged Puffbirds incubate for 15 days in total, but their different-sized young suggest that they start with the first

The Swallow-winged Puffbird has a small head, a short bill, long wings, and a short tail, and it is highly adapted for aerial activity. Perched on a bare twig atop an emergent tree, its silhouette is very martin-like. It is thought to be exclusively insectivorous, particularly favouring bees, wasps, flying ants and winged termites, and catching its prey in rapid aerial sallies from exposed perches. In general its prey items tend to be smaller than those caught by other puffbirds, and its prey is often swallowed in flight; there are no reports of this species beating its prey after capture. Its nest is a tunnel in flat ground or an earth bank, and its hatchlings are unique among puffbirds in having the skin black, rather than pink. Chicks of this and other burrow-nesting species of puffbirds are unusually mobile, being able to crawl to the entrance of the tunnel to receive food from their parents on the very day of hatching!

[*Chelidoptera tenebrosa tenebrosa*.

egg, while in other puffbirds incubation may begin with the last. The nestlings hatch blind, naked and pink, although those of the Swallow-winged are black. Despite this appearance of an altricial condition, however, they can immediately move about actively on their bed of dead leaves. This remarkable mobility, so far observed only among ground-nesting puffbirds, enables them, from day one, to crawl up the tunnel, which is often over a metre long, to the entrance to receive food from the parent, which, presumably for security reasons, never places its body farther than half-way into the tunnel. Curiously, it is the male that broods the young in the burrow, leaving only for brief periods during the first few days, whereas the female carries out all the feeding of the brood in their first week or so of life. Even after brooding has completely ceased, the female continues to take by far the greater share of provisioning. In one case, the ratio of feeds provided by female and male during a fortnight of observation was 25 to 3; in another, it was 32 to 3. In nunbirds, as many as five adults may attend a nest, but that these groups are composed of the two parents and their recent offspring can only be surmised.

The rate of food delivery to the nest varies with the size of prey items. The adults, especially the female, appear extremely sensitive to the condition of the young, bringing them food

This White-faced Nunbird stands alongside the first nest described for this species, as recently as in the year 2000.

Observations at this site provided much new information on the breeding biology of the species. The nest was a tunnel dug into a bank amid humid forest at an elevation of 1900 m; it took at least 25 days, and possibly as long as 46 days, to construct. Two eggs were laid in late May, and the young hatched in mid-June, leaving the nest in the latter part of July; the precise figures that emerged were an incubation period of 15-18 days and a nestling period of 37-38 days. Both sexes shared in nest-building, incubation, and brood-rearing duties.

[*Hapaloptila castanea*, Tandayapa Valley, Pichincha, Ecuador. Photo: Nicholas Athanas]

promptly when they are eager for it, but staying away for long periods if the last feed was particularly substantial. A lizard seems to satisfy a nestling's hunger for several hours.

When the nestlings are six days old, their pin-feathers are sprouting, especially on the head and wings. Two or three days later, they bristle with long, unopened feather sheaths. At ten days, the feathers begin to break through the sheath, expanding at the tips, and the eyes open; the bill is whitish. During the next two or three days the feathers develop rapidly, and at the age of 14 days the chicks are well clothed, with plumage rather similar to that of the parents. Fledging takes place at around 20 days, although the period for nunbirds is 30 days.

Predation is a major risk for puffbird eggs and nestlings, and disappearances of either have often been attributed to snakes. The safety of the earth burrow depends on several factors: its concealment; the parents' caution when visiting; the minimization of the number of visits; the silence and invisibility of the nestlings; and the absence of odour in the tunnel. Moreover, there is a remarkable phenomenon that takes place within the nest: once brooding stops at around the ninth day, and after their last feed of the day, the young retreat to the nest-chamber and throw up a screen of leaves that conceals them at night. This probably serves to deceive predators which hunt by touch or heat, such as snakes and large spiders, rather than those which hunt by sight or scent. The young also seem to have qualities which render them uninteresting to army ants. This is indicated by the fact that the ants have been seen to swarm around burrows, yet have left the occupants, and even the maggots in the nest's detritus, unharmed.

Newly fledged puffbirds sally to take proffered prey from the bill of a parent. They are usually not capable of foraging independently until at least a month after fledging. On one occasion, involving White-fronted Nunbirds, an older immature which attempted to hover-snatch food from an adult was rebuffed by the latter, which gave a bill-down display and uttered a loud screech. Nevertheless, among many buconids, including apparently all nunbirds, there is a long period of association, and sometimes food-exchanging, between parents and offspring. Sightings of amicable trios towards the start of the breeding season suggest that the young often stay on the natal territory for the best part of a year.

## Movements

The Bucconidae are highly sedentary birds, and there have been no studies that show them to undertake any real migrations. Notably, one Rufous-necked Puffbird which was ringed in June at Belém, in Brazil, was recaptured at the same site five times, in the months of July, November, March and April. Even circumstantial clues to migratory habits, such as birds entering houses at night or being killed by cats or cars in unusual areas, have never been reported for any members of this family. Only four of the southernmost species have been thought, albeit on slender evidence, to undertake migrations, and even then only in part of their ranges.

Conversely, the Two-banded Puffbird is a species which dwells in seasonal habitat, yet it has not been reported as a seasonal visitor to such habitat. On the other hand, it seems to show a curious unevenness of temporal distribution. An example of this is the fact that one museum collector spent the three years from 1944 to 1946 in a study area without once finding this species, and then, during June 1947 to May 1949, found it to be fairly common throughout that same area.

Since the Bucconidae have not reached Panama's offshore islands, they must be considered poor dispersers across open terrain and water. White-whiskered Puffbirds are territorial, and one ringed individual remained on its territory for nine years. This seems likely to be the norm for the majority of species, especially those inhabiting wetter forests, where the seasons are ill-defined. The group behaviour of nunbirds is another sign of a deep-rooted sedentariness in the family, which clearly evolved in the equatorial lowlands where food resources are largely stable throughout the year.

## Relationship with Man

The most obvious and, in fact, almost the only relationship that puffbirds have with man is as the target of his abuse, and the word "stupid" has frequently been applied to members of this family. This is due mostly to the fact that perch-and-pounce feeders, in which category the puffbirds excel, tend to use their stillness between pounces as a camouflage, both to make them less

Nesting exclusively in holes that they excavate in level or gently sloping ground, Black Nunbirds time their breeding to coincide with the start of the dry season, presumably so as to minimize the chance of nest tunnels becoming flooded. Tunnels are dug at a shallow angle and may extend up to 1.5 m in length, ending in a chamber lined with bits of vegetation. Nunbirds apparently pile up leaves to form a frame around the nest entrance, which no doubt helps to conceal the nest from the view of predators, among other possible functions.

Like woodpeckers (Picidae), puffbirds lay relatively small white eggs. A replacement clutch may be produced if the first clutch is lost, but no species is known to attempt a second brood in the same nesting season. Exhibiting the white lesser coverts that are the hallmark of the species, an adult carries a small lizard to the nest entrance and presumably is about to provision the brood within. Apart from lizards, Black Nunbirds take a wide variety of insects and other arthropods, most prey being obtained from a solid substrate rather than in the air. They also follow army-ant swarms and have been observed below flocks of Red-rumped Caciques (Cacicus haemorrhous), presumably looking for prey that flee as the icterids move through the canopy.

[*Monasa atra*,  
French Guiana.  
Photos: Olivier Tostain]

visible to potential prey and to conceal them from potential predators. In the event of an onslaught, therefore, their abiding reaction is simply to freeze. Collectors, however, regarded this highly adaptive behaviour as the height of stupidity. In 1873, E. L. Layard reported on a successful outing as follows:

"I subsequently obtained two more, and was struck with their extreme stupidity. Three birds were in company on a very high tree. I had only my little collecting gun, with a quarter of a dram of powder and dust-shot, but, selecting the lowest, fired at him. He swung round on his twig and hung suspended. I loaded quickly and aimed at the next, who never moved; at the first report he fell dead, and the third remained. I fired again, without effect; but the next shot brought it down."

Again and again one finds them vilified for this trait. Comments such as "the most stupid birds imaginable", "a picture of stupid lethargy", "rather dull and stupid", "stupidly watching one until they can be almost taken in the hand", and so on, abound in the earlier literature. Children in Venezuela call the Two-banded Puffbird *aguantapiedra*, "stone-endurer", because it refuses to fly when they pelt it; similarly, the White-necked Puffbird earned the local name *cabeza piedra* from its ability to withstand being hit by stones flung by slingshot. The Portuguese settlers of Brazil nicknamed the Crescent-chested Puffbird *João doido*, meaning "dozy John", *doido* being the word that Portuguese settlers elsewhere in the world applied so aptly to the Dodo (*Raphus cucullatus*).

Many other colloquial names bestowed upon puffbirds, including *João bobo*, *Durmili* and *Durmilon*, as well as scientific ones such as *Nystalus* (drowsy) and *Ecchaunornis* (puffed-up or arrogant bird), emphasize the perceived stupidity or laziness of these birds, for which early explorers such as F. de Azara, as long ago as 1805, heaped scorn upon them. Despite such widespread and long-standing ideas, there is no objective evidence for a lack of intelligence among the members of this family, and all are certainly capable of bursts of activity.

Nevertheless, although this physical lethargy disguises a keen alertness, puffbirds do have a dumb-looking appearance, too: "there is something very grotesque in the appearance of all the Puff-birds", wrote W. Swainson. Perhaps the Amerindians knew

better. Wetmore, in a 1968 volume on the birds of Panama, reported a superstition regarding the White-whiskered Puffbird in that country. Boys watching him skinning a specimen called it *pájaro brujo*, meaning witchdoctor bird, because its call was like the singing of the Guaymí witchdoctors.

Also in Panama, White-fronted Nunbirds were not common in the Darién woods, but they were abundant in and around the Indian settlements in that region. There they could be seen at any time, dusting on a little pathway or "perched about the house almost as tame as the little paraquets". This reveals an interesting aspect of puffbird "tameness", namely that where they remained unpersecuted they were ready to live in such proximity to man.

The German name *Faulvogel* is still used for all the Bucconidae with the sole exception of the *Monasa* nunbirds. Like so many other vernacular names attached to members of this family, it means an idle or slothful bird, although it could equally be translated as a bird that is rotten or putrid and, hence, foul-smelling. It is interesting that many buconid species have been found by preparers of specimens to be malodorous (see Morphological Aspects), and as long ago as 1815 Shaw noted that puffbirds are not very edible. As a consequence, puffbirds are not sought after for food, although Shaw mentioned that native peoples do sometimes eat them. Nor are they sought after for captivity, since their diet of large insects, their lethargic habits, their infrequent and unspectacular vocalizations, their relative ungracefulness and their dull colours make them hardly suitable or attractive as pets.

## Status and Conservation

No species of buconid is threatened with global extinction, and only one, the Sooty-capped Puffbird, is currently considered Near-threatened. The Lanceolated Monklet and the Chestnut-headed Nunlet were formerly placed in this latter category, but the conservation status of both appears now to be more secure than was previously thought. Nevertheless, all three remain extremely poorly known, and in the absence of information it would seem wise to view their status with some precaution.

Four buconids are species of restricted range, as defined by BirdLife International, which means that the extent of occurrence of each is less than 50,000 km<sup>2</sup>. The Sooty-capped Puffbird is con-

The Lanceolated Monklet was formerly classified as Near-threatened by BirdLife International. It ranges from the Caribbean slope of Costa Rica south to western Brazil and extreme northern Bolivia. Often considered to be rare throughout much of its range, this tiny species, which weighs only some 20 g, is generally silent and retiring and thus is difficult to detect in the middle and upper storeys of the humid forest that it prefers. More recent information indicates that, fortunately, its populations appear to be in better shape than was previously thought. The species feeds mainly on insects and is one of only a few puffbirds known to eat berries.

[*Micromonacha lanceolata*, near Taisha, Morona-Santiago, Ecuador. Photo: Doug Wechsler/VIREO]

No buconid is classed as threatened, and only the Sooty-capped Puffbird is listed as Near-threatened.

It inhabits humid lowland forest in coastal Colombia, within the Chocó Endemic Bird Area. It is common in Los Katíos National Park but in recent years has been found in only one other area. Elsewhere, it has suffered from widespread habitat conversion and human encroachment associated with livestock grazing and agricultural development. On the bright side, most of the localities from which specimens are known have not been visited since the mid-1960's, so this species may be more widespread than is currently thought.

[*Nystactes noanamae*.

Ardea]

finied to the Chocó Endemic Bird Area in western Colombia, a region under threat from deforestation on a grand scale. The Semicollared Puffbird helps to define the South-east Peruvian Lowlands Endemic Bird Area, which stretches into both Brazil and Bolivia; this area remains relatively intact at present, although oil and gas extraction are becoming increasingly important in the region. The other two buconids in this category are both nunlets of the genus *Nonnulla*. The Brown Nunlet is found in the Upper Amazon-Napo Lowlands Endemic Bird Area, and the Chestnut-headed Nunlet in the Amazon Flooded Forests Endemic Bird Area.

The fact that puffbirds are often so difficult to detect may be a pointer to the likelihood that virtually all species will be found to be moderately common. Only the Sooty-capped Puffbird appears to have a sufficiently constrained distribution and to be experiencing habitat loss significant enough to warrant concern in the near term.

Within its very small range in western Colombia, the Sooty-capped Puffbird has been recorded from only two sites in recent years. At one of these, the Los Katíos National Park, it appears to be common, and it is possible that this species survives in reasonable numbers elsewhere, as few of the ten or so localities from which specimens are known have been visited by ornithologists since the mid-1960's. On the other hand, its lowland forest habitat is under severe threat from logging and conversion to agricultural uses. Plantations of bananas and oil palms (*Elaeis guineensis*) are rapidly replacing the natural forest, while cattle ranching and settlement by human populations, with their attendant developments, are an increasing threat to this species. The fact that even the Sooty-capped Puffbird has been found in non-pristine habitat may, however, be a reason for optimism.

In general, puffbirds have profited very little from human actions, but their widespread use of edge habitats means that at least some species must have benefited from the construction of roads and railways through pristine forest areas. The most obvious beneficiary is the Swallow-winged Puffbird, which may have increased its numbers as a result of new nesting and foraging sites being opened up. The White-eared Puffbird uses suburban trees, but in all likelihood the species was present in such areas long before housing developments created their mock-savanna effect, and it is therefore probably merely hanging on in these places.

Regardless of the fact that so few puffbirds have been registered as being of conservation concern, they do belong to a guild, known as the subcanopy sallying insectivores, that has been well documented as experiencing difficulties in the face of habitat

modification and loss. The use by some buconids of edge habitats has, however, proved to be the saving grace for the species concerned. Work carried out by J. M. Thiollay in logged and unlogged forest established that larger insectivorous birds of the upper storeys, such as the Black Nunbird and the Collared and White-chested Puffbirds, declined with selective logging. By contrast, members of the family that use edge habitats or clearings with scattered trees and vine-tangles to sally-glean, including the Pied, White-necked and Swallow-winged Puffbirds, showed an increase in numbers. It is clearly important to establish the responses of other buconids to the impact of major habitat disturbances, such as logging.

Meanwhile, a study of a very small forest island, 87 ha in extent, in lowland Ecuador revealed that puffbirds do poorly in such isolation. Several species appeared to drop out within a few years, as was the case with Pied and Barred Puffbirds, while others, in this instance the White-necked and White-whiskered Puffbirds, were so infrequently recorded that their populations were thought to be unviable. Since two of the species seen to be faring badly when their habitat is fragmented are two of the buconids found by Thiollay to improve their status with selective logging, it would appear that there are few grounds for complacency over the status of any of the puffbirds in the long term. It is widely accepted that large areas of pristine habitat are important for the long-term conservation of biological diversity. The more this perception is put into practice in Central and South America, the greater will be the benefit to the puffbirds.

PLATE 3

inches 4  
cm 10

Genus *NOTHARCHUS* Cabanis & Heine, 1863

1. White-necked Puffbird

*Notharchus macrorhynchos*

**French:** Tamatia à gros bec      **German:** Weißhals-Faulvogel      **Spanish:** Buce Picogordo

**Taxonomy.** *Bucco macrorhynchos* J. F. Gmelin, 1788, Cayenne. Forms a superspecies with *N. swainsoni*, with which usually regarded as conspecific (see page 105). Races *hyperhrynchos* and *paraensis* markedly distinct from nominate, and together may constitute a separate species. Birds from El Salvador and NW Nicaragua sometimes separated as race *cryptoleucus*, but probably indistinguishable from *hyperhrynchos*. Population of Santa Marta Mts (N Colombia) may represent a separate race; further study needed. Three subspecies currently recognized.

**Subspecies and Distribution.**

*N. m. hyperhrynchos* (P. L. Sclater, 1856) - S Mexico (Oaxaca) S to N & NE Venezuela, and S to Colombia, Ecuador, E Peru, N Bolivia and W Brazil (E to R Tapajós and S to Mato Grosso).

*N. m. macrorhynchos* (J. F. Gmelin, 1788) - extreme E Venezuela, the Guianas and extreme N Brazil S to the Amazon.

*N. m. paraensis* Sassi, 1932 - lower Amazon Valley in Brazil (Pará E of R Tapajós and into N Maranhão).

**Descriptive notes.** 25 cm; 81-106 g. Plumage strongly pied. Mostly glossy blue-black, narrow white forehead, white throat, sides of face and upper breast, thin white nape-collar; broad black breastband, white central abdomen, narrowly white-barred black patches on sides; narrow white edgings to feathers of upperparts; tail black with narrow white tips; bill all black; iris red, brown or straw-coloured; feet black. Immature duller black with buffy feather edgings; pectoral band may be incomplete; white areas washed buffy; iris brown. Race *hyperhrynchos* differs from nominate in much broader white forehead, larger bill, broader

white hindcollar, much less extensive black patches on sides; *paraensis* similar, with bill exceptionally long. **VOICE.** Song a very high weak trill at variable speeds, usually descending, "ui-ui-... wi-di-dik wi-di-dik wi-di-dik..."; melodious and harsh calls, notably a clear nasal falling "düür".

**Habitat.** Occurs from ground level to canopy and in edge of humid to semi-arid formations, chiefly in second-growth woodland (often where *Cecropia* dominant) and edge habitats, open woodland and savanna, mixed woods of oak (*Quercus*) and pine (*Pinus*), clearings with scattered tall trees, abandoned plots and forest openings; also primary tropical evergreen and semi-evergreen forest, *terra firme* forest, transitional forest, flooded and swampy forest with many dead trees, landward side of mangroves, river margins, and plantations. Proximity to running water may be important. Generally found from sea-level up to 1200 m; in Venezuela reaches 1200 m N of R Orinoco, but only at 100-250 m S of it.

**Food and Feeding.** Insects, including Orthoptera (Locustidae), Hymenoptera (Apidae, Xylopidae), Hemiptera, Homoptera (Fulgoridae), Coleoptera (Cetoniidae) and Lepidoptera; also small vertebrates, some vegetable matter. Once noted taking the large green scarab *Macraspis lucida* when it was abundant in high tree crowns. Investigates swarms of army ants. Still-hunts from high bare perch, diving at prey, which is beaten on perch before ingestion.

**Breeding.** Mar-May in Costa Rica; Jan-Jul in Panama; May and Sept in Colombia; Jun in Venezuela; hole excavation recorded in Jul and Aug in Brazil (Manaus). Nest in cavity, excavated by both sexes, in large arboreal territory, or hole in tree, usually 12-15 m up, but recorded to 18 m and as low as 3 m; hole in ground and earth bank reportedly also used; pair in Brazil dug hole in termite nest in Jul, and dug third hole in same nest in Aug. Clutch size and incubation and fledging periods not documented.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Very to fairly uncommon in Mexico; now rare in El Salvador owing to clearance of lowland forest; uncommon in Honduras. In Costa Rica, occurs in Corcovado National Park and Santa Rosa National Park. Commonest puffbird in Canal Zone, Panama. Fairly common in Colombia, where occurs in Tayrona National Park. Rare to uncommon in Ecuador; present in Cotacachi-Cayapas National Park. Widespread in French Guiana, but rarer in coastal areas. Fairly common to common in Amazon region, perhaps less frequent in Bolivia (where judged rare at 2 study sites) and Peru, although sedentary habits thought to lead to underestimation of true numbers. In Peru, up to 2 pairs/km<sup>2</sup>, although only 0.5 pairs/km<sup>2</sup> in *Ficus/Cedrela* transitional forest.

**Bibliography.** Álvarez del Toro (1980), Anon. (1998b), Binford (1989), Brace *et al.* (1997), Carriker (1910), Chapman (1917, 1926), Cohn-Haft *et al.* (1997), Cory (1919), Darlington (1931), Dickey & van Rossem (1938), Dugand (1947), Friedmann (1948), González-García (1993), Griscom (1932), Gyldenstolpe (1945b), Haffer (1975), Haverschmidt & Mees (1994), Henriques & Oren (1997), Hilty & Brown (1986), Howell & Webb (1995), López *et al.* (1989), Meyer de Schauensee & Phelps (1978), Monroe (1968), O'Neill & Pearson (1974), Olivares (1957), Oniki & Willis (1982), Parker, Foster *et al.* (1993), Parker, Parker & Plenge (1982), Paynter (1955), Peres & Whitaker (1991), Ridgely & Greenfield (2001), Ridgely & Gwynne (1989), Robinson & Terborgh (1997), van Rossem (1934), Sargeant (1994), Sassi (1939), Schäfer & Phelps (1954), Short (1975), Sick (1993), Slud (1960, 1964), Sneider (1954), Stiles & Skutch (1989), Stotz *et al.* (1996), Tashian (1952), Terborgh *et al.* (1990), Thiollay (1992), Thurber *et al.* (1987), Todd (1943a), Todd & Carriker (1922), Tostain *et al.* (1992), Wetmore (1968a), Willis (1982a), Willis & Eisenmann (1979), Zimmer *et al.* (1997).

2. Buff-bellied Puffbird

*Notharchus swainsoni*

**French:** Tamatia de Swainson      **German:** Swainson-Faulvogel      **Spanish:** Buce de Swainson

**Taxonomy.** *Bucco swainsoni* G. R. Gray, 1846, Brazil. Forms a superspecies with *N. macrorhynchos*, and usually regarded as conspecific (see page 105). Monotypic.

**Distribution.** SE Brazil (Espírito Santo to Santa Catarina), E Paraguay, and NE Argentina (Misiones).

**Descriptive notes.** 23-5 cm. Black upperparts glossed green, feathers buffy-edged; very narrow white forehead, white throat and upper breast, greyish-white sides of face and thin nape-collar; black breastband, pale rufous abdomen, grey patches on sides; bill black; iris red, brown or straw-coloured; feet black. Differs from very similar *N. macrorhynchos* mainly in green gloss above, pale rufous belly with much more limited, greyer flank marks, greyer face and hindcollar, narrower black breastband, smaller bill. Immature duller; pectoral band may be incomplete; iris brown. **VOICE.** A descending sequence of whistles,

varying in rhythm, "ui-ui---dibule-dibule...".

**Habitat.** Lowland humid forest, and logged and tall secondary forest.

**Food and Feeding.** Insects, including Orthoptera, Hymenoptera, Hemiptera, Coleoptera and Lepidoptera; also small vertebrates, some vegetable matter. Investigates army-ant swarms. Still-hunts from tops of tall bare trees.

**Breeding.** Breeds in Sept-Oct in S of range. Excavates hole in termite nest; one cavity in Paraguay was 12 m above ground. No information on clutch size, or other aspects of breeding.

**Movements.** Unclear; possibly a summer migrant, Sept-Mar, to Atlantic Forest in Brazilian state of São Paulo; resident in Iguazú, in extreme NE Argentina.

**Status and Conservation.** Not globally threatened. In Brazil, relatively rare in São Paulo state, uncommon in Paraná; frequently encountered in E Paraguay; generally rare in Argentina (Misiones), though regularly recorded in Iguazú area.

**Bibliography.** Aguirre & Aldrichi (1983), Aleixo & Galetti (1997), dos Anjos *et al.* (1997), Barnes *et al.* (1993), Brooks *et al.* (1993), Canevari *et al.* (1991), Chebez (1994), Cory (1919), Forrester (1993), Hayes (1995), Olrog (1968), de la Peña (1994), Pereyra (1950), Saibene *et al.* (1996), Sargeant & Wall (1996), Schmidtz *et al.* (2001), Schubart *et al.* (1965), Short (1972b, 1975), Sick (1993).

3. Black-breasted Puffbird

*Notharchus pectoralis*

**French:** Tamatia à plastron      **German:** Gürtelfaulvogel      **Spanish:** Buce Pechinegro

**Taxonomy.** *Bucco pectoralis* G. R. Gray, 1846, no locality. Forms a superspecies with *N. ordii*. Monotypic.

**Distribution.** Canal Zone of Panama E to C Colombia and S to NW Ecuador.

**Descriptive notes.** 19-23 cm; 60-69 g. Mostly glossy blue-black; white throat, separated by a broad black band from white auricular patch, narrow white nuchal collar; scapulars, wing-coverts, rump and uppertail-coverts narrowly fringed white; tail black, slightly graduated, narrowly tipped white; broad black band from breast to upper belly, lower belly whitish, sides dark grey with buffy fringes; bill all black; iris dark brown or dark red; feet blackish. Immature not described. **VOICE.** Song 10-30 loud "kwee" whistles followed by 3 or so lower, slower "whew" whistles ending with a few fading "wheet-whew" wolf-whistles; rasping

"chah-chah-chah" in territorial disputes.

**Habitat.** Humid and wet lowland forest, second-growth woodland, often near running water; less frequently at forest edge, associated with heliconias and bamboo; more restricted to forest than *N. macrorhynchos*. Mainly occupies canopy foliage; much less often on exposed open perches, but drops low at army-ant swarms with some frequency. Occurs up to 1000 m.

**Food and Feeding.** Large centipedes (Chilopoda), millipedes (Diplopoda), scorpions (Scorpiones), spiders, roaches (Blattodea), grasshoppers or katydids (Orthoptera), mantises (Mantidae), stick-insects (Phasmida), beetles, caterpillars and lizards. Commonly follows swarms of the ant *Eciton burchelli*, which often penetrate the upper understorey and subcanopy; moves down to forage around foliose palms and rotten, liana-draped or epiphyte-laden branches. Still-hunts, diving after prey and returning to perch, where beats prey before swallowing it.

**Breeding.** Mar-May in NW Colombia; Mar-Jul in Panama. Nest in hole c. 18 cm deep, excavated by both sexes, in arboreal termitarium 2.3-12.5 m up in subcanopy tree. Clutch 3 eggs, but only 1-2 young observed in fledged broods; incubation by both sexes, period unknown.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Generally uncommon, but common at least locally, and habit of spending long periods motionless inside canopy probably mask its status elsewhere. Sensitive to habitat disturbance.

**Bibliography.** Anon. (1998b), Best *et al.* (1997), Borrero (1962), Brabourne & Chubb (1912a), Chapman (1917, 1926), Cory (1919), Eisenmann (1952), Hilty & Brown (1986), Krabbe (1991), Olivares (1957), Ridgely & Greenfield (2001), Ridgely & Gwynne (1989), Ridgely *et al.* (1998), Ridgway (1914), Rodner *et al.* (2000), Rodríguez (1982), Skutch (1948c, 1983), Stotz *et al.* (1996), Strauch (1977), Taylor (1995), Wetmore (1968a), Willis (1980, 1982a), Willis & Eisenmann (1979).

4. Brown-banded Puffbird

*Notharchus ordii*

**French:** Tamatia de Cassin      **German:** Braunbinden-Faulvogel      **Spanish:** Buce Pechipardo

**Taxonomy.** *Bucco Ordii* Cassin, 1851, Venezuela. Forms a superspecies with *N. pectoralis*. Monotypic.

**Distribution.** S Venezuela (Amazonas), NW & NC Brazil (N of Amazon and in Mato Grosso), E Peru and N Bolivia; also probably E Colombia.

**Descriptive notes.** 20 cm; 51.5 g. Slightly glossy black above, narrow white forehead and hindcollar, thin black line from gape to eye; uppertail-coverts fringed white, tail one-third graduated, black with narrow white tips; face and chin to upper breast white, black band across mid-breast, passing at lower edge to olive-brown, then breaking into brown spots, these becoming black on sides; central belly and undertail-coverts white; white central band on undertail; underwing-coverts mostly black, broad white wingband on bases of remiges below; bill black; iris dark brown; feet black. Immature not described. Voice.

Song lengthy, with several clear, loud introductory whistles followed by cadenced couplets and triplets.

**Habitat.** Canopy and edge of rainforest, transitional forest, open stunted forest growing on white-sand soils and rock areas, also forest clearings and scrubby vegetation at edge of *terra firme* forest. 150–300 m.

**Food and Feeding.** Unrecorded; observation of individual making a sallying flight suggests that feeding habits, and presumably prey, probably typical of genus.

**Breeding.** Nest excavation in Dec and specimen with developed gonads in Feb, in Venezuela. One nest a cavity in termitarium, 4–5 m up in largely bare tree, excavated by both sexes. No information on clutch size, incubation period or fledging period.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Evidently occurs at low densities, although widely distributed throughout the upper reaches of the Orinoco and the Amazon. Uncommon in Amazonas, Brazil; present in Cristalino River Private Reserve, N Mato Grosso. Recently discovered (1990's) in NE Peru, near Iquitos, representing significant range extension; this site, in an area of white-sand soils, has subsequently been protected as Alpuhuayo-Mishana Reserve. Although thought to occur in E Colombia, status there uncertain and further study required.

**Bibliography.** Berlepsch (1908), Clements & Shany (2001), Cory (1919), Donahue (1994), Foster *et al.* (1994), Friedmann (1948), Meyer de Schauensee & Phelps (1978), Parker & Remsen (1987), Parker *et al.* (1982), Peres & Whittaker (1991), Phelps & Phelps (1958), Remsen & Traylor (1989), Rodner *et al.* (2000), Ruschi (1979), Sick (1993), Snethlage (1914), Stotz *et al.* (1996), Willard *et al.* (1991), Zimmer & Hilty (1997), Zimmer *et al.* (1997).

## 5. Pied Puffbird *Notharchus tectus*

**French:** Tamatia pie

**German:** Elsterfaulvogel

**Spanish:** Buco Pfo

**Taxonomy.** *Bucco tectus* Boddaert, 1783, Cayenne.

Sometimes placed in genus *Bucco*. Race *subtectus* considered a distinct species by some authors. Three subspecies recognized.

**Subspecies and Distribution.**

*N. t. subtectus* (P. L. Selater, 1860) - Caribbean Costa Rica S to W & NC Colombia and NW Ecuador.

*N. t. tectus* (Boddaert, 1783) - S Venezuela, the Guianas and N Amazonian Brazil (E as far as Maranhão).

*N. t. piceatus* (P. L. Selater, 1856) - SE Colombia, E Ecuador and E Peru to E Bolivia and WC Brazil.

**Descriptive notes.** 14–17 cm; 21–40 g. Mainly glossy black above and white below; dark bare patch behind eye; distinct short white line from nasal bristles to behind eye, small white spots on crown; white on some scapulars; white patches near tail base and at tail tips, distal outer webs black on most rectrices; broad black pectoral band, black flank patches lightly barred white; bill all black; eyes brown; feet black. Immature duller, browner above, white areas tinged buff, wing-coverts spotted buffy-white, rectrices paler, breastband pale-fringed; pale-tipped bill. Race *subtectus* smaller than nominate.

with smaller bill, narrower pectoral band, less or no white spotting on crown, and greyer flanks vaguely barred white; *piceatus* larger than nominate, darker, less white on lateral tail feathers. Voice. Song a thin but loud, high-pitched, bat-like series of whistles, "tee-oo" or "pweee pweee pweee" in various patterns, slowing at end; call "pseeee tidit, tidit-tidit", like tyrant-flycatcher (Tyrannidae), also twitters, etc.

**Habitat.** Inhabits tropical lowland humid evergreen forest, edges, clearings and streamsides, second growth with scattered tall trees, abandoned clearings, gallery and riverine forest, mangroves, woodland, savanna. In Costa Rica apparently confined to the tropical belt, frequenting clearings with scattered trees, plantations and pastures inside generally wooded country, and appears to avoid primary forest. In the Guianas occupies high forest, also other habitats such as coastal mangroves, plantations, sand-ridge and savanna forest, shrubby second growth, and granite vegetation in form of low, dense, vine-clad woodland. Occurs in lowlands up to 1000 m; below 300 m in Costa Rica.

**Food and Feeding.** Dragonflies (including Libellulidae), Orthoptera (including Locustidae), bugs (Hemiptera), butterflies and moths, bees and wasps (including Sphegidae), beetles (including Elateridae), termites (Isoptera). One stomach contained hard-shelled beetles of a single species. Forages from open or dead branch, usually high in canopy, sometimes lower down.

**Breeding.** Jun in Panama; Feb–Aug in Colombia; apparently around Mar in Ecuador; Sept in Surinam; Mar–May and Nov in French Guiana. Nest in hole excavated in arboreal termitarium, situated 4–25 m above ground. Clutch 2 eggs; no information available on incubation and fledging periods.

**Movements.** Presumably resident, but appears to move around countryside in irregular pattern, at least seasonally.

**Status and Conservation.** Not globally threatened. In Costa Rica, increasingly rare with deforestation. Fairly common in Panama in 1970's. Common in W Colombia, where present in Los Katíos National Park. Common in the Guianas. In Venezuela, occurs in Imataca Forest Reserve and El Dorado. Generally uncommon in C & S Amazon region, uncommon near Manaus, and apparently rare in Rondônia; fairly common in E Amazon. Apparently rare in Peru and Bolivia; occurs in Noel Kempff Mercado National Park, Bolivia.

**Bibliography.** Anon. (1998b), Bates *et al.* (1989), Bond (1954), Borges (1994), Brosset (1964), Chapman (1917, 1926), Cohn-Haft *et al.* (1997), Cory (1919), Davis (1986), Dubs (1992), Haffer (1959, 1975), Haffer & Borroro (1965), Haverschmidt (1948), Haverschmidt & Mees (1994), Henriques & Oren (1997), Hilty & Brown (1986), Meyer de Schauensee & Phelps (1978), O'Neill & Pearson (1974), Olivares (1957), Oren & Parker (1997), Parker, Foster *et al.* (1993), Parker, Parker & Plenge (1982), Pinto (1966), Ridgely & Greenfield (2001), Ridgely & Gwynne (1989), Ridgway (1914), Rodríguez (1982), Romero (1977), Sick (1993), Slud (1960, 1964), Snyder (1966), Stiles (1985), Stiles & Skutch (1989), Stotz & Bierregaard (1989), Stotz *et al.* (1996), Thiollay (1992), Tostain *et al.* (1992), Wetmore (1968a), Willis (1980, 1982a), Willis & Eisenmann (1979), Willis & Oniki (1990), Zimmer & Hilty (1997), Zimmer *et al.* (1997).

## Genus ARGICUS Cabanis & Heine, 1863

### 6. Chestnut-capped Puffbird

#### *Argicus macrodactylus*

**French:** Tamatia macrodactyle **German:** Braunkappen-Faulvogel **Spanish:** Buco Cabecirrojo

**Taxonomy.** *Cyphos macrodactylus* Spix, 1824, Fonte Boa, Brazil.

Usually placed in genus *Bucco*. Birds from R Caura region of S Venezuela often treated as race *caurensis*, but probably inseparable from other populations. Monotypic.

**Distribution.** S Venezuela, E Colombia and E Ecuador S to E Peru, upper Amazonian Brazil and N Bolivia.

**Descriptive notes.** 14–15 cm; 25 g. Crown chestnut; long narrow whitish supercilium, broader white stripe just below cheek bisecting black patch on side of face and broad collar across lower throat; chin and upper throat rufescent-white, varying in extent, elongated shafts of chin feathers recurving over bill; narrow bright orange-rufous nuchal collar; rest of upperparts dark brown, a few lighter bars on back, many on rump; light buffy-rufous scalloping on lower mantle, scapulars and wing-coverts; remiges dark brown; tail rather long, narrow, graduated about a third of its length, dark warm brown; whitish upper breast, remaining underparts mainly buffy with fine vague dusky barring except on lower belly; bill all black; iris red to brown, bare eye-ring dark grey; feet brownish-grey or greenish-grey. Immature similar, differs in having shorter bill. Voice. Song a series of plaintive but abrupt rising notes ending in twitter, "pup pup pep pep peep peep pip pip pip pip".

**Habitat.** Usually found in the subcanopy, understorey and undergrowth near water at borders of humid *terra firme* and *várzea* forest, especially along *várzea* river edge and in riverine bamboo, also *igapó* and creek margins, second-growth woodland, early successional growth, riverbank forest, lake margins, transitional forest, willow (*Salix*) bars, wet shrubbery in clearings, gallery forest, palm groves; also scrubby forest away from water. Occurs from sea-level up to at least 600 m.

**Food and Feeding.** Large roach (Blattodea) found in one stomach. Observed once to appear at dusk to catch moths on the wing. Almost always solitary, pair members apparently not foraging together. No other information.

**Breeding.** Nest in hole in arboreal termitarium. No other details known.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Locally common in Venezuela, e.g. 6 heard calling simultaneously. Uncommon in Colombia and Ecuador. Uncommon generally in Peru; density of 1 pair/km<sup>2</sup> in floodplain-forest at Cocha Cashu, increasing to 19 pairs/km<sup>2</sup> in earliest successional stages; observed in Peru along Cuzco-Manu Road and at Amazonia Lodge. In Brazil, uncommon in Amazonas, at Manaus and in Rondônia.

**Bibliography.** Allen (1995), Angehr & Aucua (1997), Bond (1954), Bond & Meyer de Schauensee (1943), Chapman (1917, 1926), Clements & Shany (2001), Cory (1919), Donahue (1994), Goodfellow (1902), Gyldestolpe (1945a, 1951), Hilty & Brown (1986), Meyer de Schauensee & Phelps (1978), Newman (1993), O'Neill & Pearson (1974), Parker *et al.* (1982), Peres & Whittaker (1991), Ridgely & Greenfield (2001), Ridgely *et al.* (1998), Robinson & Terborgh (1997), Rodner *et al.* (2000), Sick (1993), Stotz *et al.* (1996), Terborgh *et al.* (1990), Traylor (1958), Willard *et al.* (1991).

## Genus NYSTACTES Gloger, 1827

### 7. Spotted Puffbird

#### *Nystactes tamatia*

**French:** Tamatia tacheté

**German:** Fleckenfaulvogel

**Spanish:** Buco Moteado

**Taxonomy.** *Bucco Tamatia* J. F. Gmelin, 1788, Cayenne and Brazil.

Genus usually merged into *Bucco*. Forms a superspecies with *N. noanamae*. Several other races proposed, including *inexpectatus* (NC Brazil), *punctuliger* (C Brazil) and *interior* (SW Brazil), but these apparently represent nonconstant, intergrading populations. Three subspecies currently recognized.

# Subspecies and Distribution.

*N. t. tamatia* (J. F. Gmelin, 1788) - E Colombia (S to Vaupés) E to Venezuela, the Guianas, and S to N bank of Amazon.

*N. t. pulmentum* (P. L. Sclater, 1856) - SE Colombia S to E Ecuador, NE Peru, W Brazil and NE Bolivia.

*N. t. hypneus* (Cabanis & Heine, 1863) - Amazonian Brazil E of R Tapajós.

**Descriptive notes.** 18 cm; 33-42 g. Diffuse rufous band at base of bill to above and behind eye, changing to indistinct rufous spots on dark brown crown; poorly marked blackish line from base of bill through and below eye to upper ear-coverts, bordered below by white stripe connecting to narrow white nuchal band; triangular black patch below white cheekstripe, whitish chin with long, stiff, recurved white bristles; rufous throat to upper breast and sides of neck; upperparts dark brown as crown, with buffy scalloping on lower mantle, back and especially rump and uppertail-coverts; flight-feathers dark brown,

secondaries edged buffy; tail graduated for quarter of length, dark brown with buffy edges; whitish breast to lower flanks spotted and scaled black, markings diminishing in size and number on flanks; centre of belly and undertail-coverts white with small black spots; buffy underwing-coverts and bases of undersides of flight-feathers; bill all black; iris bright red, bare eyering dark grey; feet dark grey or greenish. Immature may have barred paler throat, more chevron-like spots below, buffier lower underparts, indistinct face pattern, heavily buff-barred upperparts, buffy collar. Race *pulmentum* has very pale throat, brighter forehead, and heavier spotting; *hypneus* larger but smaller-billed than nominate, heavier spotting below, notably across breast. **Voice.** Song a series of 10-20 whistled "chyo!" notes (c. 2 per second), then a few at lower pitch and slower, ending with c. 4 inflected "pchooii, pchooii, pchooii, peejee" whistles; faint wheezy whistles in disputes.

**Habitat.** Mainly found in *várzea* and *igapó* forest, humid forest borders, mature second growth, impoverished sandy savanna woodland, sand-ridge forest, gallery forest, palm groves, and marshy edges, shrubby and bushes, often near water; rarely in deep forest. Occurs from lowlands up to 1400 m.

**Food and Feeding.** Caterpillars, scorpions (Scorpiones), flies (Brachycera), beetles (Carabidae, Curculionidae), Isoptera, bees; also berries of mistletoe (Loranthaceae). One bird seen catching large hawkmoths (Sphingidae) attracted to flowering shrubs at dusk. Still-hunts from low exposed perch. Sometimes follows army ants.

**Breeding.** Apr in Venezuela; courtship feeding in Jun in French Guiana; laying in Sept in Bolivia. Clutch 2 eggs. Other details not documented.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Uncommon in most of range, including the Guianas, Peru and most of Brazil. In Amazonas, Brazil, evidently common in one area along R Purus and on R Urucu. Occurs in Amacayacu National Park, Colombia.

**Bibliography.** Bates *et al.* (1992), Bierregaard (1988), Chapman (1926), Cherrie & Reichenberger (1921), Cohn-Haft *et al.* (1997), Cory (1919), Dubs (1992), Friedmann (1948), Griscom & Greenway (1941), Gyldestolpe (1951), Haffer (1975), Haverschmidt (1977), Haverschmidt & Mees (1994), Henriques & Oren (1997), Hilty & Brown (1986), Meyer de Schauensee & Phelps (1978), Newman (1993), Parker *et al.* (1982), Peres & Whittaker (1991), Phelps & Phelps (1949), Pinto (1966), Remsen & Parker (1983), Ridgely & Greenfield (2001), Sargeant (1994), Schubert *et al.* (1965), Sick (1993), Sneath (1914), Snyder (1966), Stotz *et al.* (1996), Todd (1943a), Tostain *et al.* (1992), Willis (1982b), Zimmer & Hilty (1997).

## 8. Sooty-capped Puffbird

### *Nystactes noanamae*

**French:** Tamatia de Colombie **German:** Rußkappen-Faulvogel **Spanish:** Buco de Noanamá

**Taxonomy.** *Bucco noanamae* Hellmayr, 1909. Noanamá, Río San Juan, Chocó, Colombia.

Genus usually merged into *Bucco*. Forms a superspecies with *N. tamatia*. Monotypic.

**Distribution.** Coastal W Colombia from Gulf of Urabá S to R San Juan.

**Descriptive notes.** 18 cm. Crown and nape blackish to greyish-black; long, prominent white supercilium becoming grey towards rear, broad black line through and below eye and including ear-coverts; dark brown mantle; tail rather short, strongly graduated, dusky, narrowly fringed buff; white chin, lower face and throat; very broad black pectoral band; lower underparts buffy-white with black scalloping; bill all black; iris red, bare eyering dark grey; feet pale grey. Immature not described. **Voice.** No information available.

**Habitat.** Inhabits humid and wet forest, second-growth woodland and adjacent non-forest

areas (once an abandoned cocoa plantation), also scrub; keeps to lower parts of vegetation. Occurs in lowlands, up to 100 m.

**Food and Feeding.** Limited information available. Known to take insects. Perches for long periods on open branches, motionless and inconspicuous, before stooping on large insects in foliage of understorey.

**Breeding.** Pair delivering food to nest in arboreal termitarium, late Aug. No further information.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Chocó EBA. Generally uncommon. Common in Los Katíos National Park, in Chocó. Although recent confirmed records from just 2 sites, only few of the c. 10 localities from where this species is known (specimens collected) have been investigated since 1966. Considerable deforestation caused by logging and by conversion of forest to banana and oil palm (*Elaeis guineensis*) plantations, along with human settlement, development, cattle ranching and other land-use changes, are all regarded as significant threats.

**Bibliography.** Chapman (1917), Collar *et al.* (1994), Cory (1919), Haffer (1959, 1975), Hellmayr (1911), Hilty & Brown (1986), Meyer de Schauensee (1982), Nicéforo & Olivares (1967), Olog (1968), Pearman (1993a), Rodner *et al.* (2000), Rodríguez (1982), Stattersfield & Capper (2000), Stotz *et al.* (1996).

## Genus *BUCCO* Brisson, 1760

### 9. Collared Puffbird

#### *Bucco capensis*

**French:** Tamatia à collier

**German:** Halsband-Faulvogel

**Spanish:** Buco Musú

**Taxonomy.** *Bucco capensis* Linnaeus, 1766. Cape of Good Hope; error = the Guianas.

Birds from SE Colombia to Ecuador and E Peru sometimes treated as race *dugandi*, but this form is doubtfully distinct. Monotypic.

**Distribution.** Amazon Basin from E Ecuador and SE Colombia E to S Venezuela, the Guianas and N Brazil (E to Belém), and S to NE Peru and N Mato Grosso.

**Descriptive notes.** 19 cm; 46-62 g. Dark rufous above, crown to mantle, wing-coverts and tertials finely barred, rump paler rufous with fewer black bars; complete black collar around upper mantle and breast, bordered on nape and sides of neck by narrow buffy collar; primaries, primary coverts and secondaries dark brown, secondaries edged rusty; tail rather short, square-tipped, graduated for about a quarter of length, orange-chestnut narrowly banded black; chin and throat white to buffy-white; lower breast to centre of belly and undertail-coverts buffier, grading to bright orange-fulvous on lower flanks; bill variably orange to dusky upper mandible, orange lower; iris whitish, orange or vermilion, bare skin around eye orange-yellow; feet light green, orange or brown; claws entirely pale. Immature very like adult, but bill and head paler. **Voice.** Song a repeated "cua-will, cua-will...", "qu'a'a'a'al" cua-will" in response to playback of song.

**Habitat.** Understorey and sometimes middle storey to subcanopy of primary humid *terra firme* forest, dry hilly country, bamboo bordering rivers; also *várzea* in lower Amazon, and possibly restricted to denser patches. Lowlands to 1700 m.

**Food and Feeding.** Lizards, snakes and frogs, taken from the forest floor or from foliage; also beetles, orthopterans, cicadas (Cicadidae) and other large insects. Still-hunts from shaded perch. Sometimes joins mixed-species flocks; more rarely follows army ants.

**Breeding.** May in Venezuela; laying female in Sept in Guyana. Excavates a hole in arboreal termitarium. No information on clutch size, nor on incubation and fledging periods.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Uncommon to common in most of range. Rare to locally uncommon in Ecuador. Generally rare in Peru, though locally not uncommon, e.g. near Iquitos. In Brazil, common along R Urucu, in Amazonas, but less frequent in N Mato Grosso. Reported rarity may perhaps be simply a result of its extreme unobtrusiveness, but this species appears to be highly sensitive to habitat disturbance. Present in several protected areas, e.g. Amacayacu National Park (Colombia), Manu National Park (Peru) and Cristalino River Private Reserve (Brazil).

**Bibliography.** Bierregaard (1988), Chapman (1917, 1926), Cohn-Haft *et al.* (1997), Cory (1919), Dugand & Borrero (1946), Friedmann (1948), Gilliard (1949a), Griscom & Greenway (1941), Gyldestolpe (1945a, 1951), Haverschmidt & Mees (1994), Hellmayr (1910), Henriques & Oren (1997), Hilty & Brown (1986), Maxwell (1937), Meyer de Schauensee (1951), Meyer de Schauensee & Phelps (1978), O'Neill (1969), O'Neill & Pearson (1974), Olivares (1962, 1964b), Pearson *et al.* (1977), Peres & Whittaker (1991), Phelps & Phelps (1958), Pinto (1938b, 1953), Ridgely & Greenfield (2001), Robbins *et al.* (1987), Sclater & Salvin (1893), Sick (1993), Sneath (1914), Snyder (1966), Stotz, Fitzpatrick *et al.* (1996), Stotz, Lanyon *et al.* (1977), Thiollay (1992), Thiollay & Julien (1998), Tostain *et al.* (1992), Traylor (1958), Willard *et al.* (1991), Willis (1982b), Zimmer *et al.* (1997).

## Genus *NYSTALUS* Cabanis & Heine, 1863

### 10. Barred Puffbird

#### *Nystalus radiatus*

**French:** Tamatia barré

**German:** Grünschnabel-Faulvogel

**Spanish:** Buco Barrado

**Taxonomy.** *Bucco radiatus* P. L. Sclater, 1854. Nova Grenada = Magdalena Valley, Colombia.

May form a superspecies with *N. striolatus*. Form described as race *fulvidus* is probably only a colour morph. Monotypic.

**Distribution.** C Panama E to W Colombia and S to W Ecuador.

**Descriptive notes.** 22 cm; 63 g. Rufescent overall, with black barring; large whitish loreal spot grading to pale rufous-white stripe over eye; blackish crown with dark rufous bars widest on forehead, grading to narrow, more spot-like bars near nape; upper napeband solid black, lower pale yellowish-rufous; black upper mantle broken by rufous spotting, grading to dark chestnut rear upperparts and wings with narrow black bands; primaries less regularly barred, blotchier on outer feathers; tail long, narrow, slightly graduated, chestnut with narrow black bands; chin whitish, grading to pale rufous underparts with fine blackish barring

except on central abdomen; undertail-coverts brighter rufous; bill greyish-yellow to blackish; iris creamy-yellow; feet greenish-grey. Probable dark rufous morph ("*fulvidus*") deeper rufous all over, rufous line above eye indistinct. Immature has shorter bill, paler hindcollar, paler with chevron-like

marks below. **VOICE.** Call a long, slow, ventriloquial and very human-like wolf-whistle, "phweeeeee- weeeeeeuuuu", c. 4-5 seconds long, repeated about twice per minute.

**Habitat.** Lower storeys of lowland humid and wet forest borders, second-growth woodland, edges of forest trails, relatively open streamside vegetation, overgrown clearings with scattered trees, and thickets in open plains; locally in Ecuador, can regularly be seen perching on wires over agricultural land. Occurs up to 900 m, and locally up to 1500 m above Mindo (Ecuador).

**Food and Feeding.** Beetles, Orthoptera, large caterpillars, and small lizards. Foraging behaviour apparently not reported.

**Breeding.** Apparently breeds about Mar in Ecuador. No other information on breeding or reproductive biology.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Locally common in Colombia, but rarely seen. Uncommon to fairly common in Ecuador: present in Río Palenque Science Centre, and occurs along Chiriboga (Old Santo Domingo) Road.

**Bibliography.** Allen (1998), Angehr (2001), Best *et al.* (1997), Brosset (1964), Burton (1973), Chapman (1917, 1926), Cory (1919), Engelman (1997), Goodfellow (1902), Haffer (1967b, 1975), Hilty & Brown (1986), Kirwan & Marlow (1996), Olivares & Romero (1973), Ridgely & Greenfield (2001), Ridgely & Gwynne (1989), Ridgely *et al.* (1998), Ridgway (1914), Robbins & Ridgely (1990), Robbins *et al.* (1985), Rodner *et al.* (2000), Rodríguez (1982), Salvin & Godman (1888-1904), Stotz *et al.* (1996), Taylor (1995), Wetmore (1968a).

## 11. White-eared Puffbird

### *Nystalus chacuru*

**French:** Tamatia chacuru

**German:** Weißohr-Faulvogel

**Spanish:** Buce Chacurú

**Taxonomy.** *Bucco chacuru* Vieillot, 1816, Paraguay.

Two subspecies recognized.

**Subspecies and Distribution.**

*N. c. uncirostris* (Stolzmann, 1926) - E Peru, NE Bolivia and adjacent Brazil.

*N. c. chacuru* (Vieillot, 1816) - NE, E & S Brazil, E Paraguay and NE Argentina.

**Descriptive notes.** 21-22 cm; 48-64 g. White above bill, becoming narrow white crown-stripe; short pale supercilium; white upper ear-coverts, malar region and throat; large black patch mainly on lower ear-coverts connecting to black postocular line; dark brown crown variably spotted and barred dull rufous, broad white nuchal collar; mantle, dark brown rump and wings heavily dappled dark rufous, barred effect on tertials; tail medium length, slightly graduated, dark brown with narrow, widely spaced buffy bars, pale tip; whitish below, variably washed ochraceous, some narrow dark scalloping on breast, heavier on flanks; bill

reddish; iris brown or greyish-green; legs and feet dusky flesh-coloured or light olive-green. Immature has dusker bill, dark barring on nuchal collar, and blackish striations on underparts. Race *uncirostris* has larger bill, whiter underparts, slightly longer wing. **VOICE.** Loud, whistled whinnying song of c. 8 double low/high whistles, tremulous and descending, "fufu-fofo-fufu-fofo-fufufuu...", often by pair in duet.

**Habitat.** Mid-stratum and edge of tropical dry forest, second growth, gallery forest, open woodland, wooded grassland, *campos*, *cerrado*, tropical savanna, scrub, clearings, pastures, open country with scattered vegetation; also cultivated fields (e.g. coffee groves) bordering railroads, tree-lined streets in rural suburbs. Perches on telephone and fence wires and posts. Sometimes hunts along well-vegetated streams, and ranges from ground level to canopy. Recorded up to 2500 m in Peru.

**Food and Feeding.** Arthropods, and small vertebrates such as lizards, commonly taken from the ground. Invertebrate prey includes insects caught in mid-air, often along streams, but also non-flying animals such as millipedes (Diplopoda), centipedes (Chilopoda), scorpions (Scorpiones), and even velvet worms (*Peripatus*) and crabs. Vegetable matter also reported. Still-hunts from mid-levels.

**Breeding.** Sept-Dec in SE Brazil; at start of rains in C Brazil. Nest-hole dug in ground or bank, occasionally in road cutting or railroad embankment. Clutch 2-4 eggs. No information on incubation and fledging periods.

**Movements.** Mainly resident; apparently migratory in extreme S.

**Status and Conservation.** Not globally threatened. Uncommon and local in Peru; uncommon in Argentina; fairly common in Bolivia. Common in parts of SE & C Brazil (e.g. Bahia, Distrito Federal), moderately so in Rio Grande do Sul, fairly common in Mato Grosso; present in several protected areas in Brazil, including Itatiaia National Park, Serra da Canastra National Park, Brasília National Park, Emas National Park and Chapada dos Guimarães National Park.

**Bibliography.** dos Anjos & Schuchmann (1997), Antas & Cavalcanti (1988), Azara (1802-1805), Barnes *et al.* (1993), Belton (1984), Canevari *et al.* (1991), Capper *et al.* (2000), Carriker (1935), Chubb (1910), Cory (1919), Dubs (1992), Eckelberry (1962), da Fonseca (1922), Gyldenstolpe (1945b), Hayes (1995), Hellmayr (1929), Laubmann (1930, 1939), Lourenco & Dekeyser (1976), Mitchell (1957), Oniki & Willis (1999), Parker & Bailey (1991), Parker *et al.* (1982), Pearman (1993b), de la Peña (1994), Pinto (1936, 1940, 1943, 1944a, 1944b, 1948, 1952), Pinto & Camargo (1948), Raw (1997), Remsen (1986), do Rosário (1996), Saibene *et al.* (1996), Schmitt *et al.* (1997), Schubart *et al.* (1965), Selater & Salvin (1879), Scott & Brooke (1985), Sick (1958b, 1993), Sneathlage (1927-1928), Stotz *et al.* (1996), Willis (1992), Willis & Oniki (1990, 1991).

## 12. Striolated Puffbird

### *Nystalus striolatus*

**French:** Tamatia striolé

**German:** Strichelfaulvogel

**Spanish:** Buce Estriado

**Taxonomy.** *Bucco striolatus* Pelzel, 1856, Dourado and Engenho do Capitão Gama, Rio Guapore, Mato Grosso, Brazil.

May form a superspecies with *N. radiatus*. Two subspecies recognized.

**Subspecies and Distribution.**

*N. s. striolatus* (Pelzel, 1856) - upper Amazon in E Ecuador, E Peru, W & C Brazil, and N Bolivia.

*N. s. torridus* Bond & Meyer de Schauensee, 1940 - NC Brazil (E Pará S of Amazon).

**Descriptive notes.** 20 cm; 47 g. White loreal spot, chin and upper throat, buffy sides of head and supercilium finely streaked dusky; dark brown crown broadly barred rufous, becoming mostly blackish at nape; broad buffy hindcollar; upper mantle blackish, dark brown rest of upperparts with buffy-

**Habitat.** Canopy, subcanopy and edges of humid lowland tropical forest, *terra firme* and low-lying swamp-forest, also transitional forest, forest openings, second growth, usually near water and/or clearings; also foothill forest to 1700 m in Ecuador (Cordillera de Cutucú).

**Food and Feeding.** No information on diet. Still-hunts from canopy, or sometimes in middle storey.

**Breeding.** Sept in Peru. Nest in underground cavity; 4 eggs. No other information available.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Rare to locally uncommon in Ecuador, though may be overlooked. Fairly common in Peru, where holds mean territory size of 9 ha at Cocha Cashu. Locally quite common in Brazil; frequently recorded in Cristalino River Private Reserve. Rarely recorded in Bolivia. Densities may reflect habitat preference: 5-0 territories/km<sup>2</sup> in middle successional-stage woodland (*Ficus/Cedrela*), 13-0 in later *Ficus/Cedrela* transitional forest, 7-0 in mature floodplain forest.

**Bibliography.** Best *et al.* (1997), Bond & Meyer de Schauensee (1940), Brace & Hornbuckle (1998), Brace *et al.* (1997), Chapman (1921b, 1926), Clements & Shany (2001), Cory (1919), Donahue (1994), Dubs (1992), Parker *et al.* (1982), Pelzel (1867-1871), Pinto (1947), Remsen *et al.* (1986), Ridgely & Greenfield (2001), Ridgely *et al.* (1998), Robbins *et al.* (1987), Robinson & Terborgh (1997), Rodner *et al.* (2000), Sick (1993), Sneathlage (1927-1928), Stotz *et al.* (1996), Taylor (1995), Terborgh *et al.* (1990), Zimmer, J.T. (1930), Zimmer, K.J. *et al.* (1997).

## 13. Spot-bellied Puffbird

### *Nystalus maculatus*

**French:** Tamatia tamajac

**German:** Fleckmantel-Faulvogel

**Spanish:** Buce Durmili

**Other common names:** Spot-backed Puffbird; Streak-bellied Puffbird (*striatipetis*)

**Taxonomy.** *Alcedo maculata* J. F. Gmelin, 1788, Brazil = Ceará.

Race *striatipetis* may be a separate species, on basis of morphology, but vocalizations apparently similar; further study required in zone of probable contact, in Pantanal. Proposed race *parvirostris* (C Brazil) not reliably separable from nominate; *pallidigula* (SW Brazil) synonymous with *striatipetis*, showing only minor, apparently clinal, differences. Two subspecies currently recognized.

**Subspecies and Distribution.**

*N. m. maculatus* (J. F. Gmelin, 1788) - NE & C Brazil (to SW Mato Grosso).

*N. m. striatipetis* (P. L. Selater, 1854) - SC & SE Bolivia (Cochabamba, Chuquisaca, Santa Cruz) and SC Brazil (W Mato Grosso do Sul) S to W & C Paraguay and NW Argentina (S to Córdoba).

**Descriptive notes.** 18-19 cm; 32-38 g (nominate), 33-42 g (*striatipetis*). Off-white feathers around base of bill and face lightly marked dusky, ear-coverts more heavily streaked, postocular streak and malar even more so; buffy supercilium; dark brown crown boldly spangled buffy; pale rufous hindcollar; mantle and wing-coverts to uppertail-coverts barred and spangled buffy; tail long, narrow, slightly graduated, broadly banded black with narrow buffy bars and tip; underparts mainly white, bright orange-rufous lower throat, upper breast and sides of neck; lower breast and sides boldly spotted black, flanks streaked black; lower central

underparts white, flanks and undertail-coverts buffier; bill mainly red with dusky base, culmen and tip; iris pale yellow; legs rather long, feet brownish-olive. Immature has short dusker bill, paler hindcollar and breast, underpart spotting shaped as diamonds or streaks. Race *striatipetis* has face more heavily streaked, hindcollar paler, crown spotting whiter, upperparts less spangled, tail more narrowly banded, breast more extensively but paler rufous, lower breast and upper flanks streaked rather than spotted, bill thinner, more arched, duller. **VOICE.** Undulating "tewre-tewretewretewre"; *striatipetis* also has disyllabic 3-note whistle, "tuhú tuhú tuhú", repeated at intervals; sings in duos or trios.

**Habitat.** Low and medium levels in the *cerrado*, *caatinga* and *campo* regions, occupying lowland and foothill semi-deciduous woodland and woodland edge, savanna and palm groves, arboreal-arbustive *caatinga*, shrubs, scrub, pastures and cultivation. In S of range (*striatipetis*), in chaco, dry subtropical forest, transitional forest, isolated woodland patches; in arid montane vegetation in Bolivia, extending above 2000 m. Perches on wires by railroads.

**Food and Feeding.** Chiefly insects, including caterpillars; recorded taking colubrid snake *Chironius flavolineatus* in Brazil. Still-hunts from low perches, capturing prey on ground or foliage.

**Breeding.** Apparently unrecorded for nominate race. Race *striatipetis* breeds in Oct in Paraguay, in Jan-Feb in Bolivia. Nest in underground cavity, lined with leaves, in earth bank or level soil. Clutch 2-3 eggs. Incubation and fledging periods not documented.

**Movements.** Presumably resident; possibly some seasonal wandering by nominate race in parts of EC Brazil.

**Status and Conservation.** Not globally threatened. Common in NE Brazil, including inside Serra da Capivara National Park, in Piauí; in 1947, described as one of the commonest birds in Pernambuco. Race *striatipetis* supposedly rare in Paraguay, but probably under-recorded; common in S Brazil; in Argentina, common in Jujuy and Salta, uncommon in Córdoba.

**Bibliography.** Canevari *et al.* (1991), Contino (1980), Contreras *et al.* (1990), Cory (1919), Dubs (1992), Fjeldså & Mayer (1996), Friedmann (1927), Hartert & Venturi (1909), Hayes (1995), Henriques & Oren (1997), Krabbe *et al.* (1996), López de Casenave *et al.* (1998), Medeiros-Neto *et al.* (1997), Ménégau (1925), do Nascimento (2000), Norez *et al.* (1983), Novas (1992), Olmos (1993), de la Peña (1994, 1997), Pereira (1950), Pinto (1935, 1947), Pinto & Camargo (1961), Piratelli, Pereira & Siqueira (1996), Piratelli, Siqueira & Marcondes-Machado (2000), Remsen *et al.* (1986), Salvadori (1895), Sargeant & Wall (1996), Schmitt *et al.* (1997), Schubart *et al.* (1965), Short (1975, 1976), Sick (1993), da Silva (1991), Steinbacher (1962), Stotz *et al.* (1996), Todd (1943a), Tubelis & Tomás (1999), Wetmore (1926), Willis (1992), Willis & Oniki (1993).

## Genus *HYPNELUS* Cabanis & Heine, 1863

### 14. Russet-throated Puffbird

#### *Hypnelus ruficollis*

**French:** Tamatia à gorge rousse    **German:** Rostkehl-Faulvogel    **Spanish:** Buco Bobito

**Taxonomy.** *Capito ruficollis* Wagler, 1829, Mexico; error = Santa Marta, Colombia. Forms a superspecies with *H. bicinctus*, and often considered conspecific owing to hybridization in Maracaibo region of Venezuela and in Catatumbo lowlands of Colombia; however, hybridization apparently rather limited, with most individuals belonging clearly to one or the other of these well-distinguished forms, and treatment as separate species seems the most realistic approach, pending in-depth studies. Proposed race *striaticollis* (NW Venezuela) may form part of a cline and herein included in *decolor*, but further study required. Three subspecies currently recognized.

#### **Subspecies and Distribution.**

*H. r. decolor* Todd & Carriker, 1922 - extreme NE Colombia (Guajira Peninsula) and NW Venezuela (Falcón).

*H. r. ruficollis* (Wagler, 1829) - N Colombia, and NW Venezuela W of L Maracaibo.

*H. r. coloratus* Ridgway, 1914 - W Venezuela (S of L Maracaibo).

**Descriptive notes.** 20-22 cm; 41-57 g. Head dark brown, rufescent spot over nares, rufous and white spot in front of eye, whitish cheek patch, crown spotted pale brown; partial buffy or white hindcollar; dull brown upperparts mottled greyish, notably on scapulars and tertials; wing-coverts buff-edged, rump and uppertail-coverts buffy-scaled; tail long, square-tipped, slightly graduated, dark brown with narrow pale edgings; chin white, rich rufous lower throat and upper breast, whitish breastband, broad black lower breastband, rest of underparts buffy-rufous with some black spots or bars on sides; bill all black; iris yellow to white; feet black or dull green. Immature has buffy scaling above and on breastband and ear-coverts, paler throat, shorter pale-tipped bill, spottier flanks, finely dark-marked sides of neck. Race *decolor* paler above, especially on cheeks, whiter lower breast and belly with less black barring on flanks; *coloratus* as nominate, but has blacker cheeks, deeper orange throat patch, and richer orange-buff underparts. **Voice.** Noisy, duets with repeated rhythmic "woduk" notes in crescendo for up to 20 seconds, then diminishing, ending with only 1 bird calling; high insect-like "seeeeep" call.

**Habitat.** Low-lying areas in open deciduous forest and edge, tree savanna, along waterbodies, dense second growth, woodland, arid scrub with scattered trees, dry thickets.

**Food and Feeding.** Many beetles found in one stomach, seeds in another; diet presumably much as for other Bucconidae, but in one emetic sample invertebrates (9 species) composed 87% and fleshy fruit (1 species) 13%.

**Breeding.** May in Colombia. Nest in arboreal termitarium; sometimes takes over the oven-shaped nest of Pale-legged Hornero (*Furnarius leucopus*). Clutch 3 eggs. No details of incubation and fledging periods.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Common to abundant along the dry littoral open woods of Colombia; less common in heavier forest. Occurs in Salamanca National Park (Colombia) and Morrocoy National Park (Venezuela).

**Bibliography.** Barnes & Phelps (1940), Cory (1919), Dugand (1947), Haffer (1959, 1961, 1975), Haffer & Borrero (1965), Hilty & Brown (1986), Meyer de Schauensee & Phelps (1978), Olivares & Romero (1973), Phelps (1944), Phelps & Phelps (1958), Poulin *et al.* (1994), Ridgway (1914), Rodner *et al.* (2000), Salvin & Godman (1888-1904), Stotz *et al.* (1996), Todd & Carriker (1922), Vereza & Solórzano (1998), Vereza *et al.* (2000).

### 15. Two-banded Puffbird

#### *Hypnelus bicinctus*

**French:** Tamatia bifascié    **German:** Doppelband-Faulvogel    **Spanish:** Buco Bicinto  
**Other common names:** Double-banded Puffbird

**Taxonomy.** *Tamatia bicincta* Gould, 1837, Cayenne; error = Venezuela.

Forms a superspecies with *H. ruficollis*, and commonly treated as conspecific owing to hybridization in Maracaibo region of Venezuela and in Catatumbo lowlands of Colombia; however, hybridization apparently rather limited, with most individuals belonging clearly to one or the other of these well-distinguished forms, and treatment as separate species seems the most realistic approach, pending in-depth studies. Two subspecies recognized.

#### **Subspecies and Distribution.**

*H. b. bicinctus* (Gould, 1837) - interior NE Colombia (in *llanos*), and N Venezuela (S to NE Bolívar and NW Amazonas).

*H. b. stoicus* Wetmore, 1939 - Margarita I, off N Venezuela.

**Descriptive notes.** 20-21 cm; 35-44 g. Head dark brown, buff from nares to eye, whitish cheek patch; partial whitish hindcollar; dull brown upperparts with whitish mottling, notably on scapulars and tertials, whitish edgings to wing-coverts; tail long, square-tipped, slightly graduated, dark brown with narrow pale edgings; chin whitish, grading to buffy-rufous underparts; two black breastbands, upper broader and joining with black patch on lower face, lower narrow and somewhat broken, thin partial black band across belly, black spots on flanks; bill all black; iris yellow, bare orbital ring blackish; feet dark grey. Differs from *H. ruficollis* in paler throat, double breastband, paler mottling above. Immature has black areas sullied with brown. Race *stoicus* slightly browner and paler above, larger bill, less marked face, upper breastband with buffy tips. **Voice.** Song a rhythmic repeated "tak-ta-tóoo"; call a croaking note, surprisingly loud, sometimes given in flight.

**Habitat.** Occupies areas of thinly wooded tropical savanna (*llanos*), thickets, abandoned cultivation, streamside trees, and upper stages and edges of deciduous woodland, perching on thin open shaded branches under canopy, restricted to lowlands, below 500 m. Found in bushland and woods on plains and in foothills on Margarita I.

**Food and Feeding.** Small beetles, dragonflies and other insects found in gizzards and stomachs. Still-hunts from exposed high perch on thin branches, or shaded, mid-storey or subcanopy perch.

**Breeding.** May and Jun, and recent fledgling seen in Dec, in Venezuela. Excavates nest in arboreal termitarium. No information on clutch size, nor on incubation and fledging periods.

**Movements.** No seasonal movements recorded, although a species of seasonal habitat. Nevertheless, observed to be absent from an area for several years, then very common in that same area.

**Status and Conservation.** Not globally threatened. Generally common in Venezuela. Common throughout much of *llanos*, where vast areas of suitable habitat remain, and human land uses do not appear to pose any immediate threats. On Margarita I, extremely common at Ochenta in 1930's, but no recent details regarding current status.

**Bibliography.** Beebe (1909), Carriker (1955), Cherie (1916), Cory (1919), Friedmann (1948), Friedmann & Smith (1950, 1955), Gines *et al.* (1953), Hilty & Brown (1986), Lowe (1907), Meyer de Schauensee (1982), Olrog (1968), Phelps & Phelps (1958), Robinson & Richmond (1895), Rodner *et al.* (2000), Schäfer & Phelps (1954), Vereza *et al.* (1999), Wetmore (1939), Yeppez *et al.* (1940).

## Genus *MALACOPTILA* G. R. Gray, 1841

### 16. Crescent-chested Puffbird

#### *Malacoptila striata*

**French:** Tamatia rayé    **German:** Halbmond-Faulvogel    **Spanish:** Buco Rayado  
**Other common names:** Striated Puffbird

**Taxonomy.** *Bucco striatus* Spix, 1824, Rio de Janeiro and Bahia, Brazil.

Two subspecies recognized.

#### **Subspecies and Distribution.**

*M. s. minor* Sassi, 1911 - NE Brazil (N Maranhão).

*M. s. striata* (Spix, 1824) - E & SE Brazil (S Bahia S to Santa Catarina).

**Descriptive notes.** 17.5-20 cm; 41-45 g. Rufescent around base of bill to above and in front of eye, moustache buffy or white; rest of head blackish, streaked buffy, continuing to blackish upperparts; dark brown uppertail-coverts tipped or scalloped rufous-brown; dark brown wings, small buffy arrow-shaped tips on coverts; tail longish, steeply graduated, dark brown; white crescent on upper breast, bordered below by broad black band; diffuse rufous area below band in centre of breast, grading to dull brown sides scalloped buffy; centre of belly whitish; bill all black; iris brown, bare orbital ring blackish; feet bluish or grey.

Immature not described. Race *minor* smaller, breast brighter, lower underparts whiter. **Voice.** High whistle of 10 or more notes, like a small tyrannid, "bieh, bieh, bieh...".

**Habitat.** Interior of humid lowland forest with abundance of fallen leaves; logged forest, second-growth forest, forest edges with grass. Usually stays low at edges of clearings, roads and other openings, more rarely moving into deeper forest. Ranges up to 2100 m.

**Food and Feeding.** Observed taking prey at an army-ant swarm along a dirt road. No other information.

**Breeding.** Apr and Oct in São Paulo state, in SE Brazil. Nest excavated in earth bank along road. Clutch size and incubation and fledging periods not documented.

**Movements.** Status unclear; a summer migrant, Sept-Mar, to Atlantic Forest in São Paulo state.

**Status and Conservation.** Not globally threatened. Little known, and no data on relative abundance. Occurs in Nova Lombardia (Augusto Ruschi) Biological Reserve and Sooretama Biological Reserve, both in Espírito Santo.

**Bibliography.** Aguirre & Aldrich (1983), Aleixo & Galetti (1997), Cory (1919), Ferreira de Vasconcelos *et al.* (1999), Figueiredo & Lo (2000), Goerck (1999), Holt (1928), Machado (1996), Mallet-Rodrigues *et al.* (1997), Mitchell (1957), Oniki (1981), Oniki & Emerson (1981), Parker & Goerck (1997), Pinto (1952), do Rosário (1996), Sargeant & Wall (1996), Schubart *et al.* (1965), Scott & Brooke (1985), Sick (1993), Sick & Pabst (1968), Stotz *et al.* (1996), Venturini *et al.* (2001), Willis (1982c).

### 17. White-chested Puffbird

#### *Malacoptila fusca*

**French:** Tamatia brun    **German:** Weißbrust-Faulvogel    **Spanish:** Buco Pechiblanco

**Taxonomy.** *Bucco fuscus* J. F. Gmelin, 1788, Cayenne.

Forms a superspecies with *M. semicincta*. Birds from S Venezuela sometimes separated as race *venezuelae*, but appear indistinguishable from other populations. Monotypic.

**Distribution.** E Ecuador and SE Colombia E to S Venezuela and the Guianas and S to NE Peru and N Brazil (N of Amazon).

**Descriptive notes.** 18-19 cm; 39-45 g. Head and upperparts mostly dark brown with conspicuous buffy shaft streaks; background colour of crown blackish-brown; whitish lores, whiskers and chin; tail medium length, strongly graduated, warm brown; white patch on upper breast; streaks on lower breast grade into vaguely striped and mottled belly; flanks, centre of belly and undertail-coverts whiter; bill black on upper mandible except basal third, black on distal half of lower, rest yellow to pinkish; iris yellow or red; feet pale olive. Immature has dark brown eye, bill more yellow. VOICE. High thin "seeee", sometimes lasting 2

seconds and descending.

**Habitat.** From near the ground to middle storey in primary humid evergreen *terra firme* forest on well-drained soils, second-growth woodland, plantations, woodland borders, saplings along riversides, clearings with scattered trees. Generally occurs up to 750-900 m, but locally even up to 1200 m.

**Food and Feeding.** Large insects, notably Orthoptera (Acrididae), as well as caterpillars; also Arachnoidea (Araneida). Makes sharp sallies from perch to take prey from low branches or ground. Occasionally follows ant swarms and also mixed-species flocks. Usually solitary, but sometimes in pairs.

**Breeding.** No certain information. Observer close to hole in arboreal termitarianium elicited alarm calls.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. In Ecuador, generally uncommon but locally quite common. Uncommon in Peru and Amazon region. Apparently nowhere very common; often considered rare, but is also particularly unobtrusive, so may often be under-recorded. Occurs in Amacayacu National Park (Colombia) and in Cuyabeno Reserve (Ecuador).

**Bibliography.** Bierregaard (1988), Clements & Shany (2001), Cohn-Haft *et al.* (1997), Cory (1919), Dugand & Phelps (1948), Haverschmidt & Mees (1994), Hilty & Brown (1986), Meyer de Schauensee & Phelps (1978), Newman (1993), Parker *et al.* (1982), Penard & Penard (1908-1910), Phelps & Phelps (1947), Reynaud (1998), Ridgely & Greenfield (2001), Ridgely *et al.* (1998), Rodner *et al.* (2000), Sick (1993), Snyder (1966), Stotz & Bierregaard (1989), Stotz *et al.* (1996), Thiollay (1992), Thiollay & Jullien (1998), Tostain *et al.* (1992), Traylor (1951a), Willis (1982c), Zimmer (1930).

## 18. Semicollared Puffbird

### *Malacoptila semicincta*

**French:** Tamatia à semi-collier **German:** Halbring-Faulvogel **Spanish:** Buceo Mediocollar

**Taxonomy.** *Malacoptila semicincta* Todd, 1925, Hyutanahan, Rio Purús, Brazil.

Forms a superspecies with *M. fusca*, Monotypic.

**Distribution.** Extreme W Brazil, SE Peru and NW Bolivia.

**Descriptive notes.** 18-19 cm; 44 g. Blackish-brown head and upperparts with conspicuous pale shaft streaks; rufous hindcollar; white lores, whiskers and chin; tail medium length, strongly graduated, brown; thin white patch on upper breast; blackish streaks on lower breast, paler and more diffuse on flanks, rest of underparts whitish; bill black on upper mandible except base, black tip of lower, rest orange-yellow; iris dark red, white eye-ring; feet pale greenish-flesh. Differs from *M. fusca* in whiter crown streaks, rufous hindcollar, more orange bill, more extensive black on upper mandible but less on lower; darker eye, white

eyering; paler feet. Immature slightly duller. VOICE. A series of thin, rather high-pitched, melancholy, descending "Féféur" or "pseuu" whistles, each at first widely spaced, less than 1 second long, and starting on the same pitch; then dropping in pitch, "pseuu-uuu-uuu", several being given in rapid succession without pause on the same lower pitch. A second bird may simultaneously give a few higher, well-spaced whistles.

**Habitat.** Inhabits understorey, undergrowth and lower middle storey at edges of humid tropical lowland *terra firme* evergreen forest, and also transitional forest. Occurs from sea-level up to 1050 m.

**Food and Feeding.** No information available.

**Breeding.** No information.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Restricted-range species: present in South-east Peruvian Lowlands EBA. Occurs in Tambopata Reserve, Peru. Has been judged to be rare, but 2-3 pairs/km<sup>2</sup> found in mature floodplain-forest at Cocha Cashu, in Peru. In Brazil, uncommon along R Urucu, in Amazonas.

**Bibliography.** Allen (1995), Angehr & Aucca (1997), Clements & Shany (2001), Donahue (1994), Gyldestolpe (1945b, 1951), Meyer de Schauensee (1982), Morrone (2000), Novaes (1957), Olrog (1968), Parker *et al.* (1982), Peres & Whittaker (1991), Remsen & Traylor (1989), Robinson & Terborgh (1997), Seilern (1934), Sick (1993), Stotz *et al.* (1996), Terborgh *et al.* (1990), Todd (1925), Traylor (1951a).

## 19. Black-streaked Puffbird

### *Malacoptila fulvogularis*

**French:** Tamatia à gorge fauve **German:** Ockerkehl-Faulvogel **Spanish:** Buceo Listado

**Taxonomy.** *Malacoptila fulvogularis* P. L. Sclater, 1854, Bolivia.

May form a superspecies with *M. panamensis* and *M. mystacalis*. Previously recognized Colombian races *substriata* (Meta) and *huilae* (Huila) remain poorly known and are probably invalid. Monotypic.

**Distribution.** E slope of Andes from C Colombia to S Ecuador, Peru and NW Bolivia.

narrow white eye-ring; feet dark. Immature not described. VOICE. Song is a very high-pitched ascending whistle, lasting under 4 seconds.

**Habitat.** Understorey of humid primary subtropical and montane forest and open woodland on E Andean foothill and lower slopes, at 500-2300 m; in Bolivia penetrates dry and semi-deciduous forest.

**Food and Feeding.** Large invertebrates recorded. Perches immobile for long periods in middle or lower storeys, periodically making sudden sallies forth to take prey from branches or leaves. Sometimes follows ant swarms and joins mixed-species feeding flocks.

**Breeding.** No information.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Few localities known in Colombia. Generally uncommon in Ecuador, but fairly common in R Bombuscaro area of Podocarpus National Park. Uncommon in Peru; occurs on Cuzco-Manu Road. Apparently rare in Bolivia, but occurs along La Paz-Coroico Road.

**Bibliography.** Best *et al.* (1997), Chapman (1926), Clements & Shany (2001), Cory (1919), Dunning (1993), Hilty & Brown (1986), Hornbuckle (1999), Meyer de Schauensee (1945, 1946a), Parker *et al.* (1982), Perry *et al.* (1997), Remsen & Traylor (1989), Ridgely & Greenfield (2001), Ridgely *et al.* (1998), Robbins *et al.* (1987), Rodner *et al.* (2000), Salaman *et al.* (1999), Stotz *et al.* (1996), Taylor (1995), Williams & Tobias (1994), Zimmer (1930).

## 20. Rufous-necked Puffbird

### *Malacoptila rufa*

**French:** Tamatia à col roux **German:** Goldstirn-Faulvogel **Spanish:** Buceo Cuellirrojo

**Taxonomy.** *Bucco rufus* Spix, 1824, "in sylvis fl. Amazonum" = São Paulo de Olivença, westernmost north Brazil.

Two subspecies recognized.

**Subspecies and Distribution.**

*M. r. rufa* (Spix, 1824) - S of Amazon from NE Peru to W Brazil (E to R Madeira) and S to E Bolivia and E Mato Grosso.

*M. r. brunnescens* J. T. Zimmer, 1931 - S Amazon Basin E of R Madeira (N Brazil).

**Descriptive notes.** 18 cm; 36-44 g. Large rufous loreal spot, dark grey crown and upper ear-coverts streaked pale; full dark rufous collar, at rear grading into rather dark brown mantle and rest of upperparts, warmer on uppertail-coverts and tail edgings; tail brown; white patch on upper breast with narrow black band below, patch of rufous-brown on lower breast grading to paler dull brown on lower underparts, whiter in centre of belly; bill dark blue-greyish on upper mandible, largely paler blue-grey on lower; iris dark brown or dark red, thin bluish orbital ring; feet olive-grey. Immature slightly paler and duller. Race

*brunnescens* has stronger white streaks on darker grey crown, with paler rufous lores and forehead, and slightly less rufous upperparts. VOICE. Song a high, thin, descending, slightly modulated whistle lasting c. 1.5-3.0 seconds; call similarly high, thin, slightly descending plaintive "seeeee", c. 0.5 seconds.

**Habitat.** Understorey (1-10 m) of primary humid *terra firme* forest, edges, *várzea* undergrowth, *igapó*, low and vine-rich riverine forest, and *cerrado*.

**Food and Feeding.** No information on food, except that an individual at an ant swarm took tiny prey off a leaf. Still-hunts from low to mid-level perch, capturing prey in lower foliage. Sometimes joins mixed-species flocks, and follows army ants.

**Breeding.** Nest reported as tunnel 0.5 m long in ground. No other details reported.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. In Brazil, common in part of Rondônia but uncommon on R Urucu, in Amazonas; rare in Mato Grosso, but frequently recorded near Alta Floresta. Rare in Peru, where has been recorded in Pacaya Samiria National Reserve. Occurs in Noel Kempff Mercado National Park, Bolivia.

**Bibliography.** Begazo & Valqui (1998), Clements & Shany (2001), Cory (1919), Gyldestolpe (1951), Henriques & Oren (1997), Hilty & Brown (1986), Novaes (1970, 1976), Oren & Parker (1997), Parker *et al.* (1982), Peres & Whittaker (1991), Pinto (1947), Schönwetter (1967), Schubart *et al.* (1965), Sick (1993), da Silva (1995), da Silva *et al.* (1990), Sneath (1914, 1935), Stotz, Fitzpatrick *et al.* (1996), Stotz, Lanyon *et al.* (1997), Willis (1982c), Zimmer, J.T. (1931), Zimmer, K.J. *et al.* (1997).

## 21. White-whiskered Puffbird

### *Malacoptila panamensis*

**French:** Tamatia de Lafresnaye **German:** Weißzügel-Faulvogel **Spanish:** Buceo Barbón  
Other common names: Brown Puffbird

**Taxonomy.** *Malacoptila panamensis* Lafresnaye, 1847, Panama.

May form a superspecies with *M. fulvogularis* and *M. mystacalis*. Birds from SE Nicaragua to W Panama sometimes separated as race *fuliginosa*, but this name probably based on an aberrant bird and these populations are indistinguishable from *inornata*; birds from Pacific coast of Chocó, NW

Colombia, described as race *chocoana*, inseparable from *panamensis*. Four subspecies currently recognized.

#### Subspecies and Distribution.

*M. p. inornata* (Du Bus de Gisignies, 1847) - Caribbean slope from SE Mexico (N Chiapas, E Tabasco) to W Panama (including Bocas del Toro).

*M. p. panamensis* Lafresnaye, 1847 - Pacific slope from SW Costa Rica to NW Colombia.

*M. p. magdalenae* Todd, 1943 - Magdalena Valley (WC Colombia).

*M. p. poliopis* P. L. Slater, 1862 - SW Colombia and W Ecuador.

**Descriptive notes.** 18-21 cm; 33-46 g. Male mainly rufous, in particular on lores and on supercilium; ear-coverts long with pale rufescent shaft streaks; whitish central streak on forehead; upperparts behind crown browner, speckled buffy; rump brighter rufous; wing dull brown with rufescent edgings; tail medium length, strongly graduated, bright rufous; elongate white malar feathers, rufescent throat and breast; lower breast to flanks streaked blackish, ground colour grading to whitish on sides and centre of belly; undertail-coverts dull buff; pale rufous inner webs of flight-feathers on underwing; bill black above,

pale horn below; iris red; legs and feet bluish-grey to dull yellow-green. Female greyer overall, breast tinged ochraceous, rest of underparts more streaked. Juvenile like adult of respective sex, but shorter-billed, female breast duller. Race *inornata* male almost unstreaked and completely rufous-washed below, crown tinged grey, female less boldly marked below; *poliopis* male rather rufous overall, heavily streaked below, female darker grey above than nominate, rufous breast, more strongly streaked below; *magdalenae* somewhat less dimorphic than other races, both sexes more strongly streaked below than nominate, male darker above and on ear-coverts. VOICE. Weak peep or high, thin whistles; high, faint "tsinnnn" in alarm; in territorial fights, various high-pitched squeaks and a rapidly repeated high "see-it-hee-hee" or similar phrase.

**Habitat.** Understorey (3-8 m) of primary humid and wet forest near treefalls, edge, older adjacent second growth, also younger forest, thicket-like tangled shaded second growth mixed with emergent trees, and wooded edges of openings with scattered trees generally; also shady pastures, cacao plantations, vine-tangled jungles, often along trails; in Honduras more a bird of interior forest. Lowlands to 900 m on Caribbean slope, to 1400 m on Pacific slope.

**Food and Feeding.** Large invertebrates, including scorpions (Scorpiones), spiders, roaches (Blattodea), crickets, mantids, stick-insects (Phasmida), beetles, neuropterans, caterpillars, termites, cicadas (Cicadidae), and especially large grasshoppers; also certain armour-plated terrestrial centipedes (Chilopoda) several inches long. The stomach of a gravid female was distended with insects, principally locusts. Vertebrate prey comprises small frogs, lizards and snakes, including poisonous coral snakes (Elapidae). Sallies from perch. Sometimes attends mixed flocks of small birds, or foraging swarms of army ants.

**Breeding.** Jul in Mexico; Apr-Jul in Nicaragua; Mar-Jul, main activity Apr-May, in Costa Rica; May-Aug in Panama, with digging noted Jan-Oct; Feb-Mar in Colombia. Nest in hole in level, slightly sloping or sometimes steeply sloping ground, usually in primary forest (once in tall secondary forest); occasionally hole in tree, bamboo stem or arboreal termitarium; sometimes same hole used in subsequent year. Clutch 2-3 eggs; incubation period unknown; nestling period 20 days.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Like many other species of tropical rainforest in Central America, it decreases rapidly from S to N, and is not really common anywhere N of Costa Rica. Very rare in Mexico; rare in Belize; rather rare in Nicaragua. Common in S Costa Rica, where the most frequently observed puffbird, most abundant in lowlands below 300 m; distinctly uncommon inside virgin forest, far more abundant in edge habitats; occurs in Caracara Biological Reserve and in Corcovado National Park, Costa Rica. Fairly common on Barro Colorado I, Panama; rare in Darién, E Panama, but common at low levels in adjacent NW Colombia. Common generally in NW Colombia, and abundant in coffee plantations. Fairly common locally in W Ecuador; present in Río Palenque Science Centre.

**Bibliography.** Álvarez del Toro (1980), Álvarez-López (1987), Anon. (1998b), Cariker (1910, 1955), Chapman (1917), Cory (1919), Dearborn (1907), Eisenmann (1957), González-García (1993), Haffer (1968, 1975), Hilty & Brown (1986), Howell, S.N.G. & Webb (1995), Howell, T.R. (1957), Land (1970), Meyer de Schauensee (1950), Monroe (1968), Olivares (1957), Richmond (1893), Ridgely & Greenfield (2001), Ridgely & Gwynne (1989), Ridgway (1914), Robbins *et al.* (1985), Rodríguez (1982), Russell (1964), Salaman (1994), Salvin & Godman (1888-1904), Skutch (1948c, 1958a), Slud (1960, 1964), Stiles (1985), Stiles & Skutch (1989), Stiles *et al.* (1999), Stotz *et al.* (1996), Tashian (1952), Taylor (1995), Wetmore (1968a), Willis (1980, 1982c), Willis & Eisenmann (1979).

## 22. Moustached Puffbird

### *Malacoptila mystacalis*

**French:** Tamatia à moustaches    **German:** Schnurrbart-Faulvogel    **Spanish:** Buco Bigotudo

**Taxonomy.** *Monasa mystacalis* Lafresnaye, 1850, Valparaíso, Santa Marta, north Colombia.

May form a superspecies with *M. fulvogularis* and *M. panamensis*. Population of SW Colombia possibly merits subspecific status, as race *pacifica*. Monotypic.

**Distribution.** Andes of Colombia and NW & N Venezuela.

**Descriptive notes.** 20-23 cm; 47-50 g. Male drab brown above; dark-bordered white area around lores and base of forehead, small blackish patch above nares, white half-ring at rear of eye; ear-coverts richer brown with pale shaft streaks; dark-surrounded white malar whiskers; chin feathers long, pale rufous; upperparts with white to buffy spots, large and in rows on wing-coverts, as narrow bars on back to uppertail-coverts; wings plain brown with narrow buffy edgings; tail longish, strongly graduated, brown with narrow buffy tips; throat to breast pale rufous, vague band of dark streaks around lower edge; lower flanks dull brown, barred and streaked whitish, central abdomen and undertail-coverts white; underwing-coverts and bases of remiges buffy; bill black, most of lower mandible bluish; iris red, dark orbital ring; feet silvery-bluish. Female gen-

**Breeding.** Evidence suggests Feb-Sept in Colombia, May-Aug in Venezuela. Nest in hole in earth bank. Clutch size and incubation and fledging periods not known.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Uncommon in Colombia. Fairly uncommon in Venezuela; occurs in Henri Pittier National Park.

**Bibliography.** Chapman (1917), Cory (1919), Donegan *et al.* (1998), Gines *et al.* (1953), Hellmayr (1911), Hilty (1997), Hilty & Brown (1986), Meyer de Schauensee (1982), Meyer de Schauensee & Phelps (1978), Olog (1968), Rodner *et al.* (2000), Salaman (1994), Schäfer & Phelps (1954), Stotz *et al.* (1996), Todd (1943a), Todd & Carriker (1922), Vélez & Velázquez (1998), Vereá & Solórzano (2001), Vereá *et al.* (1999), Wetmore (1939).

## Genus MICROMONACHA P. L. Slater, 1881

### 23. Lanceolated Monklet

#### *Micromonacha lanceolata*

**French:** Barbacou lancéolé    **German:** Streifenfaulvogel    **Spanish:** Monjilla Lanceolada

**Taxonomy.** *Bucco lanceolata* Deville, 1849, Pampa del Sacramento, upper Ucayali River, eastern Peru. Birds from Costa Rica to W Panama named as race *austinsmithi*, but characters weak and inconsistent. Monotypic.

**Distribution.** Caribbean slope of Costa Rica and WC Panama; also from SW & WC Colombia S on both sides of Andes, in W to NW Ecuador and in E to NE Peru, extreme W Brazil and N Bolivia.

**Descriptive notes.** 13-15 cm; 19-22 g. Entirely dark, buffy-scaled warm brown above; profuse long recurved whitish nasal tufts and chin feathers, black-bordered white loreal patch continuing across forehead, white rim at rear edge of eye; dark brown wings; tail shortish, narrow, rather graduated, brown above, grey below, with broad blackish subterminal bands and buffy tips; white underparts heavily but variably streaked black, most markedly on side of throat, with central belly plain white, undertail-coverts tinged ochraceous; buffy underwing-coverts and bases of remiges; bill black; iris brown; feet leaden, upper tarsi washed reddish-pink. Immature has less distinct face pattern, less streaking below. VOICE. Rarely heard, 1-5 high, thin, plaintive rising whistles, each slightly higher than preceding one; thin, high-pitched "tsip tsip" as contact call.

**Habitat.** Middle and upper storeys, shady open borders, edges and natural treefall clearings in primary forest and mature second growth, even in small forest patches and shaded coffee plantations; possibly showing some link to water, as sometimes perches over small streams; also middle and upper storeys of wet primary lowland and montane evergreen forest. Occurs at 300-2100 m, mostly below 1500 m.

**Food and Feeding.** Feeds on insects, including cicadas and katydids; also berries. Sallies for insects from exposed perch. Sometimes follows mixed-species flocks of small birds.

**Breeding.** May in Costa Rica; May in Ecuador; young being fed in Dec in Bolivia. One nest found in Ecuador was an excavated tunnel, 40 cm long, in a trail embankment; entrance 6 cm high by 5 cm wide; burrow curved down to enlarged chamber, floor of which littered with leaves. Clutch 2 eggs; estimated incubation period c. 15 days; no details available on fledging period.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Formerly considered Near-threatened. Has been described as rare throughout range, but this may reflect fact that this species is difficult to detect. Rare in Costa Rica. Few records from Panama; recorded along Oleoducto Road, in W Panama. Uncommon in W Colombia and in W Ecuador. Present in Jatun Sacha Biological Station, in E Ecuador, but habitat there possibly threatened by plans to construct a road through centre of the reserve. Regular records from SE Ecuador suggest that this area may be a stronghold, but equally the species may be evenly distributed throughout range. Common on R Urucu, in Amazonas (Brazil). Generally rare and local in Peru, but regularly recorded in area of R Sucuary, near Iquitos.

**Bibliography.** Allen (1998b), Anon. (1998), Balchín & Toyne (1998), Cardiff (1983), Chapman (1917), Collar *et al.* (1994), Cory (1919), Davis (1986), Dwight & Griscom (1924), Fjeldså & Krabbe (1986), Freile & Endara (2000), Gandy (1994, 1995), Hilty (1977, 1997), Hilty & Brown (1986), Hornbuckle (1999), Marin *et al.* (1992), Parker *et al.* (1982), Peres & Whittaker (1991), Ridgely & Greenfield (2001), Ridgely & Gwynne (1989), Sagot (1998), Salaman (1994), Sick (1993), Slud (1964), Stiles (1985), Stiles & Skutch (1989), Stotz *et al.* (1996), Taylor (1995), Wetmore (1968a), Williams & Tobias (1994), Young *et al.* (1998).

## Genus *NONNULA* P. L. Sclater, 1854

### 24. Rusty-breasted Nunlet

#### *Nonnula rubecula*

**French:** Barbacou rufalbin **German:** Rotkehl-Faulvogel **Spanish:** Monjilla Macurú

**Taxonomy.** *Bucco rubecula* Spix, 1824, Malhada, Rio São Francisco, western Bahia, Brazil. Forms a superspecies with *N. sclateri* and *N. brunnea*. Taxonomy uncertain and confused: listed races may involve more than one species; also some of listed races probably comprise more than one taxon (e.g. nominate race in E Brazil has plumage soft and silky, in SE of range plumage loosely webbed, in both cases numerous tonal differences from "typical" nominate); also validity of some recognized races possibly doubtful; extensive revision needed. Seven subspecies tentatively recognized.

#### **Subspecies and Distribution.**

*N. r. duidae* Chapman, 1914 - E Venezuela in S Amazonas (N of R Orinoco).  
*N. r. interfluvialis* Parkes, 1970 - S Venezuela (S of R Orinoco) S to R Negro in N Brazil.  
*N. r. tapanahoniensis* Mees, 1968 - S Guianas and N Brazil (N bank of lower Amazon).  
*N. r. simulatrix* Parkes, 1970 - SE Colombia, and NW Brazil (between R Negro and R Amazon).  
*N. r. cineracea* P. L. Sclater, 1881 - NE Ecuador, NE Peru, and W Brazil S of Amazon (S to Rondônia).  
*N. r. simplex* Todd, 1937 - S bank of lower Amazon, N Brazil.  
*N. r. rubecula* (Spix, 1824) - E & SE Brazil (Bahia and Goiás S to Paraná), E Paraguay and NE Argentina (Misiones).

**Descriptive notes.** 14-16 cm; 17-20 g. Whitish band from nasal tufts joining white eyering; blackish moustachial line, white chin; plain dark grey-brown upperparts and sides of head, greyer crown, slightly more rufescent uppertail-coverts and wing-coverts, secondaries edged buffy-rufescent (in E Brazil paler and greyer above, especially crown, lores rufous; in SE of range, much darker and browner overall, lores also rufous); tail square-tipped, rather graduated, dark brown (warmer brown in SE); throat to lower breast and flanks brown with rufescent tinge, abdomen grading to whitish (in E Brazil bright orange-rufous lower

throat to mid-belly, paler orange flanks, white central belly and vent, silver-grey undertail); underwing-coverts buffy; bill mainly black; iris brown; feet blackish-grey or brown. Immature duller, throat to breast drab pale brown, upperparts faintly edged rufescent, bill dark with pale tip. Races vary in structure and coloration, N races having longer, narrower bill with well-curved tip and paler gonyes, shorter tail with contrasting silvery edgings, whereas E Brazilian races have short, broad, straighter bill with darker gonyes, longer plain tail, and races N of Amazon with rufescent lores, S of Amazon paler and duller: *tapanahoniensis* has prominent dark grey crown, cinnamon-tinged vent; *duidae* has rufous lores and chin; *simulatrix* darker-tailed than last, *interfluvialis* greyer; *simplex* drab, dark; *cineracea* paler, warmer brown underparts than last. **VOICE.** Song a series of "weep, weep, weep" notes; repeated sharp "tick"; excited squealing in response to playback of *N. frontalis*.

**Habitat.** Found mainly in middle storey (but from ground level to canopy) of humid *terra firme* and (vine-bordered) *várzea* forest, and also second growth and forest edge with or without bamboo; mainly occurs in sandy-belt forest in Venezuela; occupies scattered riverine woods in SE Brazil (Paraná). Locally occurs in lowlands up to 1000 m. In upper Amazonia excluded from *igapó* forest by *N. amaurocephala*.

**Food and Feeding.** Large arthropods reported, including beetles, crabs and katydids (Orthoptera) up to 2.5 cm long. Sometimes follows mixed-species flocks.

**Breeding.** Immature seen in Nov in lower Amazon. Nest in hole in bank or in tree. No further details of nest, nor of clutch size or other aspects of breeding biology.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Widely reported as being rare, on basis of very low contact rates during fieldwork, but species is probably under-recorded owing to unobtrusive habits. Rare around Manaus (Amazon) and in SE Brazil, but in latter region variably rare to common in Paraná. Generally rare in Peru. Not uncommon around Sapucay, in Paraguay; occurs in several protected areas in that country, including Reserva Natural del Bosque Mbaracayú, La Golondrina Private Nature Reserve and Estancia Itabó Private Nature Reserve. Scarce in Argentina; occurs in Iguazú National Park. Only recently recorded in Ecuador, during 1990's, where occurs in Cuyabeno Reserve.

**Bibliography.** dos Anjos & Schuchmann (1997), dos Anjos *et al.* (1997), Barnes *et al.* (1993), Bierregaard (1988), Braun *et al.* (2000), Brooks *et al.* (1993), Canevari *et al.* (1991), Chapman (1914a), Chrostowski (1921), Chubb (1910), Cohn-Haft *et al.* (1997), Cory (1919), Ferreira de Vasconcelos *et al.* (1999), Friedmann (1948), Gyldestolpe (1951), Haverschmidt & Mees (1994), Hayes (1995), Hilty & Brown (1986), Machado (1999), Marini (2001), Mees (1968), Meyer de Schauensee & Phelps (1978), Novaes (1980), Olivares (1967), Oren & Parker (1997), Parkes (1970), de la Peña (1994), Piratelli *et al.* (2000), Ridgely & Greenfield (2001), Romero (1978), do Rosário (1996), Saibene *et al.* (1996), Sick (1993), Stotz *et al.* (1996), Todd (1919, 1937, 1943a), Tostain *et al.* (1992), Whittaker & Oren (1999), Whittaker *et al.* (1995), Willard *et al.* (1991), Zimmer & Hilty (1997).

### 25. Fulvous-chinned Nunlet

#### *Nonnula sclateri*

**French:** Barbacou de Sclater **German:** Gelbkinn-Faulvogel **Spanish:** Monjilla de Sclater

**Taxonomy.** *Nonnula sclateri* Hellmayr, 1907, Humaythá, Rio Madeira, Brazil.

Forms a superspecies with *N. rubecula* and *N. brunnea*; sometimes treated as a race of latter. Monotypic.

**Distribution.** SE Peru, W Brazil S of Amazon (E to R Madeira) and N Bolivia.

**Descriptive notes.** 14-15.5 cm; 15-17 g. Overall dull brown; lores rufous-brown; conspicuous grey patch below and behind eye, including ear-coverts; edgings to secondaries often buffy; chin pale rufous, grading to rufescent-brown of throat and breast; sides dull fulvous; abdomen grading to whitish in centre; undertail-coverts white; tail relatively long and narrow; bill largely black, partly grey below; iris brown, reddish eyering; legs pale brown to dark grey. Immature not described. **VOICE.** Song is a series of up to 30 plaintive "weep, weep, weep" notes, similar to that of *N. rubecula* but with more, longer and less

stressed notes.

**Habitat.** Occupies open understorey of humid primary and disturbed *terra firme* and *várzea* forest, and forest edge, commonly in or near bamboo thickets close to water. Restricted to lowlands.

**Food and Feeding.** No information on diet. May follow understorey bird flocks.

**Breeding.** No information.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. In Peru, rare overall, but locally common at Balta. In general, very infrequently encountered in Brazil. Status in Bolivia uncertain, but available evidence suggests it to be rare.

**Bibliography.** Clements & Shany (2001), Cory (1919), Gyldestolpe (1945a, 1951), Hellmayr (1910), Meyer de Schauensee (1982), Morrone (2000), Novaes (1957), O'Neill (1969), Olrog (1968), Parker & Remsen (1987), Parker *et al.* (1982), Remsen & Traylor (1989), Ruschi (1979), Sick (1993), Stotz *et al.* (1996), Todd (1943a), Whittaker & Oren (1999).

### 26. Brown Nunlet

#### *Nonnula brunnea*

**French:** Barbacou brun **German:** Einfarb-Faulvogel **Spanish:** Monjilla Canela

**Taxonomy.** *Nonnula brunnea* P. L. Sclater, 1881, Sarayacu, Peru.

Forms a superspecies with *N. rubecula* and *N. sclateri*; sometimes considered conspecific with the latter of these. Has at times been treated as conspecific with *N. frontalis* and *N. ruficapilla*. Monotypic.

**Distribution.** SC Colombia, E Ecuador and N Peru.

**Descriptive notes.** 14-15 cm. Buffy-rufous band from short nasal tufts to eye, narrow buffy eye-ring, dark greyish-brown ear-coverts; rest of head and upperparts dark plain brown, edges of secondaries buffy; tail slightly graduated; chin and central abdomen pale rufous, grading to dull dark rufous throat and flanks; centre of belly and undertail-coverts buffy-rufous; underwing-coverts rufous; bill mostly dark; iris dark brown; feet dark. Immature undescribed. **VOICE.** Song is a series of 20-25 "tree" notes, repeated steadily, starting quietly, building up, and then fading again towards end.

**Habitat.** Occupies understorey to subcanopy of humid lowland *terra firme* forest, as well as cluttered second-growth woodland. In Ecuador, mainly occurs below 400 m, but locally recorded up to c. 700 m.

**Food and Feeding.** No information available on diet. Sometimes joins antwren (*Myrmotherula*) flocks in lower storeys.

**Breeding.** No information.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Restricted-range species: present in Upper Amazon-Napo Lowlands EBA. Rare to uncommon in Ecuador, being uncommon at Limoncocha; present in Cuyabeno Reserve and also at Jatun Sacha Biological Station, but habitat of latter possibly threatened by plans for construction of a road through the centre of the reserve. Rare in Peru. Little known; research required.

**Bibliography.** Best *et al.* (1997), Borrero (1960), Clements & Shany (2001), Cory (1919), Curson & Lowen (2000), Hilty & Brown (1986), Meyer de Schauensee (1946a, 1982), Olrog (1968), Parker *et al.* (1982), Pearson *et al.* (1977), Ridgely & Greenfield (2001), Ridgely *et al.* (1998), Rodner *et al.* (2000), Stotz *et al.* (1996), Taylor (1995).

### 27. Grey-cheeked Nunlet

#### *Nonnula frontalis*

**French:** Barbacou à joues grises **German:** Grauwangen-Faulvogel **Spanish:** Monjilla Carigris

**Taxonomy.** *Malacoptila frontalis* P. L. Sclater, 1854, interior of Colombia.

Forms a superspecies with *N. ruficapilla* and *N. amaurocephala*; has at times been treated as conspecific with the former of these, and also with *N. brunnea*. Nominat race somewhat variable in colour, and is thought possibly to comprise more than one taxon; further investigation and analysis required. Race *pallidus* has on occasion been considered to belong to *N. ruficapilla*, although both geographically and morphologically they are decidedly distant. Three subspecies currently recognized.

**Subspecies and Distribution.**

*N. f. stulta* Wetmore, 1953 - C Panama to extreme NW Colombia.  
*N. f. pallescens* Todd, 1919 - Caribbean lowlands of N Colombia.  
*N. f. frontalis* (P. L. Sclater, 1854) - interior N Colombia.

**Descriptive notes.** 14-15 cm; 14.5-19.5 g. Crown very dark chestnut, upperparts plain brown, rump brighter; grey lores, supercilium, and ear-coverts, thin darker eyestripe; tail graduated about a quarter length, square-tipped, dark brown, blackish near tip; chin to lower breast and flanks rufous, centre of abdomen buffy, undertail-coverts white; bill silvery-blue or grey, black on culmen and cutting edges; iris dark brown, bare orbital ring reddish; feet dull brown or greenish-grey. Immature paler, duller. Race *pallescens* has entire upperparts paler, crown very dull, throat and breast buff; *stulta* has crown very dark and dull,

tail blacker except for outer feathers, rump drabber. **VOICE.** A plaintive, measured series of up to 20 notes, "weeep weeep, weeep..."

**Habitat.** Moist to humid forest, gallery forest, edge, and second-growth woodland, borders and thickets in lowlands, preferring vine-tangled and riverine woodlands, usually not deep inside unbroken humid forest; to 1000 m. Generally in lower storeys (3-12 m), but ranges up to lower canopy.

**Food and Feeding.** Orthopterans, caterpillars, earwigs (Dermaptera), small beetles, membracids, and spiders. Sometimes joins mixed foraging flocks of antwrens (*Myrmotherula*), small flycatchers (Tyrannidae) and others.

**Breeding.** Feb-Jun in Colombia, and recent fledgling seen in May. No other details.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Considered uncommon to rare in Panama. Race *pallescens* apparently rare, but may be overlooked and under-recorded; species judged to be generally fairly common in Colombia.

**Bibliography.** Anon. (1998b), Bangs & Barbour (1922), Cory (1919), Dugand (1947), Eisenmann (1952), Griscom (1929), Haffer (1967b, 1974, 1975), Haffer & Borrero (1965), Hilty & Brown (1986), Ridgely & Gwynne (1989), Ridgway (1914), Rodner *et al.* (2000), Rodríguez (1982), Salvin & Godman (1888-1904), Stotz *et al.* (1996), Todd & Carriker (1922), Wetmore (1953, 1968a), Willis & Eisenmann (1979).

## 28. Rufous-capped Nunlet

*Nonnulla ruficapilla*

**French:** Barbacou à couronne rousse

**German:** Rotscheitel-Faulvogel

**Spanish:** Monjilla Coronada

**Taxonomy.** *Lypornix ruficapilla* Tschudi, 1844, Peru.

Forms a superspecies with *N. frontalis* and *N. amaurocephala*; has been treated as conspecific with former, and also with *N. brunnea*. Race *pallescens* of *N. frontalis* has on occasion been considered to belong in present species, although geographically and morphologically distant. Four subspecies currently recognized.

**Subspecies and Distribution.**

*N. r. rufipectus* Chapman, 1928 - NE Peru.

*N. r. ruficapilla* (Tschudi, 1844) - E Peru and W Brazil S of Amazon.

*N. r. nattereri* Hellmayr, 1921 - S Amazon Basin in Mato Grosso, N Bolivia and N Brazil (W Pará).

*N. r. inundata* Novaes, 1991 - R Tocantins, in E Pará.

**Descriptive notes.** 13.5-14 cm; 14-22 g. Extensive deep chestnut crown patch; entire face, nape and sides of breast cold grey; upperparts from mantle plain dull brown, more rufescent on secondary edges and uppertail-coverts; chin to breast orange-rufous, flanks paler rufous, grading to whitish central underparts and undertail-coverts; bill silvery-blue, black on culmen and cutting edges; iris dark brown, bare orbital ring reddish and swollen; feet dark brownish-grey. Immature has yellowish-brown eyelids. Race *rufipectus* brighter, especially breast, darker cap; *nattereri* duller breast, darker cap; *inundata* darker and duller still.

**VOICE.** A long series (13-30 notes) of sharp, clear, short, upward-inflected whistles, "fwick!-fwick!...", given at a fairly even rate of 2-3 per second, the series slightly softer and lower in pitch near beginning and end.

**Habitat.** Inhabits subcanopy and undergrowth in humid forest edges, *terra firme* forest, second growth, transitional forest, river margins, dense low forest along streams, and *igapó*. In most of its range species is associated with bamboo (notably river-edge bamboo thickets), but also found in habitats without bamboo; at one site in Rondônia (W Brazil) territories found along roadside forest edge with abundant viny second growth; in Peru strongly associated with *Tessaria*, the early successional floodplain-forest stage; in hilly forest often found along streambeds.

**Food and Feeding.** Insects found in 4 stomachs of specimens from Bolivia. No further details documented.

**Breeding.** No information; 4 adults collected in Jun in Bolivia, and 3 in Jun and Aug in C Brazil, were not breeding.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Described as rare or uncommon in Peru, but this is probably in part a matter of perception, and in part a question of habitat; thus, records show 19.0 territories/km<sup>2</sup> in earliest successional stage (*Tessaria*) but only 3.0 territories/km<sup>2</sup> in later stages, in backwaters, and this species is infrequent in mature forest; frequently recorded at Manu Wildlife Centre (SE Peru). Common on R Uruçu, in W Amazonas, Brazil. Apparently uncommon to rare in Bolivia.

**Bibliography.** Aleixo *et al.* (2000), Allen (1995), Angehr & Auca (1997), Anon. (1998b), Bates *et al.* (1989), Bond (1954), Borrero (1962), Chapman (1928a), Clements & Shany (2001), Cory (1919), Donahue (1994), Dubs (1992), Novaes (1991), Oren & Parker (1997), Parker *et al.* (1982), Robinson & Terborgh (1997), Schulenberg & Remsen (1982), Sclater & Salvin (1866), Sick (1993), da Silva *et al.* (1990), Stotz *et al.* (1996), Terborgh *et al.* (1990), Zimmer (1930), Zimmer *et al.* (1997).

## 29. Chestnut-headed Nunlet

*Nonnulla amaurocephala*

**French:** Barbacou à face rousse **German:** Rotkopf-Faulvogel **Spanish:** Monjilla Cabeciparda

**Taxonomy.** *Nonnulla amaurocephala* Chapman, 1921, Manacapurú, Rio Solimões, Brazil.

Forms a superspecies with *N. frontalis* and *N. ruficapilla*. Monotypic.

**Distribution.** NW Brazil N of Amazon and W of R Negro.

**Descriptive notes.** 14-15 cm; 15-16 g. Rather distinctive a species within its fairly uniform genus. Shows large rufous nasal tufts; entire head to upper mantle and breast to upper belly bright rufous; back, wings and tail plain dull brown, rump washed olive; abdomen grading to whitish; bill mostly black, blue-grey at base; iris red; feet lead-grey. Immature similar to adult but has brown iris. **VOICE.** No information available.

**Habitat.** Occupies understorey of shaded *igapó* forest (relatively stunted seasonally flooded blackwater woodland), where is usually observed c. 3 m above ground level, some

times up to 7-8 m up. Apparently excluded from *terra firme* forest by *N. rubecula*, but birds seen moving through secondary growth where thick vines climbed into tree canopies and tangled in lower bushes.

**Food and Feeding.** Presumably chiefly invertebrates; observed making short sallying flights of 0.5-3 m.

**Breeding.** No information.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Formerly considered Near-threatened. Restricted-range species: present in Amazon Flooded Forests EBA. Recent information on habitat suggests that the species is relatively secure for the present: *igapó* forest is widespread within the basin of R Negro, W of the river itself, and is under little pressure; moreover, this is a quiet and immobile species, making it likely to be overlooked. Present in Jau National Park, and has been observed at Manaus.

**Bibliography.** Collar *et al.* (1994), Gyldestolpe (1945a), Meyer de Schauensee (1982), Morrone (2000), Olrog (1968), Pearman (1994b), Pinto (1938a), Ruschi (1979), Sick (1993), Stotz *et al.* (1996), Todd (1943a), Whittaker *et al.* (1995).

Genus *HAPALOPTILA* P. L. Sclater, 1881

## 30. White-faced Nunbird

*Hapaloptila castanea*

**French:** Barbacou à face blanche **German:** Diademfaulvogel **Spanish:** Buco Cariblanco  
**Other common names:** White-faced Nunlet

**Taxonomy.** *Malacoptila castanea* J. Verreaux, 1866, Santa Fé de Bogotá = Frontino, Antioquia, Colombia.

Monotypic.

**Distribution.** W Colombia, C Ecuador and NW Peru.

**Descriptive notes.** 23-25 cm; 75-84 g. Heavy whitish nasal tufts, large black-bordered white patch from base of bill right across forehead; crown grey-brown, grading to dark brown mantle and sides of face, to even darker brown on wings and tail; tail rather long, graduated for a third of length; chin and throat white, contrasting with bright chestnut rest of underparts; underwing-coverts and bases of remiges rufous; bill all black; iris red; legs and feet grey. Immature not described. **VOICE.** Song a series of upward-inflected single hoots, or double hoots like pygmy-owl (*Glaucidium*), sometimes extending to trill; call a mournful,

downslurred "wuooooo".

**Habitat.** Humid and wet forest and cloudforest, edges and small clearings, on steep slopes and by ravines. In foothills, in range 750-2900 m, mostly above c. 1500 m.

**Food and Feeding.** Coleoptera (once many small beetles), Hymenoptera, Orthoptera, Lepidoptera (larvae); in one study, a few small insects together with plant material, either buds or fruit, found in stomachs. Food given to nestlings at nest in Ecuador was 78% insects, 8-4% other items (including lizards, nestling birds, a mouse, a frog) and 13-6 unseen and/or unidentified. Mainly forages in canopy, but active at all levels and sometimes very low down.

**Breeding.** Apr in Colombia; eggs laid in late May, in Ecuador. Only nest known to date, in Ecuador, was burrow dug into bank above recent landslide; tunnel 38 cm long led to chamber 23 cm long by 16 cm wide by 10 cm high; construction at least 25 days, possibly 46 days or more. At same nest: clutch 2 eggs; incubation 15-18 days; fledging 37-38 days; both adults shared duties in nest building, incubation and feeding of young.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Rare and local in parts of Colombian range; occurs in La Planada Nature Reserve. Uncommon and apparently very local in Ecuador, where thought to be absent from extensive tracts of apparently suitable habitat. Decidedly uncommon in Peru.

**Bibliography.** Allen (1998), Athanas & Davis (2000), Berlioz (1954), Best *et al.* (1997), Chapman (1926), Clements & Shany (2001), Cory (1919), Davies *et al.* (1994), Fjeldså & Krabbe (1990), Hilty & Brown (1986), Krabbe (1991), Miller (1963), Parker, Parker & Plenge (1982), Parker, Schulenberg *et al.* (1985), Pearman (1995), Ridgely

& Greenfield (2001), Ridgely *et al.* (1998), Rodner *et al.* (2000), Salaman (1994), Sneidern (1955), Stotz *et al.* (1996), Strewé (2000a), Taylor (1995).

## Genus *MONASA* Vieillot, 1816

### 31. Black Nunbird

#### *Monasa atra*

**French:** Barbacou noir **German:** Mohrenrappist **Spanish:** Monja Negra  
**Other common names:** Black Nunlet

**Taxonomy.** *Cuculus ater* Boddaert, 1783, Cayenne.

Forms a superspecies with *M. nigrifrons* and *M. morphoeus*. Monotypic.

**Distribution.** S & E Venezuela and the Guianas S to N Brazil (N of Amazon and E of R Negro); possibly also extreme E Colombia (E Vichada, E Guainía).

**Descriptive notes.** 25-29 cm; 74-104 g. Glossy blue-black above, conspicuous white lesser coverts along upper edge of wing, grading to white and then grey scalloping on median and lower coverts; tertials large and broad, edged grey; tail long and broad, rounded; throat feathers long; underparts dark grey, grading to medium grey on abdomen; underwing-coverts pale grey to whitish; bill entirely red; iris red to brown, with patch of bare blackish skin behind eye; legs and feet slate-black. Immature sootier above than adult, and browner below; apparently has darker eye (birds with medium or dark brown

eyes may be non-adult). Voice. Flute-like "whoo-doo-doo" and descending "hyoo-hoo-hoo-oo-oo"; loud "yawkl-diddl" or "quee-didada" in duet; call surprisingly loud, often uttered by several birds in company.

**Habitat.** Understorey to canopy of humid *terra firme*, gallery and *várzea* forest, strongly favouring areas near water, forest edge, scrub and more open situations. In one study birds were often found high in subcanopy, near huge trees, near liana-crowned trees, near palms, and at rotted stumps or on dead limbs, and regularly used tall second growth, partly cleared plantations, treefall and escarpment gaps. Lowlands to 1000 m.

**Food and Feeding.** Insects including Orthoptera (Locustidae), Coleoptera (Buprestidae), Malacodermata (Rutelidae), Hemiptera, Heteroptera (Coreidae), and larvae of Lepidoptera; also stick-insects (Phasmida), Scorpions (Scorpiones), spiders, large centipedes (Chilopoda) and lizards also taken. Sallies and hovers to take prey. Some insects caught on the wing, but prey more usually plucked from substrate. Follows ant swarms; sometimes moves underneath groups of Red-rumped Caciques (*Cacicus haemorrhous*) in the canopy, possibly to watch for downward-flushed prey.

**Breeding.** Mar-May in Venezuela; Aug-Sept in main dry season, but probably also Apr-May, in French Guiana; apparently also 2 nesting seasons per year at Manaus (N Brazil). Nest in hole in level ground. Clutch size and incubation and fledging periods not documented.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Common locally in Venezuela, and very common at Cerro de la Neblina. Perhaps scarcer in Brazilian range, but common near Manaus. Common in the Guianas, and described by one mid-20th-century explorer as "one of the most abundant non-colonial forest birds of the interior of Guyana", but also common in coastal forest and savanna areas.

**Bibliography.** Aguirre & Aldrich (1983), Bierregaard (1988), Blake (1950), Borges (1994), Borges & Guilherme (2000), Cherrie (1916), Chubb (1916), Cohn-Haft *et al.* (1997), Cory (1919), Friedmann (1948), Haverschmidt & Mees (1994), Meyer de Schauensee & Phelps (1978), Parker *et al.* (1993), Phelps & Phelps (1958), Rodner *et al.* (2000), Snyder (1966), Stotz *et al.* (1996), Thiollay (1992), Thiollay & Jullien (1998), Todd (1943a), Tostain *et al.* (1992), Willard *et al.* (1991), Zimmer & Hilty (1997).

### 32. Black-fronted Nunbird

#### *Monasa nigrifrons*

**French:** Barbacou unicolore **German:** Schwarzstirtrappist **Spanish:** Monja Unicolor  
**Other common names:** Black-fronted Nunlet

**Taxonomy.** *Bucco nigrifrons* Spix, 1824, Rio Solimões, Brazil.

Forms a superspecies with *M. atra* and *M. morphoeus*. Two subspecies recognized.

**Subspecies and Distribution.**

*M. n. nigrifrons* (Spix, 1824) - SE Colombia, E Ecuador, E Peru, and much of Brazil (E, N of Amazon, to R Negro and, S of Amazon, to Pará and Alagoas and S to E Mato Grosso do Sul and W São Paulo).

*M. n. canescens* Todd, 1937 - E Bolivia.

**Descriptive notes.** 26-29 cm; 68-98 g. All sooty-black plumage, blackest around bill, with rear part of body blue-grey, tail blue-black, underwing-coverts sooty-black; bill red; iris dark, a little area of dark bare skin behind eye; legs black. Immature dirty slate with irregular reddish markings, throat mixed with reddish. Race *canescens* slightly paler and greyer than nominate. Voice. Song is a rapid series of melodious upslurred "clerry" or "curry" whistles, broken by occasional downslurred "turra turra" trill, often given as group chorus lasting for several minutes; call is a sporadic single dull note.

**Habitat.** Chiefly in low riverbank and lake-margin trees and bamboo. Unlike other nunbirds, forages low in open understorey of *várzea*, *igapó* and gallery and other riverside woodland, second-growth forest, dry deciduous and semi-deciduous woodland, palm groves of *Orbignya mertensiana* along streambeds through savanna, swampy river islands, transitional forest, and middle and late successional floodplain-forest. Absent from *terra firme* forest, which is occupied by *M. morphoeus*. Occurs up to 1000 m.

**Food and Feeding.** Arthropods, and small lizards; prey 1-4 cm long, mostly less than 2 cm. Most prey insects, chiefly Lepidoptera, also Orthoptera, Hemiptera and Homoptera, Hymenoptera (wasps), and others. Prey taken mostly in flight, e.g. butterflies, alate termites; also from ground, and from foliage up to 5 m up. Follows primate troops, taking prey they dislodge; also follows army ants, when recorded prey includes leaf-mimic katydids, grasshoppers, caterpillars, spiders and lizards.

**Breeding.** Jun and Oct in Colombia; in dry season in Peru; in lower Amazon evidence of grown young in Feb; nest excavation in May in S Brazil; female ready to lay in Jun in W Brazil (Acre). Nest in hole in bank or flat ground. Clutch 3 eggs; incubation and fledging periods not documented.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Common in Colombia and common in Ecuador. Common to abundant in Amazonian Brazil and around Pantanal. Common in Peru, where at one study site (Cocha Cashu) as many as 28 birds/km<sup>2</sup>, territory size 8 ha; in most favourable habitat (mid-successional stages) as many as 22 territories/km<sup>2</sup>, decreasing to 7 territories/km<sup>2</sup> in mature floodplain-forest. Fairly common to frequent in Bolivia.

**Bibliography.** Aguirre & Aldrich (1983), Allen (1995), Best *et al.* (1997), Bond (1954), Brace *et al.* (1997), Bronaugh (1984), Cavalcanti (2000), Cory (1919), Donahue (1994), Dubs (1992), Dugand (1948, 1952), Goodfellow (1902), Gyldestolpe (1945a), Hellmayr (1929), Hilty & Brown (1986), Marini (2001), de Mello & Mello (1998), de Melo & Marini (1999), Novaes (1957), O'Neill & Pearson (1974), Olivares (1962), Oniki & Willis (1999), Oren & Parker (1997), Parker *et al.* (1982), Pelzelin (1867-1871), Peres & Whittaker (1991), Perry *et al.* (1997), Pinto (1936), Pinto & Camargo (1954, 1957), Piratelli, de Mello & Mello (1998), Piratelli, Siqueira & Marcondes-Machado (2000), Ridgely & Greenfield (2001), Robinson (1997), Robinson & Terborgh (1997), Schubart *et al.* (1965), Sick (1993), Skutch (1948c, 1972), Sneath (1914), Stotz, Fitzpatrick *et al.* (1996), Stotz, Lanyon *et al.* (1997), Taylor (1995), Teixeira *et al.* (1988), Terborgh *et al.* (1990), Todd (1937), Willis (1982b), Willis & Oniki (1990), Zimmer *et al.* (1997).

### 33. White-fronted Nunbird

#### *Monasa morphoeus*

**French:** Barbacou à front blanc **German:** Weißstirtrappist **Spanish:** Monja Frentiblanca  
**Other common names:** White-fronted Nunlet

**Taxonomy.** *Bucco Morphoeus* Hahn & Küster, 1823, Brazil.

Forms a superspecies with *M. atra* and *M. nigrifrons*. Nominates and races *grandior* and *fidelis* have been considered three distinct species by some authors. Birds from NE Bolivia sometimes separated as race *boliviana*, but apparently indistinguishable from *peruana*. Seven subspecies currently recognized.

**Subspecies and Distribution.**

*M. m. grandior* P. L. Slater & Salvin, 1868 - E Honduras and E Nicaragua to W Panama.

*M. m. fidelis* Nelson, 1912 - Caribbean E Panama and NW Colombia (E to S Córdoba).

*M. m. pallescens* Cassin, 1860 - SE Panama to W Colombia (S to upper R San Juan).

*M. m. sclateri* Ridgway, 1912 - N & C Colombia (Magdalena Valley S to N Tolima).

*M. m. peruana* P. L. Slater, 1856 - E Ecuador, SE Colombia and S Venezuela S to E Peru, upper Amazonian Brazil (E to R Tapajós) and NE Bolivia.

*M. m. rikeri* Ridgway 1912 - Amazonian Brazil from R Tapajós E to Piauí.

*M. m. morphoeus* (Hahn & Küster, 1823) - E Brazil (Bahia S to Rio de Janeiro).

**Descriptive notes.** 21-29 cm; 90-101 g (Central America), 63-80 g (Venezuela), 77-87 g (E Amazon), 80-84 g (Bolivia). Dark greyish-black, greyer below, with white forehead and chin; bill orange-red; iris brown; legs black. Differs from *M. nigrifrons* in white forehead and chin, greyer body plumage, more orange-red bill. Immature buffy-rufous face, plumage tinged brownish with brownish edges to body feathers and wing-coverts, paler and dusker bill. Races differ from nominate in darkness of plumage, extent of white on face, and size, largest and with black hood, paler wings and broad purplish-glossed tail in N

to W Colombia), smaller and darker with white chin, mostly grey neck and narrower bronzier tail in Amazonia and S; of N races, *sclateri* has black chin, little contrast between black neck and grey body, moderately pale wing-coverts, *pallescens* similar but much paler and more contrasting, with most white on forehead of any race. *fidelis* as previous but whitish chin and slightly darker body and wing-coverts, *grandior* as previous but slightly darker body and little neck/breast contrast, larger bill; in S range, *rikeri* slightly paler than nominate, *peruana* paler still. Voice. Rather varied; common call is a blurred descending whistle with short rippling trill, "peeur-r-r-r-r"; also a loud, mournful "how how how" and various rippling trills, churrs and rattles; group choruses of loud gobbling, barking notes, sustained for up to 20 minutes at a time, chiefly at beginning and end of day.

**Habitat.** Mid-levels to canopy of tall humid lowland *terra firme* and low hill-country rainforest, treefall gaps, adjoining shady semi-open areas, high trees bordering river beaches, gallery forest, transitional forest, mature floodplain-forest, also abandoned clearings with scattered trees, borders in partly deforested areas, shaded cacao plantations and uninhabited tree-scattered clearings; sometimes contiguous patches of second growth. Noted as common around Indian clearings in forest. Mostly found below 300 m, but up to 750 m in Panama (Cerro Pirre); reaches 1050 m in Peru and locally 1350 m in Ecuador (head of R Guataraçu).

**Food and Feeding.** Bush-crickets, ground-crickets and other Orthoptera up to 6 g, also beetles, stick-insects (Phasmida), mantises (Mantidae), cicadas (Cicadidae), caterpillars, moths, small butterflies, dragonflies, spiders, large plated centipedes (Chilopoda), millipedes (Diplopoda), scorpions (Scorpiones), frogs and small lizards; also fruits of *Trichilia micrantha*. Follows army ants, foraging flocks of caciques (*Cacicus*) and oropendolas (*Psarocolius*, *Gymnostinops*), and troops of monkeys.

**Breeding.** Dec-May in Costa Rica; Feb-May in Colombia; newly fledged young recorded in area of lower Amazon in Jan-Feb. Nest is an oblique tunnel in level or sloping forest floor, 80-140 cm

long and 8 cm wide, the mouth surrounded by a collar of dead leaves and twigs, nest-chamber lined with leaves; attended by 3-6 adults. Clutch 2-3 eggs; incubation and fledging periods not documented.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Considered common to abundant in Costa Rica. Uncommon to locally common in Panama. Fairly common in C Colombia. Common at Cerro de la Neblina in Venezuela. Generally uncommon to fairly common in Ecuador. Common in Peru, where population density recorded was of 1 pair or group/km<sup>2</sup> in final successional stage of floodplain-forest. Common in Amazonian Brazil, and fairly common in E Brazil (Atlantic Forest). Fairly common in Bolivia.

**Bibliography.** Allen (1995), Anon. (1998b), Argel-de-Oliveira (1992), Bangs & Barbour (1922), Bond & Meyer de Schauensee (1943), Bronaugh (1984), Carriger (1910), Cory (1919), Davis (1972), Dubs (1992), Friedmann (1948), Gyldestolpe (1945a, 1951), Hafler (1975), Hellmayr (1929), Henriques & Oren (1997), Hilty & Brown (1986), Meyer de Schauensee & Phelps (1978), Monroe (1968), Oren & Parker (1997), Peres & Whittaker (1991), Pinto (1947), Pinto & Camargo (1954), Ridgely & Greenfield (2001), Ridgely & Gwynne (1989), Ridgway (1914), Robinson & Terborgh (1997), Salvin & Godman (1888-1904), Sargeant & Wall (1996), Scott & Brooke (1985), Sherry (1983b), Sick (1993), da Silva & Oniki (1988), Skutch (1972), Slud (1960, 1964), Sneath (1914), Stiles (1985), Stiles & Skutch (1989), Stiles *et al.* (1999), Stotz *et al.* (1996), Todd (1943a), Wetmore (1968a), Willard *et al.* (1991), Young *et al.* (1998), Zimmer (1930).

## 34. Yellow-billed Nunbird

### *Monasa flavirostris*

**French:** Barbacou à bec jaune **German:** Gelbschnabeltrappist **Spanish:** Monja Piquigualda  
**Other common names:** Yellow-billed Nunlet

**Taxonomy.** *Monasa flavirostris* Strickland, 1850, Peru.  
Monotypic.

**Distribution.** Amazon Basin in SE Colombia and E Ecuador S through E Peru, W Brazil (E to R Negro and R Purus) and N Bolivia.

**Descriptive notes.** 23-25 cm; 39 g. Sooty-black overall, with lesser wing-coverts mainly white, lower underparts very dark grey; underwing-coverts white, axillaries and bases of remiges greyish; tail rather long, slightly graduated, with rectrices rather narrow for the genus, greenish-black; bill yellow, noticeably shorter than those of congeners; iris dark, bare dark skin by eye; feet blackish. Immature slightly duller black than adult, white areas somewhat sullied, culmen ridge dusky. Voice. Song consists of full melodious lengthy phrases in choruses, typically including a frequently repeated "wheekit-wheeyk, wheekit-

wheeyk...".

**Habitat.** Occupies subcanopy and understorey of humid forest, transitional forest, and second growth or borders at forest openings; also *terra firme* borders, second-growth woodland, and overgrown clearings with scattered trees; bamboo stands in SW Amazonia. Largely replaced inside lowland *terra firme* forest by *M. morphoeus* and in *várzea* by *M. nigrifrons*. In Colombia, mainly occurs in or near foothills, ranging up to 1400 m; in Ecuador, usually below 400 m, but locally up to 750 m.

**Food and Feeding.** Details of diet not recorded. Appears to forage more in air, less at substrates, than congeners, also showing stronger tendency to perch on exposed branches high up at forest edge.

**Breeding.** No information.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Considered to be rather local in Colombia, although observations there suggest that it is extremely easy to overlook; occurs in Amacayacu National Park. Uncommon and local in Ecuador. Rather rare in Peru, where observed at Tingo María and in the area around Iquitos. Reckoned to be comparatively rare throughout its range, but this may be due to this species' unobtrusive habits and the consequent difficulties of detecting its presence.

**Bibliography.** Allen (1995), Angehr & Auca (1997), Best *et al.* (1997), Borrero (1960), Clements & Shany (2001), Cory (1919), Donahue (1994), Gyldestolpe (1951), Hilty & Brown (1986), Meyer de Schauensee (1982), Otrog (1968), Parker *et al.* (1982), Ridgely & Greenfield (2001), Ridgely *et al.* (1998), Rodner *et al.* (2000), Rusehi (1979), Salaman *et al.* (1999), Sick (1993), Sneath (1914), Stotz *et al.* (1996), Taylor (1995), Willis (1982b).

## Genus *CHELIDOPTERA* Gould, 1837

## 35. Swallow-winged Puffbird

### *Chelidoptera tenebrosa*

**French:** Barbacou à croupion blanc **German:** Schwalbenfaulvogel **Spanish:** Buco Golondrina  
**Other common names:** Swallow-wing

**Taxonomy.** *Cuculus tenebrosus* Pallas, 1782, Surinam.

Three subspecies recognized.

**Subspecies and Distribution.**

*C. t. pallida* Cory, 1913 - NW Venezuela.

*C. t. tenebrosa* (Pallas, 1782) - Venezuela (except NW), E Colombia and the Guianas S to E Ecuador, E Peru, Brazil (except SE) and N Bolivia.

*C. t. brasiliensis* P. L. Selater, 1862 - coastal SE Brazil.

**Descriptive notes.** 14-15 cm; 30-41.5 g. Sooty-black overall with some bluish iridescence above; lower back to uppertail-coverts white; wings long and pointed, tertials large; tail short, square, broad, black with small pale tips when fresh; chin whitish and throat greyish, with long hair-like feathers; breast grading from black to grey, orange-chestnut band on lower underparts, white undertail-coverts; underwing-coverts and axillaries white; bill black; iris dark brown; feet dark grey or black. Immature resembles adult. Race *brasiliensis* large, more ochraceous lower underparts below whitish band, rather variable rufescent tint

to rump, underwing-coverts, axillaries and undertail-coverts; *pallida* paler below, with well-marked whitish band between black breast and chestnut abdomen. **VOICE.** Twittering song often given in flight; calls include "tsi-tsi-tsi" and high clear "di-didi di-didi di-didi...".

**Habitat.** Optimum breeding habitat appears to be open areas with sandy soils and scattered bushes surrounded by forest, but also recorded from open tree and shrub savannas, clearings, edges of transitional forest, second-growth and deciduous forest, scrub, roadside trees, river margins, *várzea*, riverine and gallery forest in *llanos*; typically perches in riverside emergents and lake-margin trees. Lowlands, chiefly below 1000 m, rarely to 1750 m.

**Food and Feeding.** Takes relatively slow-moving, small to medium-sized flying insects, including Hymenoptera (Apidae, Meliponinae, Formicidae), Coleoptera (once "stink bugs", apparently referring to beetles), Homoptera (Fulgoridae), Heteroptera, Orthoptera, Isoptera, Diptera; targets termite emergences and winged ants. Captures aerial insects in rapid level or upward sorties from exposed branches. Prey usually swallowed in flight.

**Breeding.** Jan-Jun and Nov in Venezuela; Jul-Dec and Mar-Apr in Surinam; Aug-Nov in French Guiana. Nest in oblique tunnel dug usually in flat sandy ground, but often in earth bank, frequently near river; commonly takes advantage of man-made openings and embankments, such as airstrip, railway cutting or roadside. Clutch 1-2 eggs; incubation 15 days; fledging period not documented.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Best characterized in general as locally common, since it occurs patchily within its range, according to habitat availability. In Brazil, common in much of Amazonas, Pará and Mato Grosso, yet reported as uncommon to common in Rondônia, and noted as rare at a study plot in Manaus. Uncommon to quite common in Ecuador. Fairly common generally in Peru, but uncommon in Tambopata Reserve. Fairly common in Bolivia. Presumably benefits from opening-up of continuous forest; for example, the species was recently reported to be abundant along the Trans-Amazonian Highway by Tapajós National Park, in W Pará, Brazil, with 1-4 birds perched atop trees seemingly every few 100 m; and in Surinam it is common along the railway S from Paramaribo wherever it cuts through forest.

# Order PICIFORMES

Class AVES  
Order PICIFORMES  
Family CAPITONIDAE (BARBETS)

- Small to moderately large, robust arboreal birds with strong bill and sharp claws.
- 9-35 cm.

- Pantropical, with greatest diversity in Afrotropical.
- Forest, woodland and scrub.
- 13 genera, 82 species, 214 taxa.
- 1 species threatened; none extinct since 1600.

### Systematics

Fossils provide little help in determining the relationships of the barbets (Capitonidae) with other avian families. Indeed, fossilized wood cavities from the Eocene, ascribed to early woodpeckers (Picidae), could have been excavated by ancestral barbets. Miocene barbets are known from Florida and, interestingly, from Europe. The genus *Capitonides* from the latter region seems very close to modern ground barbets of the African genus *Trachyphonus*, which nowadays occur only south of the Sahara.

Despite the lack of useful fossil information, it is widely agreed that the barbets are closely related to the toucans (Ramphastidae), and that both of these families are close to the honeyguides (Indicatoridae) and the woodpeckers, all four belonging in the order Piciformes. Traditionally, the jacamars (Galbulidae) and the puffbirds (Bucconidae) have been placed in this same order, although their marked differences from the remainder that have led to their frequently being partitioned off in a separate suborder, Galbulae. Current opinion, backed up by

both morphological and biochemical studies, goes still further and concludes that they are almost certainly not piciform, calling instead for their isolation in a separate order, Galbuliformes; this is the arrangement adopted herein (see page 74).

The barbets are short-necked, large-headed, strong-billed and sturdy birds. They develop rapidly within the egg, hatch featherless, with the eyes closed, in a cavity nest, and then develop more slowly until they fledge. Barbets are less specialized and more generalized than are the toucans, honeyguides and woodpeckers, although sharing many features with them, notably including the zygodactyl foot and its "sehnenhalter" arrangement. Most capitonids are the epitome of the efficient frugivore, consuming much fruit, and regulating their activities around current sources of fruit.

The classification of the barbets is somewhat controversial. Some authorities treat them as a single family; others combine them all in one family together with the toucans, and still others separate them continentally at the family level, with the Neotropical barbets and the toucans then lumped in one family. The last two of these treatments are provisional, cladistic classifications that stress the points of branching of the various groups in time. It may be considered preferable to adopt an evolutionary approach, giving due consideration to the branching of the various groups, but also to their divergence. In fact, barbets are clearly identifiable as such on all continents. It is generally accepted that their close relatives, the toucans, are derived from an ancestor in common with American barbets, from which they have diverged. The toucans then evolved a suite of characters unique to them, and all are closely similar and differ from barbets, as E. Höfling has shown: toucans are toucans, not large barbets. Their divergence and speciation are therefore recognized by treating the toucans as a separate family from the Capitonidae. Aside from this matter, and the relative taxonomic rank of the included taxa, there seems no reason to dispute the classification of the barbets presented by R. O. Prum, or the arrangement and order of the family-level taxa given by Prum and, in earlier works, by E. V. Swierczewski and R. J. Raikow and by P. J. K. Burton.

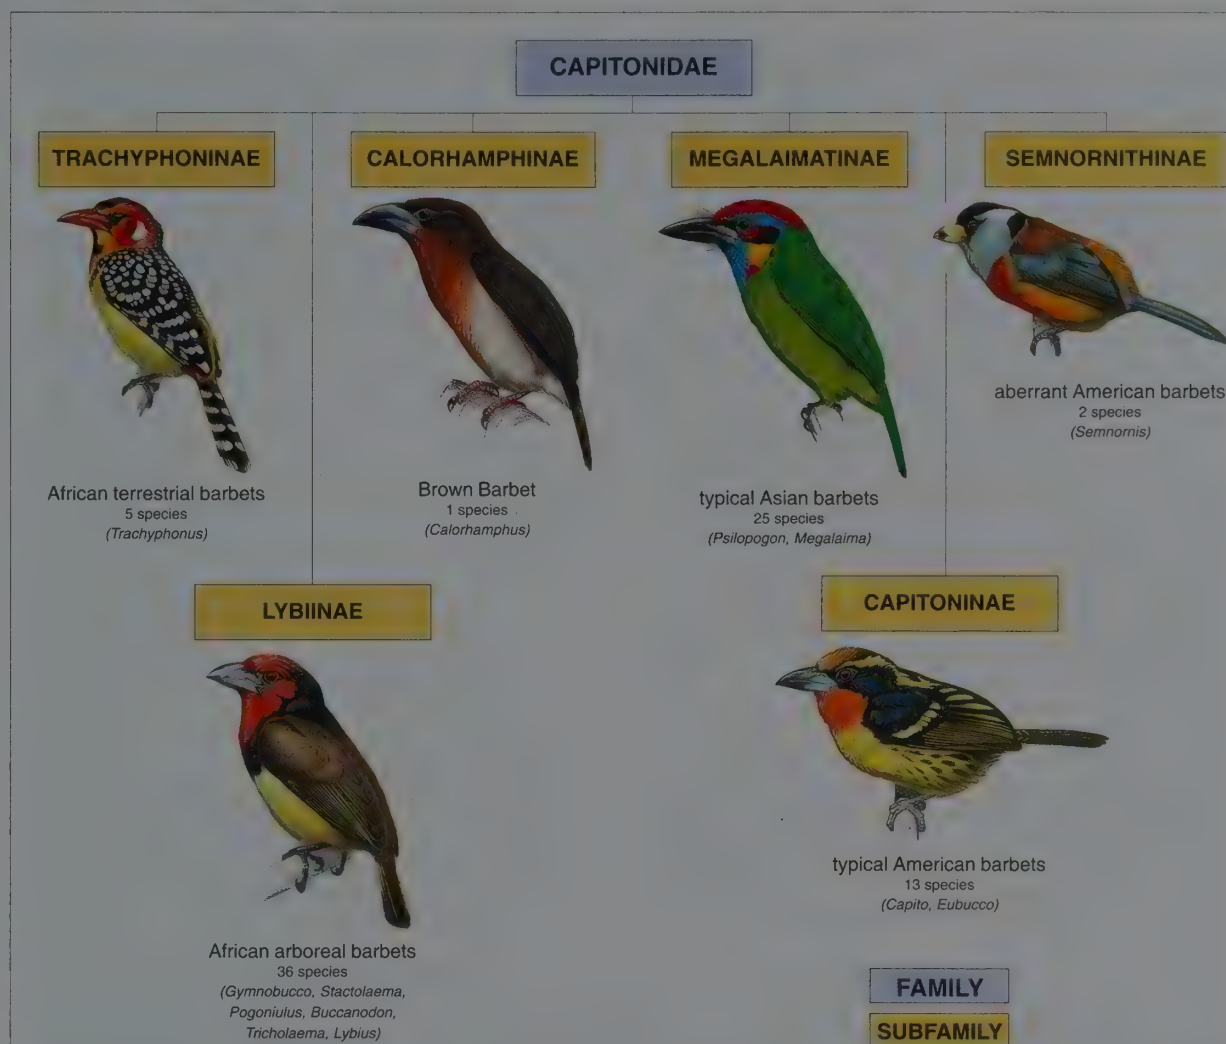

The barbets are the second most numerous of the piciform families after the woodpeckers, and are considered by Burton the least specialized of these families. Seven of the 13 genera and half of the 82 species are Afrotropical and, curiously, they outnumber the woodpeckers in that region. Tropical Asia and America each have three genera, with 26 Asian species, mostly in the genus *Megalaima*, while 15 species occupy tropical America, and in both regions they are greatly outnumbered by woodpeckers. The Neotropical barbets are strictly tropical, with but two species some-

Only very few of the currently listed species of barbet remained unknown to science into the twentieth century, the last being described in 1921, until the startling discovery of the very distinctive Scarlet-belted Barbet in July 1996, on a remote range of hills in north central Peru; the species was formally described only in 2000. It is apparently fairly common at the type locality, but its known range is so tiny that the overall population is possibly small, and the species probably deserves to be treated as threatened.

Subdivision of the  
Capitonidae.

[Figure: Ian Lewington &  
Tim Worfolk]

Although the present  
treatment of the family  
recognizes 82 species,  
there are various  
divergent subspecies that  
are often considered  
species in their own right.

One of these is  
"Woodward's Barbet", a  
race of the Green Barbet  
with two disjunct  
populations, one in  
Tanzania and the other  
in South Africa. Although  
this form differs from  
other races of Green  
Barbet in the intensity of  
yellow behind the eye  
and the ridged bill,  
it is approached  
morphologically by some  
of these races and is  
vocally identical to them.

times reaching the temperate zone of mountains. Asian barbets penetrate temperate parts of the Himalayas, and reach the temperate edge of lowland China. Afrotropical barbets occur to near the limit of trees in mountains, and extend into temperate South Africa.

In each of the three regions in which they occur, the barbets can be seen to form a number of distinctive groups. These constitute a total of six subfamilies, which could equally be regarded as tribes. Within Africa, the distinctive Trachyphoninae contains the five species of *Trachyphonus*, and the Lybiinae includes six closely interrelated genera and 36 species. Trachyphoninae once ranged at least into Europe, and today penetrates the southern fringe of the Sahara. Uniquely plumaged with spots and yellow, red, orange, black, pink and white markings, its members include three ground barbets of open to near-desert habitats. Two species show a unique plumage dimorphism between the sexes. Ground barbets burrow into earthen banks, into termite mounds, and even vertically into level ground. Pair-members duet and, except for the Crested Barbet (*Trachyphonus vaillantii*), the male and the female sing different duet songs. The only forest-dwelling species, the Yellow-billed Barbet (*Trachyphonus purpuratus*), is a bird of dense undergrowth, also feeding on the ground. These are among the most insectivorous of barbets, but they eat fruit as well.

The Lybiinae has two genera of forest barbets, *Gymnobucco* and *Buccanodon*, but most species of the other four genera occur in woodland, bushland and scrub. The four bristle-headed, often bare-faced species of *Gymnobucco* are the most social, and the most dull-coloured, of barbets. Much of their life centres around the colony, which ranges from small to 200-pairs strong, in dead forest trees. The barely separable *Stactolaema*, differing from *Gymnobucco* in having less of a keel on the culmen and in a trend towards yellow and white in the pattern of the head, is comprised of four woodland species, green to brown or black in colour, with

calls and songs similar to those of *Gymnobucco*. Some maintain anvils at which they break up insects before feeding them to the young. All are social species, and often have helpers.

The nine small tinkerbirds of the genus *Pogoniulus* live in forest, woodland and scrubland, eating fruits that include, nota-

Most barbets are brightly coloured, and all have stout, pointed bills. Although there are notable differences in shape, size and coloration, all in all barbets are immediately recognizable as such throughout their distribution. The family occupies three continents, each of which holds two endemic subfamilies, one moderately large and one small: in South America, the larger subfamily, Capitoninae, illustrated here by the Black-spotted Barbet, and Semnornithinae, with only two species; in tropical Asia, 25 species of Megalaimatinae, here represented by the Red-throated Barbet, but only a single species in Calorhamphinae; and in Africa, the more speciose Lybiinae, including the Spot-flanked Barbet, together with the five species of Trachyphoniinae. These geographical pairings of subfamilies have been treated by some recent authors as three distinct families, but there are serious problems with this course, particularly in that it is far from clear that any of the three pairings would group together taxonomically closest relatives: Semnornithinae does not appear to have any very close relatives, and shows no notable link with Capitoninae; Calorhamphinae is thought perhaps to have originated in Africa from an ancestral member of Lybiinae, and seems much closer to this subfamily than to Megalaimatinae; while Trachyphoniinae is possibly of European rather than African origin, and shows no particular connection with Lybiinae.

Not all barbets are brightly coloured. The four species in the African genus *Gymnobucco*, for example, including the Grey-throated Barbet pictured here, are rather dull, with bristled heads and a tendency towards bare faces. They are also unusually social, spending much of their lives in the vicinity of colonies containing up to 200 pairs in dead forest trees.

bly, mistletoe berries, as well as insects. Spotted and striped, with patches of black, yellow, red and white, tinkerbirds are solitary and nest in pairs, excavating tiny cavities in trees for nesting and roosting. They have a broad repertoire of vocalizations, but most sing with piping or popping notes. One form, known only from its type from Zambia and previously considered a full species, with the name "*Pogoniulus makawai*", is now generally accepted as representing an odd variant of the Yellow-rumped Tinkerbird (*Pogoniulus bilineatus*). The monotypic genus *Buccanodon* shows anatomical differences from species of *Pogoniulus*, and it connects that genus with *Tricholaema*. Larger than tinkerbirds, it is a forest frugivore that congregates at fruiting trees, and its purring song is unlike those of other barbets. The six species of *Tricholaema* differ from all the above-mentioned Afrotropical genera in having a single notch and "tooth" on each maxillary tomium, and occasionally a smaller second tooth, although the White-eared Barbet (*Stactolaema leucotis*) shows tendencies towards this. One *Tricholaema* species is a forest denizen, while the others occur in woodland to near-desert scrub conditions, and in general they are not social. They have a striped head, and distinctive, loud, hooting and nasal "nyah" songs. Two species are sexually dimorphic, the Hairy-breasted Barbet (*Tricholaema hirsuta*) in the shade of yellow of the dorsal spots, and the Spot-flanked Barbet (*Tricholaema lacrymosa*) in eye colour.

The largest genus of Afrotropical barbets is *Lybius*, with twelve species falling into two groups. All have one or two strong teeth on the tomia, and the largest species possesses ridges and grooves on the bill. Only the Double-toothed Barbet (*Lybius bidentatus*) penetrates forest, where it enters the undergrowth; like its Sahelian relatives the Bearded Barbet (*Lybius dubius*) and the Black-breasted Barbet (*Lybius rolleti*), it exhibits sexual dimorphism in its white lateral patch below, this being clear white in males and spotted black in females. Related to these three are the Brown-breasted (*Lybius melanopterus*) and the Black-backed Barbets (*Lybius minor*), the females of which occasionally have spots on the sides. All five have squawky calls or "songs", or emit a trilled song. The seven remaining *Lybius* species are social, occurring mainly in groups of three to eight individuals. They sing in duets, and have elaborate, noisy greeting ceremonies that may precede a more or less intersexual duet by the primary pair. All seven are patchily coloured, often with black, white, red and yellow patterns.

Of the two tropical Asian subfamilies, the social Calorhamphinae, with its single, monotypic genus *Calorhamphus*, is dullly coloured but showing some pinkish and bristle-like feathers on the crown. Somewhat resembling African *Gymnobucco* in its

keeled basal culmen, it has unique features of the palate and has facial bristles only on the chin. Like those of several other Asian barbets, its legs are reddish. It is further characterized by sexual dimorphism in bill colour and by its odd, squealing calls.

The Megalaimatinae is the other Asian subfamily, containing the monotypic genus *Psilopogon* and 24 largely green species of *Megalaima*. These exhibit features of the skull that demarcate them, and a laterally swollen base of the maxilla; the mandibular gonys shows a pronounced upward curve. The bristly feathers around the base of the bill are longer than those of any other barbets, some extending beyond the tip of the bill. *Psilopogon* is closely related to the "virens group" of *Megalaima*. In its hindcrown sexual marking and the "hash-mark" on its bill, as well as its very lax plumage, it displays some resemblance to American *Semnorhis*. Its graduated tail and the location of facial bristles in distinct nasal tufts are other characteristics.

*Megalaima* is a rather uniform genus, with blue and, especially, green as important colours, these colours not being significant in the Afrotropical barbets. The two-dozen species average larger than the American or African barbets; indeed, the Great Barbet (*Megalaima virens*) is the largest of all capitonids, falling within the size range of the smaller toucanets (*Aulacorhynchus*). The Great Barbet and the almost equally large Red-vented Barbet (*Megalaima lagrandieri*) share some features, such as a tendency for tuft arrangement of facial bristles, semi-lax plumage, and aspects of head colour. The remaining *Megalaima* species can conveniently be separated into five groups. The first of these includes streaky, large barbets, namely the Brown-headed (*Megalaima zeylanica*), Lineated (*Megalaima lineata*) and White-cheeked Barbets (*Megalaima viridis*) and, probably, the Green-eared Barbet (*Megalaima faiostricta*). A group of particularly heavy-billed barbets restricted to South-east Asia comprises the Brown-throated (*Megalaima corvina*), Gold-whiskered (*Megalaima chrysopogon*), Red-crowned (*Megalaima rafflesii*), Red-throated (*Megalaima mystacophanos*) and Black-banded Barbets (*Megalaima javensis*), all showing the many-patched, colourful head pattern of the remainder of the genus. The Red-throated is the only Asian barbet with very marked sexual dimorphism in head colours, the sexes appearing like separate species. The central group of the genus contains nine moderate-sized, typical *Megalaima* species with a complex head pattern: the Yellow-fronted (*Megalaima flavifrons*), Golden-throated

The Great Barbet is the largest member of the family, possessing a very bulky and unusually pale bill. Like the other twenty-three species in the Asian genus *Megalaima*, it is essentially green with patches of red and black. This species is less striking than most, however, with a much less complicated pattern of coloration on the head. In an interesting convergence with many of the Neotropical toucans, the undertail-coverts are red.

[*Megalaima virens virens*.  
Photo: Kenneth W. Fink]

The Yellow-spotted Barbet is intermediate in size and structure between another two African genera, *Pogoniulus* and *Tricholaema*. However, it shows anatomical differences from both of these groups, and its purring song is vocally unique. It is therefore classified alone in the monotypic genus *Buccanodon*.

[*Buccanodon duchaillui*.

(*Megalaima franklinii*), Black-browed (*Megalaima oorti*), Blue-throated (*Megalaima asiatica*), Moustached (*Megalaima incognita*), Mountain (*Megalaima monticola*), Yellow-crowned (*Megalaima henrici*), Flame-fronted (*Megalaima armillaris*) and Golden-naped Barbets (*Megalaima pulcherrima*). The little Blue-eared (*Megalaima australis*) and Bornean Barbets (*Megalaima eximia*) are derived from the last group. Finally, the Crimson-throated Barbet (*Megalaima rubricapillus*) and the ubiquitous Coppersmith Barbet (*Megalaima haemacephala*) are small, red-footed species with an intricate head pattern. The well-known Coppersmith is the only non-forest capitonid of tropical Asia, and is the most widely distributed, occurring from Pakistan and Sri Lanka across to China and the Philippines. The songs of all of these barbets tend to be of short phrases or single notes, or of short trills, loud and repeated over long periods, making them characteristic sounds of the tropical Asian forest. As many as seven species occur sympatrically in Malaysia, the highest degree of sympatry among any congeneric barbets.

As in the two tropical Old World regions, there are two subfamilies in the Neotropics, but with many fewer species. The Capitoninae has two genera, *Capito* of nine species and *Eubucco* of four, with several anatomical specialities; and, unlike Old World barbets and many toucans, most are strongly sexually dimorphic. Very much restricted to the tropics are the black, brown, yellow, red, orange and white species of *Capito*. Some, such as the Spot-crowned (*Capito maculicoronatus*) and the Five-coloured Barbets (*Capito quinticolor*), rather closely resemble Afrotropical species of *Tricholaema*, and the White-mantled Barbet (*Capito hypoleucus*) suggests the central African Black-backed of the genus *Lybius*, but *Capito* has no notch-tooth on the tomium. The striking Scarlet-belted Barbet (*Capito wallacei*) was discovered as recently as in 1996, on an isolated plateau in north-central Peru. The *Capito* species are essentially non-social, gathering only at fruiting trees; their songs are of low hooting or popping notes in series, sometimes as a trill in the manner of *Tricholaema* barbets. Longer-tailed *Eubucco*, the other capitonine genus, contains four smaller species, most inhabiting Andean-cordilleran slopes of Middle to northern South America; in this genus, the females are markedly different from the respective males in the colour around the head to breast, such that some females were initially described as separate species. The lowland Lemon-throated Barbet (*Eubucco richardsoni*), along with the Black-girdled (*Capito dayi*) and Cinnamon-breasted

Barbets (*Capito brunneipectus*), occurs in south-western Amazonia east only to the central Amazon Basin south of the River Amazon. No barbet reaches central-eastern and south-eastern Brazil or Paraguay, and all are forest species.

The final subfamily, the Semnornithinae, with the one genus *Semnornis*, is unique among all piciform and near-piciform birds in having the bill tip pronged above, the prong fitting into a notch in the tip below. The bill is "swollen" laterally at its base, and is relatively the shortest of all barbet bills. The genus contains two montane species of southern Central America and north-western South America. Both species exhibit sexual dimorphism involving glossy black, erectile nape feathers, recalling the Asian *Psilopogon*. The dully coloured Prong-billed Barbet (*Semnornis frantzii*) and the gaudy Toucan-barbet (*Semnornis ramphastinus*) readily "bite" out nesting cavities with the special bill tip, and sing or duet in series of deep honking or popping notes.

It is curious that the larger barbets in Africa and Asia show no convergence towards the toucans. Existing American barbets are recognizably capitonids, as has been remarked upon by C. G. Sibley and J. E. Ahlquist, and by S. M. Lanyon and J. G. Hall. Toucans are not merely very large barbets, but have evolved their own unique array of characters, including those of skull, bill, tongue, tail vertebrae, feather structure, patterns of sexual dimorphism, and large, colourful bare areas of the head and a lack of rictal and chin bristles, as well as sleeping posture, predatory habits and other features. In all of these they differ more from the barbets than the various groups of barbets differ among themselves.

Finally, it is also worth noting a major stumbling-block for those who would recognize three barbet families, one for each of their continents. Of the pairs of subfamilies present on each continent, it is far from clear that any geographical pairing would link closest relatives: there is no evidence of any close relation between the Trachyphoniinae and the Lybiinae; Calorhamphinae does not appear to be particularly close to Megalaimatinae, and may in fact be closer to Lybiinae; and Semnornithinae does not appear to be very closely related to Capitoninae. In consequence, a continental split into three families would seem decidedly ill-advised.

### Morphological Aspects

Barbets have a stout, pointed bill that is usually shorter than the head, and is not compressed laterally, but in many cases is as

The four brightly coloured members of the genus *Eubucco* live in the forests of South and Central America, principally on the slopes of the Andean cordillera. Sexual dimorphism is generally not strongly marked in barbets, but it is particularly pronounced in this genus, as illustrated by these Versicoloured Barbets, the male above and the female below. Indeed, in the case of the Red-headed Barbet (*Eubucco bourcierii*), the male and female were initially described on consecutive pages of the same publication as separate species! The four *Eubucco* barbets have ■ slenderer, sharper bill than their closest relatives, the Capito barbets; they also show a longer tail and ■ different standard plumage pattern.

 (below)]

wide as it is deep. The culmen curves downwards, from slightly to markedly so, and the gonys is straight or curves upwards. The edges of the bill, the tomia, are smooth to irregular; two of the African genera have a notch and one or two "teeth". The bill of all capitonids is sufficiently sturdy to allow the excavation of nesting cavities. The relatively short tongue is more or less brushy at the tip. Around the bill, there are short to very long nasal and rectal bristles, or at least chin bristles. The neck is short, to the extent that barbets often appear "neckless", the head being closely applied to the body as in the puffbirds, the rollers (*Coraciidae*) and the broadbills (*Eurylaimidae*). The short to occasionally long, rarely graduated tail has ten rectrices, and the rounded wings have ten primaries. The oil-gland is naked or tufted, with two lobes and a modest papilla. The palate, the skull, and the leg skeleton vary somewhat. The hair-like villi of the downy breast-feather barbules are relatively short and not strongly recurved. The bare skin around the orbit is small to moderate in extent, and usually not brightly or multicoloured, while in all genera but *Gymnobucco* the face and gular skin are feathered.

Certain structural features of the skull and palate, the musculature, and the rather long, thin bill are characters of the Trachyphoniinae that set them apart from other barbets. These Afrotropical species also have long legs and a rather long, graduated tail. A slight to strong crest characterizes these species, which also have modest rectal bristles, as do most Afrotropical barbets except for *Gymnobucco* and some *Lybius* species. Among the Lybiinae, which also exhibit particular skull characters, a strongly ridged culmen typifies *Gymnobucco*, this feature being weaker in *Stactolaema*, and even less marked but still present in *Pogoniulus*. The last genus has a tufted oil-gland, a short tail and a short first toe. *Buccanodon* has a longer first toe and tail, and a naked oil-gland, like *Tricholaema*, but it lacks the "tooth" of the latter. Members of *Tricholaema* tend to have hair-tipped feathers on the throat to breast, as do a few species of *Lybius* and *Capito*. *Lybius* barbets are generally larger than the others, with a heavier, more toothed bill.

In Asia, the single species in the Calorhamphinae, the Brown Barbet (*Calorhamphus fuliginosus*), has particularities of palate structure, perhaps responsible for its peculiar voice, as well as a ridge on the culmen, bristles only on the chin, reddish legs, and an unswollen base of the bill. The two genera in the Megalaimatinae, *Psilopogon* and *Megalaima*, have distinct features

of the skull and an expanded base of the maxilla on both sides. Strong bristles, a basically green plumage, which is also rather soft, and harlequin-like head markings characterize these barbets. The bill in profile is doubly convex, and varies among species mainly in length and stoutness.

The American subfamily Capitoninae has characteristic skull traits, less pronounced bristles than Asian barbets, a rather short tail, smooth bill tomia, and no bulging of the bill base. *Capito* tends to have a ridge across the culmen that may be flat at its base, and the outer primary is narrow and short. *Eubucco* has a more slender bill, a broad, short outer primary, and a longer tail than *Capito*, as well as a different plumage pattern. The two distinctive barbets that make up the subfamily Semnornithinae have a very short, doubly convex bill with a pronged tip, this being possibly related to the fact that they may be more frugivorous on the whole than are the members of the subfamily Capitoninae. They share some anatomical features with certain other barbets, in addition to which they have a particularly lax plumage. Compared with the Capitoninae, the two *Semnornis* species have a longer tail that is slightly graduated, longer bristles about the bill, and nostrils that are located in grooves.

Juveniles of the barbets tend to be duller than adults, and with a more lax plumage. The patches of colour present on the adults of most species are often lacking on the juveniles, and appear only gradually. Young of the "tooth-billed" or "prong-billed" species lack those respective attributes for several months. Hatchling barbets are blind and naked, and rest on the abdomen and the two spike-scuted hypotarsi.

The moult patterns of the Capitonidae are not well known. Moult commences in the second half of the breeding season, usually with the innermost primary being shed first. The primaries are moulted outwardly; the secondaries are replaced both inwardly, from number 1, and in both directions, from secondary 7 or 8. Tail moult appears to vary greatly, even within groups, but many more data are needed for any definitive conclusions to be drawn. The most common pattern, perhaps, is for the tail feathers to be moulted from rectrix 2 or 4, both inwards towards the central one and outwards towards the outermost rectrix. In *Trachyphonus*, the tail moult may start with any feather or with two adjacent feathers, and proceed inwards from the outer feather, outwards from the inner, or in both directions, from rectrix 2, 3 or 4, or from 2 and 3, or from 3 and 4.

One of the most constant feature of barbets is the stout, relatively short, pointed bill that is not usually compressed laterally. The cutting edges of the bill vary from smooth to irregular, with the Bearded Barbet occupying the latter end of this continuum. Its mandibles are distinctly ridged and grooved and there are two strong "teeth" on the cutting edge of the upper mandible. This species lives in dry forest, open woodland and secondary growth in West Africa. As can be seen here, barbets sometimes use the tail as a prop, like the related woodpeckers, despite the fact that their tail feathers are much less tough.

[*Lybius dubius*,  
Gambia.  
Photo: Michael Gore]

Almost every patch of tall woodland in tropical Asia seems to be inhabited by one or more species of the genus *Megalaima*, most members of which have a striking head-pattern combining green, blue, black, yellow or red. This species, the Black-browed Barbet, lives in the Sundaic mountains where it is strongly tied to humid forest. Indeed, most of its congeners are humid forest birds, with a few preferring dry forest, and only one species, the Coppersmith Barbet (*Megalaima haemacephala*), tolerant of very sparsely wooded areas. Barbets are associated with forest principally because of their food supply and their nesting and roosting sites.

NHPA]

### Habitat

A vital feature of habitats occupied by barbets is the presence of trees with sufficient dead wood in their branches, or dead trees or stumps, suitable for the excavation of nesting and roosting cavities. All barbets excavate such cavities and, so far as is known, roost in holes. Tropical Asian and American barbets are more or less confined to forest, mainly in the lowlands, but some species occupy lower and middle montane forest, and a few are found in temperate montane forest. These forest habitats are, for the most part, wet or humid, but some Asian barbets will at least forage in dry forest. One Asian species, the Coppersmith Barbet, is adapted

for living in forest edges, woodland, scrub and gardens, and is therefore very widespread and common. Several American capitonids, particularly the Scarlet-crowned (*Capito aurovirens*) and Scarlet-hooded Barbets (*Eubucco tucinkae*), prefer dense undergrowth of river edges and islands in western Amazonia.

Afrotropical barbets are more varied in their choice of habitats. The Red-and-yellow (*Trachyphonus erythrocephalus*), Yellow-breasted (*Trachyphonus margaritatus*) and D'Arnaud's Barbets (*Trachyphonus darnaudii*) constitute the ground barbets, all three of which live in dry scrub or wooded grassland and are free of any dependence upon tree cavities, since they nest in the earth. Most of the arboreal species of other genera prefer wood-

The African barbets are more numerous, in terms of species, and less restricted to forest habitat than their Asian and South American cousins.

Indeed, around half are birds of dry forest and semi-arid environments.

The Red-and-yellow Barbet, for example, is most at home in the wooded savanna, rocky scrub and gardens of East Africa. Unlike most other barbets it is not constrained by the availability of tree cavities, because it nests in the ground.

[*Trachyphonus erythrocephalus*  
*erythrocephalus*,  
Tanzania.

land, although all four species of *Gymnobucco* are confined to forested habitats. The tiny tinkerbirds of the genus *Pogoniulus* inhabit forest, woodland and scrub, even in semi-deserts. The Yellow-spotted Barbet (*Buccanodon duchaillui*) is strictly a forest bird, as also is the Hairy-breasted Barbet, the latter being the only one of *Tricholaema* species occupying such habitats. Otherwise, only the Yellow-billed and Double-toothed Barbets extend into the dense understorey of forest, second growth and thickets. All told, of the 41 Afrotropical barbets, eight may be termed forest-restricted, four inhabit forest undergrowth, eight occur in woodland and to some

extent in upland forest or forest edge, and the remaining 21 are denizens of woodland, bushland, scrub and semi-open country. The difference in habitat preferences between the Afrotropical barbets and those in Asia and the Neotropics probably reflects the repeated fragmentation and very restricted occurrence of Afrotropical forest in the late Tertiary period, compared with the situation in tropical Asia and America.

The greatest degree of sympatry among barbets occurs in habitats in Malaysia, where up to seven species are found together, in parts of Zaire and Gabon, with up to eight or even nine species, and in western Amazonia, with three or possibly four species together. Generally, where congeneric species of barbet are concerned, the maximum number that seem capable of living sympatrically appears to be only two. The exceptions to this rule are *Gymnobucco*, with up to three species occurring together, *Pogoniulus*, with a maximum of four species, and especially *Megalaima*, with as many as five and, locally, seven co-existing species that may be separated ecologically by their foraging and feeding habitats. Sympatric species of *Megalaima* also differ appreciably from one another in size. Most congeneric barbets that are closely related do not occur in the same areas or, if they do, they are separated altitudinally, as in the cases of the Red-crowned and Gold-whiskered Barbets in Malaysia, and the Eastern Green (*Pogoniulus simplex*) and Moustached Green Tinkerbirds (*Pogoniulus leucomystax*) in East Africa. Where close relatives do meet and marginally overlap, they tend to be separated by micro-habitat and may defend territories against one another. Thus, in eastern Rwanda, the Black-collared Barbet (*Lybius torquatus*) and the Red-faced Barbet (*Lybius rubrifacies*) meet and overlap somewhat, interacting frequently, where the latter's rolling, wooded grassland habitat abuts the lakeside and riverine woodland favoured by the Black-collared Barbet.

Degradation of habitats adversely affects those barbets that prefer more wooded areas, and favours the species of more open woodland, bushland and "edge". In parts of upland Kenya, the formerly extensive highland woods and forest favoured by the Moustached Green Tinkerbird have become highly fragmented and, to a large extent, eliminated. Here, the Yellow-rumped Tinkerbird of highland-forest edge and woodland that is successful in thickets, edges of dense woods and gardens is common, but the lower-altitude Red-fronted Tinkerbird (*Pogoniulus pusillus*) that occupies bushland and open woodland has invaded

Barbets often perch in a characteristic fluffed-up posture, as adopted by this Crested Barbet, with the feathers of the upperparts and underparts partly or fully erected. This can be with the purpose of cooling down when the bird is hot; of drying out when wet; or to show off various colours during display.

[*Trachyphonus vaillantii vaillantii*, Kruger National Park, South Africa. Photo: Nigel Dennis/Bios]

This Red-and-yellow Barbet is stretching its wings and erecting its neck feathers in the characteristic stance of sun-bathing birds. Barbets seem particularly fond of this activity, often spending regular periods sunning themselves early in the day, or especially after bathing or rainfall. Sun-bathing is often associated with other forms of comfort behaviour such as preening. Typically, paired birds or group members will allopreen between bouts of sunning.

[*Trachyphonus erythrocephalus erythrocephalus*, Olduvai Gorge, Tanzania. Photo: Mike Wilkes/BBC Natural History Unit]

Barbets have a relatively restricted vocabulary and are slow to tire of their own voice.

This Blue-throated Barbet, like most others in its genus, sings with a short phrase of hollow notes, often with a more trilling introduction, and it can continue with an almost interminable rhythmical series, a familiar background sound in the forests of Asia. As these barbet species usually sing while motionless high in the tree-tops, they can be frustratingly difficult to see.

[*Megalaima asiatica asiatica*,

the area; although some separation by habitat remains, all three species overlap locally and can be heard singing by the stationary observer. Throughout tropical Asia, the elimination of forested areas continues; where regeneration and fragmentation occur, the barbets that are restricted to primary forest suffer fragmentation of their distribution, and only those species able to occupy patchy second growth may persist. Thus, in formerly forested Singapore, the Red-crowned Barbet, tolerant of second growth, is the only species of capitonid that remains, except for the fact that the Coppersmith Barbet, which invaded degraded forested country from northern Peninsular Malaysia within the twentieth century, had colonized Singapore by 1960, and is now the only common barbet there.

Even some barbets which are rather strictly limited to forest habitats do find and visit fruiting trees in pastures and village gardens, provided that some forest is nearby. This occurs perhaps most commonly in the Indian region, with its long history of human occupation and a tolerant attitude towards wildlife. Great, Brown-headed, Lineated and Crimson-throated Barbets may join Coppersmith Barbets at village fig trees to take ripening fruits, and they can become pests in orchards. Even in South America, Orange-fronted Barbets (*Capito squamatus*) feed in fruit trees in pastureland. Isolated trees alongside forest also attract such species as the Yellow-billed and Grey-throated Barbets (*Gymnobucco bonapartei*) in Africa, the Golden-throated in Asia, and the Black-spotted (*Capito niger*) and Prong-billed Barbets in America, the birds using the trees as nesting sites. A likely reason for this is that the trees, being isolated, are somewhat protected from arboreal snakes and mammalian predators, which cannot readily reach the nest-site directly.

### General Habits

Since their roosting cavities are usually excavated by the birds themselves, and are thus less subject to infestation by pests and parasites than are secondary cavities, barbets tend to rise only moderately early, and to retire rather early in the evening. Social barbets that roost in groups, such as the Red-and-yellow and Black-collared Barbets, gather to preen for a brief period shortly after they leave the hole in the morning, and then give a greeting ceremony followed by a duet. The social barbets, and even those

that roost in pairs, may interact for a while, entering and leaving the roosting cavity several times, before settling in for the night. Near or at the equator, barbets may roost for eleven hours or more per day, and on rainy, cool days they may spend even longer in the cavity. Crimson-throated Barbets have been found to roost for an average of 12.5 hours daily, and the Coppersmith Barbet, which roosts singly, appears to spend an even greater part of the day roosting. Immatures that roost with their parents may return to the roost somewhat earlier than do the adults. Interactions of the occupants may prevent entry by very late-arriving young birds

The most complex vocalizations produced by barbets, and indeed any piciform birds, are given by members of the African genera *Trachyphonus* and *Lybius*.

These group-living species give loud choruses that initiate a synchronized duet performed by the primary pair. Calls in these species are sex-specific: this female Yellow-breasted Barbet, for example, is answering the whistled triplet of her mate with her own longer series of higher-pitched and shorter whistles.

[*Trachyphonus margaritatus somalicus*, southern Danakil Desert, near Sardo, Ethiopia.  
Photo: Gertrud & Helmut Denzau]

While the song of the Coppersmith Barbet is one of the most familiar bird sounds in many parts of tropical Asia, it is not most popular. The rapid series of tapping "tok-tok" notes that gives this bird its vernacular name can be heard almost throughout the day, and sometimes throughout the night. So persistent and invariable is its delivery that it can drive an innocent bystander to distraction!

[*Megalaima haemacephala indica*, Keoladeo National Park, India.

or helpers. One roosting hole of Prong-billed Barbets held 16 individuals on at least one occasion, and once 19.

Barbets living in more open country rest in shady bushes and trees during the heat of the day. The forest-dwelling species, however, forage for fruit all day long. The songs of barbets are often among the few that are uttered throughout the day; indeed, some capitonid species are numbered among the "brain-fever" birds, so called for the monotonous regularity with which their songs are delivered, and epitomized by certain of the cuckoos (Cuculidae). Most barbets drink water when they are able to do so, and may bathe in water-filled crevices in trees; the period

that a White-cheeked Barbet spends in a bout of bathing has been timed at up to eleven minutes. When a particular fruiting tree is laden with fruits, the movements of a barbet may be narrowly defined, between that tree and the individual bird's roosting site. During the breeding season, a pair of Moustached Green Tinkerbirds may nest and raise young on a territory less than 1 ha in size. The daily movements of other barbets, however, usually encompass much larger areas, with longer distances involved. Indeed, those species living in Sahelian Africa, such as the Yellow-breasted Barbet and Vieillot's Barbet (*Lybius vieilloti*), may forage over 1 km<sup>2</sup> or more in a day.

The complex repertoire of duet calls and group calls given by the D'Arnaud's Barbet varies racially and geographically. There are usually only two song-types given in duets by any given population, but these are not rigidly sex-specific with some individuals switching song-types. Interestingly, if one of the primary duetting pair is experimentally removed, another group member takes its place and sings the same song. These co-ordinated vocalizations probably function in maintaining group hierarchy, synchronizing breeding attempts, and mediating co-operative territory defence.

[*Trachyphonus darnaudii*, Lake Bogoria, Kenya.  
Photo: Günter Ziesler]

Over anything more than very short distances, the flight of most barbets, especially that of the larger species, may be undulating, although it may vary, as, for example, when the bird is chased by a predator. The little *Pogoniulus* tinkerbirds fly in a direct line. Barbets are not particularly fast fliers, but some are faster than others. The Black-collared Barbet is speedier than *Stactolaema* species such as Anchieta's Barbet (*Stactolaema anchietae*); their relatives and nest parasites, the longer-winged honeyguides, can outfly these and other barbets.

Barbets may perch atop a bush or tree to sun themselves in the morning, and will also do so in order to dry their plumage following rains. Much preening may occur at such times. Paired birds preen one another, and some social species, such as the Brown-breasted Barbet, engage in allopreening among all members of a group. Bill-wiping is a frequent action when the birds are feeding on fruits (see Food and Feeding). Capitonids scratch the head directly, with one foot raised over a wing. Stretching movements are typical, with one leg and wing stretched on one side, then usually the other leg and wing, and then both wings, and this can be accomplished expertly by a barbet while hanging upside-down. Under hot conditions, and after vigorous activities such as chasing, barbets pant with the bill held open.

As a rule, piciforms tend to be aggressive, even belligerent, especially at food sources and around their nesting and roosting cavities. These birds' sturdy bill and stocky build, as well as their adroitness and strength in clinging and hanging to the bark, as when excavating a cavity, are probably factors relating to their pugnaciousness. Among the barbets, interspecific aggression is most evident in the breeding season, when "innocent" birds of species that are not nest-hole competitors are attacked without cause. Competition may be reflected in cases where larger barbet species have been seen to go out of their way to chase smaller barbets. In addition, Afrotropical barbets regularly, and at times for lengthy periods, become involved with honeyguides, which they recognize and may attack even outside the breeding period. Their belligerence renders them good mobbers of hawks (Accipitridae), owls (Strigidae) and terrestrial predators. Where intraspecific aggression is concerned, the non-social barbets are fiercely protective of their territories and react instantly to the presence and singing of any conspecific within a territory. These species are intolerant of others under captive conditions, and even within a pair aggression may preclude successful breeding. So-

cial barbets, too, defend home ranges or territories; those that sing in chorus and in duet tend to patrol their territorial borders, performing greeting ceremonies and responding instantly to neighbouring groups of their own species when the latter call.

During encounters, barbets use a great range of visual and auditory displays, many involving the head and bill. When an individual is faced with a prospective antagonist, the position of the head is important, a fact rarely appreciated by observers. Most capitonids have a head that is patterned, even spectacularly so in some species of *Megalaima*, *Eubucco* and *Tricholaema*, among others. As a result, signals presented with the head and bill upwards, enhancing the malar, throat and chin feathers and obscuring the crown and upper face, as opposed to downwards, emphasizing the often erected feathers of the forehead to nape and supercilia and obscuring the ventral head pattern, are important, and the bill itself covers part of the display patterning. Bill-pointing, gaping, stilted bill-wiping and bill-snapping are included among the displays of one barbet species or another. The tail is drooped or, often so in males, cocked; rarely, it is spread, as in the case of duetting D'Arnaud's Barbets. The wings may be rapidly flicked, or spread or waved, and interactions usually involve loud, rustling wing sounds in chases and when one individual supplants another. The rump feathers are sometimes spread; often partly erected, they typically extend out over the tail base, then producing a rather characteristic barbet silhouette, one which is, incidentally, also typical of a honeyguide. In some barbets, the rump is brightly coloured and shows well when fluffed. The breast feathers may be fluffed, showing off colours and particular patterns, such as the red lateral spots of some species of *Megalaima*, or the coloured hair-tipped feathers of the Black-throated Barbet (*Tricholaema melanocephala*) and the Yellow-billed Barbet. In a few cases, the flanks and sides are important, and these feathers may be spread to show colour patches, as in the Spot-crowned Barbet, emphasizing sexual markings as in the "*bidentatus* group" of *Lybius*, or simply contrasting with the dark thigh colours as in the Brown-breasted Barbet. Considering the prevalence of red undertail feathering in the toucans, it is worth noting the absence of a red undertail patch on American barbets; interestingly, such a patch is found in a few Old World species, such as the Asian Red-vented Barbet, and most notably in species of ground barbet.

Nobody could fail to be impressed with these various display patterns and colours, epitomized by the complex greeting

All members of the barbet family are predominantly, but not entirely, frugivorous. Small fruits tend to be swallowed whole, while larger fare is broken up, mandibulated to a pulp and ingested. It is likely that the toothed bill is useful in grasping and pulverizing fruit, as shown by this Red-fronted Barbet, and that the brush-like tongue is also used in breaking down or manipulating pieces of fruit.

[*Tricholaema diademata*  
*massaica*,  
Kenya.  
Photo: Michael Gore]

This Yellow-crowned Barbet is eating a forest fig (*Ficus*), this fruit being its preferred item of diet. When an individual finds a rich source of food, such as one of the huge fruiting figs typical of mature Sundaic forests, it usually spends much of its time in and around the canopy of this tree. One study individual monitored over four days, ranged over an area of 7.5 ha, but spent 75% of its time at a *Ficus binnendykii* tree, and usually roosted nearby. At abundant sources of food, many barbets aggregate in substantial numbers. Up to 70 Coppersmith Barbets, for example, have been recorded in particularly suitable fruiting trees. This latter species eats a wide selection of fruit throughout its range, often preferring smaller varieties, as befits its modest size.

[Above: *Megalaima henrici brachyrhyncha*, Gunung Palung National Park, Borneo. Photo: Tim Laman.

Below: *Megalaima haemacephala indica*, Kuala Selangor, Malaysia. Photo: Morten Strange/ NHPA]

The foraging and feeding techniques adopted by barbets are straightforward.

Ripe fruits are plucked wherever they can be reached, sometimes snipped from their berth using the toothed bill, as the White-headed Barbet has undoubtedly done at this palm. Barbets' feet are strong, and when necessary the birds can cling acrobatically in various positions to reach fruit. Their neck is short and strong, a characteristic that presumably facilitates the removal of well-anchored fruit.

[*Lybius leucocephalus albicauda*,

Masai Mara National Park, Kenya.

Photo: Peter Craig-Cooper/VIREO]

ceremonies of social groups of the array of duetting *Lybius* species, and of the Red-and-yellow Barbet. The position of dominance of an individual in the social hierarchy of a group is probably put forward in such intricate displays.

Competitive interplay between barbets is at its most obvious where larger species not only drive away smaller ones, but also enlarge the nesting or roosting holes of the latter, usually when these are somewhat close to their own cavities. Brown-headed Barbets enlarge and render unfit for use entrances to nests of nearby Coppersmith Barbets, and the Coppersmiths also are forced to abandon nests by Blue-throated Barbets. White-cheeked Barbets in India excavate into the nesting cavities of Crimson-throated Barbets and throw out any eggs or young that they find inside. These obvious acts suggest the existence of regular, strong competition among sympatric barbets, to the extent that it may have an influence on the particular micro-habitats used by different species, and such competition may enforce the altitudinal separation of capitonids where their ranges coincide.

## Voice

Well-studied species of barbet have been shown to have a repertoire of seven to twelve calls, including the song, some of which are associated closely with visual displays. There are also non-vocal acoustic displays. Most barbets give relatively low-pitched "hoot", "hoop" or "pop" notes that may be repeated in short to long series as ■ song, uttered with the bill closed or nearly so. A few species, such as the Brown-breasted Barbet, utter squawks but have no apparent song. The most complex, even melodic songs are known from the genera *Trachyphonus* and *Lybius*. Many barbets sing throughout the year, and their songs provide a monotonous background sound characteristic of the habitat in which they live. Some smaller barbets, such as the tinkerbirds and the Black-throated Barbet, emit notes that are very loud for the size of the bird. There may be three or four calls restricted to the nestling and fledgling stages, and as many as four mechanical, non-vocal displays. The latter include bill-snapping, bill-wiping, bill-tapping associated with the nesting cavity, and wing-rustling by such species as Whyte's (*Stactolaema whytii*),

Anchieta's, Chaplin's (*Lybius chaplini*), White-headed (*Lybius leucocephalus*) and Red-faced Barbets.

Aggressive calls generally are noisy, and commonly include fast, chattery, squawky, honking, rattling, squeaky and grating sounds, usually repeated in short to long phrases and often compounded, as in a squeaky grating or a squeaky chatter.

It should be stressed that the full range of vocalizations of many capitonids remains unknown, this being especially true of Asian and some American species, for which the song may be all that has been reported. Particularly lacking is information on the usually softer, so-called "intimate" notes occurring during the interplay of the male and the female near the nest, and the soft interactive calls of adults and young. Additional information is required also with regard to the softer calls uttered in greeting ceremonies and the initial notes of choruses for those barbets in which they occur. For an understanding of the role of individuals and of the primary pair in choruses and greeting ceremonies, the soft notes and calls in choruses that do not lead to duets, compared with those that do initiate duets, appear to be important, and further knowledge of these would be particularly useful.

Some barbets have what appear to be alternate or secondary songs. The "pop-singing" tinkerbirds such as the Yellow-rumped have equally loud, faster pop notes in repeated trills, as do the Red-fronted and Yellow-fronted Tinkerbirds (*Pogoniulus chrysoconus*). These also give nasal, honking calls with short series of notes. In species of *Tricholaema*, there is ■ "hoop" song and also a "nyah" series: early in the breeding cycle, the male Red-fronted Barbet (*Tricholaema diademata*) seems to sing mainly "hoop" series as a song, sometimes answered by its mate's "nyah" "song"; later, however, a male may start with the "nyah" version, and then shift to the "hoop" version. In the Black-throated Barbet of drier, more open areas, the "hoop" song is replaced by the "kaaa" song, and the "nyah" by ■ "pyaw" or "ptaw" version, both noisier and harsher than in the Red-fronted Barbet, and uttered in shorter, staccato series.

The song has evolved into a faster trill of hoop-like notes in some species of *Capito* and in *Eubucco*, while in Africa it has become an even faster clicking trill in the Crested, Double-toothed and Black-backed Barbets and ■ purring trill in the Yellow-spot-

The Brown Barbet is an anomalous, dully coloured Asian barbet, separated in a monotypic subfamily on the basis largely of its unique palate morphology, the restriction of facial bristles to the chin, sexual dimorphism in bill colour and odd squealing vocalizations. Its diet consists largely of fruit although considerable quantities of insects are also eaten, and the stomachs of some specimens have been found to be replete with arthropods. It gathers its food, often socially, in a rather agile manner, as seen here, by hanging upside-down, tit-like, at clusters of fruit or flowers and at clumps of dead leaves. The Black-collared Barbet of Africa is also an agile and opportunistic forager, taking a wide variety of fruit, but also gleaning for insects in foliage, picking and probing along the bark of branches and twigs, or in lichen and termitaria. Like several other barbets, it has been recorded catching insects aerially by sallying out from a perch.

As is the case with other members of the Capitonidae, the Moustached Barbet, a species restricted to hill forest in South-east Asia, is quite often seen at flowers, probably because it sometimes drinks nectar but also because of the insect prey which can be found around inflorescences. Some species even squeeze flowers with their feet to extract the nectar.

[*Megalaima incognita*  
*elbeli*,

Khao Yai National Park,  
Thailand.

Photo: Mike Potts/  
BBC Natural History Unit]

ted Barbet. Many Asian species of *Megalaima* have songs comprising various phrases of "tok" or "tuk" notes, the phrases being more or less species-specific. Some *Megalaima* species incorporate tiny trills into the song phrases, as do the Black-browed and Moustached Barbets; in others, a short trill may initiate the song, as in the Lineated Barbet, or there may be a separate trill song, as in the Red-crowned Barbet. The more hooping, popping or hooting songs seem ventriloquial, and may vary in volume simply as a result of the barbet turning its head as it sings.

The American barbets in general have simple hooting songs delivered at moderate speeds, in phrases, or as more or less rapid trills. The Spot-crowned Barbet is an exception, having a harsher song of "klaaak" notes. The two montane *Semnornis* species also sing simple songs of hoarse "kaw" or "awnk" notes in rapid or slow, long series, sometimes in duets. Their voices do not differ substantially from those of other barbets.

The complex, chorus-initiated duets of barbets of the genera *Trachyphonus* and *Lybius* are the most significant of capitonid and, indeed, of all piciform vocalizations. The sex-specific, different duet songs of male and female Black-billed (*Lybius guifsohalito*), Red-faced and Black-collared Barbets, which are synchronized, are melodic vocal productions, as are the equally complex, meshing songs uttered by pair-members of the three ground barbets, the Red-and-yellow, Yellow-breasted and D'Arnaud's. These songs appear to enable the primary pair to synchronize its breeding effort, to "control" the subordinate members of its social group, and to afford a co-ordinated mode of territorial maintenance throughout the year. The fact that these vocalizations evolved within the Afrotropical barbet groups, rather than among other groups, probably reflects the more open habitats, in which displaying barbets are easily visible, occupied by these non-forest genera.

In the chorus, the intricate weaving of different calls with such visual displays as swinging of the body and head, bowing, twisting and twitching or cocking of the tail, wing-flicking and wing-spreading, bill-snapping, erection of some feathers, as well as other gyrations, makes the *Trachyphonus* and *Lybius* barbets conspicuous. The barbets also turn, jump over one another, and parade before one another, and then generally freeze in place as the primary pair initiates the duet. In the ground barbets, the primary pair faces in directions appropriate to likely responses by neighbours, but the primary male and female also move to force

downwards in the bush or tree any subordinate group-member that attempts to hop upwards towards the level at which the primary pair sings its duet.

## Food and Feeding

Well known as frugivorous birds, most capitonids have a mixed diet of animal and plant foods, with fruits predominating. All barbets, however, must of necessity exploit animal food when feeding the young immediately after the eggs hatch, when nutrients essential for growth and development are required. Barbets are sufficiently opportunistic as to shift to insectivory when there is a significant emergence of termites, with flying insects everywhere; it is thought very likely that poorly known barbets for which only fruits are reported as food will be found to sally for winged termites, or to pick them from leaves and branches, at times when these insects are briefly superabundant. The diets of many species are known from only few observations, and from stomach contents of specimens the collection dates of which do not cover all times of the year. An important observation that could be considered indicative of a degree of insectivory of a barbet species is its presence in the mixed-species foraging flocks of diverse insectivorous birds.

For the family as a whole, figs (*Ficus*), including strangler figs, are of major importance. In tropical Asia, several of these tree species, fruiting two or three times a year, may occur at a single site and substantially support local barbets. Plant families such as the Lauraceae, Moraceae and Melastomataceae are particularly important. Other major foods are fruits of the genera *Cecropia*, *Euterpe*, *Loranthus* and other mistletoes, *Macaranga*, *Micronia*, *Musanga*, *Ocotea*, *Prunus*, *Rauvolfia*, *Trema*, *Virola* and many others, of diverse families. Over 60 fruits of some 20 families of plants are eaten by the Toucan-barbet at one site. A few barbets gather in numbers, the Blue-eared Barbet sometimes occurring in flocks of 100 or more individuals at a single fruiting tree. The fruits exploited must be of an appropriate size for the open, extended mouth of the Capitonidae. Where there are barbet species of different sizes, the larger ones prefer larger fruits, it being more efficient to feed on these. Thus, several species of *Megalaima* of different sizes regularly occur together, as do the very heavy-billed Bearded Barbet and the smaller tooth-billed

Like many barbets, the Orange-fronted Barbet feeds at many levels in the forest, its movements governed mainly by the availability of ripe fruit. As it feeds, the indigestible remains of fruit are regurgitated, and in this way barbets play a major role in disseminating seeds away from the parent plants. The bird seen here feeding on *Carludovica palmata* is a female, as evidenced by the pale scaling on the scapulars and upperwing-coverts. This species occupies a restricted range in the Chocó EBA of Pacific slope Colombia and Ecuador, where it is generally uncommon.

[*Capito squamatus*, Río Palenque, Ecuador. Photo: X. Ferrer & A. de Sostoa]

Vieillot's Barbet in Sahelian Africa. The larger Black-spotted and the smaller Lemon-throated Barbet, belonging to two different genera, can also be found feeding alongside one another in South America.

Fruit stones (or pits) swallowed with a whole fruit are regurgitated. So far as is known, these stones are not left in the nest to form a carpet, as commonly occurs among the toucans. Interestingly, a barbet about to sing often regurgitates such indigestible items; playback of a barbet's song very frequently triggers regurgitation, as if the barbet were getting rid of an impediment before singing, or were moving as to seek out an "intruder". Smaller fruits are more rapidly digested, and their seeds and pits pass through the digestive system and are voided. Some tinkerbirds regurgitate sticky seeds of mistletoe berries and stick them about the tree surface next to their nest entrance, possibly to deter predators. Barbets are thus major dispersers of seeds of fruiting plants, and are thus important in maintaining the health of the ecosystems of which they are a constituent part. Plants dependent upon birds for seed dispersal may evolve larger fruits that are more likely to be digested and their seeds cast away from the tree or bush producing them. Plants have other dispersal strategies as well, these involving, for example, gradual ripening such that all fruits are not ready at once, or the location of the fruits on thin twiglets where they are difficult for individual birds to gather and eat in large numbers. Big fruits may require the barbets to take them apart: the bird has to seize a fruit, clasp it in the feet, and peck it, taking off pieces, all requiring effort and energy.

Fruits and vegetables readily eaten in cultivated orchards and plantations, and in captivity, are legion. They include apples, bananas, carrots, cherries, custard apples (*Annona*), dates, grapes and raisins, guavas, lantana berries, lettuce, mangos, melons, mulberries, papayas, pears, tomatoes, and whinberries (*Vaccinium*). In captivity, barbets also consume bread, dry and wet cereal, dogmeal, eggs, tinned and other meats, including hamburgers, milk and other foods, as well as numerous insects and dead mice. Captive Yellow-breasted Barbets survive well on a simple diet of meat and eggs. Other plant materials taken at times

by some barbets are the nectar of certain plants, such as species of *Bombax*, *Butea*, *Combretum*, *Erythrina* and *Inga*, the buds of elms (*Ulmus*), and the flower parts of rhododendrons and probably *Quararibia* and others. Black-collared Barbets tear off a piece of apple and hold it in the bill, "tonguing" it with their brush tongue until the morsel is so tiny that it is swallowed. Toucan-barbets hold tubular flowers in their feet and squeeze nectar into the bill; they also hold some berries in the bill, gradually crushing them, the juice flowing down the throat, and then tossing away the remaining berry parts. Red-crowned Barbets eat vine tendrils and thistle seeds at times.

The regularity of consumption of arthropod foods is rather questionable in that the data for many barbets consist of scattered observations. On a number of occasions, in East Africa, several pairs of *Pogoniulus*, *Tricholaema*, *Stactolaema* and *Lybius* have been watched as they worked over the bark of trees and branches, obviously gleaning and taking small insects. The Five-coloured Barbet in America and the Yellow-throated Tinkerbird (*Pogoniulus subsulphureus*) in Africa have been seen tapping into trunks of trees, and Neotropical Black-spotted Barbets forage on branches. Asian Coppermouth Barbets work on branches, tapping at times, and Red-throated Barbets tap on tree trunks, making pitted holes in the bark; the often dirty-billed Gold-whiskered Barbet pecks hard into dead wood at times, and it also may forage in arboreal termitaria. Most American barbets of the genus *Capito* eat more fruits by far than they do insects, but up to 18% of the diet of Black-spotted Barbets consists of arthropod prey, often taken from clusters of dead leaves. Observations show that *Eubucco* barbets regularly forage in dead-leaf clusters for insects and spiders; up to half the stomachs of Lemon-throated and 40% of those of Scarlet-hooded Barbets contain arthropod prey. Fully insect-laden stomachs of Brown Barbets in Asia indicate that that species does at times feed largely on insects.

Scorpions are taken by Asian and American barbets, at least. Some of the other non-insect prey known to be exploited by the Capitonidae include spiders and centipedes, eaten by some Asian and African barbets, slugs of the genus *Limax*, which are taken

Although many species of barbet in South America and Africa are quite often seen accompanying mixed-species foraging flocks, relatively few Asian barbets tend to follow flocks. They are apt to forage alone, or to congregate at fruiting trees. Up to 100 Blue-eared Barbets have been counted at a single tree in Thailand, but these are not roving flocks of barbets; they are just temporary aggregations. The forest barbets of Asia, although mostly rather similar in terms of plumage, come in a variety of different sizes. This variation, along with the differences in foraging strategies and dietary requirements that result from it, underlies the high degree of sympatry observed in some areas. In some Malaysian forests seven species of barbet, including the Blue-eared, forage alongside each other, quite often visiting the same fruiting fig (*Ficus*). Barbets are often the most numerous birds at these trees, usually accompanied by smaller numbers of other frugivores or omnivores such as bulbuls (*Pycnonotidae*), pigeons (*Columbidae*) and hornbills (*Bucerotidae*).

The diminutive tinkerbirds have the smallest and finest bills in the barbet family. It is not surprising, therefore, that they tend to consume the smallest fruit. This Yellow-fronted Tinkerbird, when it is not foraging for other fruit or flycatching for a variety of insects, specializes in collecting mistletoe berries and other dainty fare in the dry woodlands of Africa.

[*Pogoniulus chrysoconus extoni*,  
Nylsvley, South Africa.

by Green Barbets (*Stactolaema olivacea*), and snails, which are sometimes consumed by *Trachyphonus* and by one species of *Tricholaema*. Crested Barbets include some worms in their diet. Among the insects consumed at times by barbets are ants, dragonflies, cicadas, crickets, grasshoppers, locusts, cerambycid and other beetles, hornets, bees, vespid wasps, roaches, caterpillars

and some flying moths, harvestmen, mantids, stick-insects, tabanid and other flies, Hemiptera, Homoptera and flying termites, as well as some termite larvae and eggs. Large and armoured insects are bashed and broken before being swallowed; for this purpose, *Stactolaema* barbets use natural "anvils", which they may partly excavate and which they keep clean. Birds' eggs and nestlings are at times eaten by ground barbets, Miombo Pied Barbets (*Tricholaema frontata*) and Lineated Barbets, and possibly other capitonids. Lizards and frogs are captured by Lineated and Brown-headed Barbets, and by Red-and-yellow Barbets, and Yellow-fronted Barbets feed geckos to their young.

The foraging methods of the Capitonidae reveal nothing out of the ordinary. Ripe fruits are plucked as and where they can be reached by the various barbets. Those species with a "tooth" or a pronged bill tip can presumably snip off fruits more readily than can some others, but all barbets, as they have a strong neck and bill, and the ability to cling and hold on to various twig and branch surfaces, manage to secure ripe fruits. The big Asian species, such as the Great Barbet, pull powerfully to the side and twist the head slightly to pluck certain figs. Most barbets are able to hawk insects, if at times inelegantly, and they do so repeatedly in situations where emerging termites are present in swarms. The specialists that forage among dead-leaf clusters reach out to or cling to the clusters, probing, pecking and even tearing at them to locate insects. The Spot-crowned Barbet is a follower of army ants that forage voraciously over the forest floor, the bird taking as prey any moths, grasshoppers or other insects that fly up, fleeing from the ants. At least ten species of American barbet, representing both subfamilies and all three genera, have been noted as participants in mixed-species foraging flocks, and many, if not most, of the Afrotropical non-social barbets will at least occasionally take part in such flocking. Rather few Asian barbets occur in mixed-species foraging flocks, but many of these are little-known canopy-dwellers that are not often observed for periods of time sufficient to allow such determination of habits.

In-depth studies of more species of barbet are required in order that a proper evaluation can be made of their preferred feeding modes and any seasonal variations in diet. The foods of too few species are known, and in many cases information is based on stomach contents, which have often been incompletely studied and are not representative of all seasons. Simply following a

This Brown-headed Barbet is providing its offspring with food, in this case a praying mantis. Like most frugivores, barbets tend to consume a certain amount of arthropod food, but the proportion of insects caught increases greatly during the nestling and fledgling phases, presumably because there is insufficient protein available in fruit to fuel the rapid growth of tissue, feather and bone.

[*Megalaima zeylanica inornata*,

Despite the high water content of fruit, barbets drink frequently. They visit pools of water on the ground, or trapped in epiphytes or tree holes, and drink by collecting water in the bill and then raising the head to allow the liquid to trickle down into the gullet. The action is well illustrated here by this Yellow-rumped Tinkerbird, one of the most widespread and common members of the genus *Pogoniulus*.

few marked barbets throughout a day would yield significant rewards in terms of data-gathering.

## Breeding

Breeding often takes place in the rainy season, as in the monsoon rains in much of tropical Asia. Where rains are not particularly seasonal, the breeding period may be protracted, even covering essentially the entire year, but losses of nests to cavity competitors, the predation of eggs or young, and the occurrence of second or even third broods in some barbets complicate the picture. If there is an indication of seasonality, with a wetter season and a less wet, drier one, barbets tend to breed in the drier period. In the Himalayan region and in China, breeding follows the northern temperate regime, with nesting taking place mainly in March-July. In temperate and near-temperate southern Africa the austral seasonality holds, and breeding is in September or October to February. Sahelian and sub-Saharan barbets in the Afrotropics breed from February onwards. Non-forest areas with one to three wet/dry seasons have complex patterns that may vary with overall rainfall. Barbets breeding usually in the main rainy season may do so late in that season if rains are especially heavy, or they may breed in the second, less rainy period; they may also nest at the end of prolonged rains that occasionally obscure seasonality. Opportunistic breeding can be essential, for in drought years most barbets may fail to breed. In such areas, over many years, breeding records of, say, Red-fronted Barbets may occur in virtually every month.

Most barbets are capable of breeding at one year of age, but in the case of the larger species, and also many barbets of moderate size, this may happen rarely. The data concerning age of first breeding are sparse. In social barbets, one or more young of the year may remain as helpers in the next breeding season, when they will not breed. C. Restrepo, studying Toucan-barbets, observed that the earliest age at which the birds first bred was 18-19 months.

The availability of food (see Food and Feeding) and a good supply of suitable dead trees or branches for nesting and roosting cavities (see Habitat, General Habits) are obviously breeding prerequisites for barbets. The monogamous, non-social

species usually maintain territories with a larger home range. With suitable foods, mainly mistletoe berries, Moustached Green Tinkerbirds can breed in isolated forest patches of less than 1 ha in extent, but in forest with abutting territories they may defend an area of up to 20 ha. One problem for forest-breeding barbets is the occurrence of large fruiting trees, which act as a magnet

Like woodpeckers (*Picidae*), most barbets almost invariably construct their own nests and roosting holes by excavating wood to form a cavity. They do not, in general, utilize the abandoned nests of other species. By doing so, they probably reduce the risk of conferring a lethal parasite load on their offspring. This Crested Barbet is digging into a broken-ended stump, a process that is likely to take 18-30 days before completion of the cavity. As might be expected, the difficulty and length of the task is related to the softness of the substrate and to the bill morphology of the species involved.

[*Trachyphonus vaillantii*  
*vaillantii*,  
Hwange National Park,  
Zimbabwe.

Planet Earth]

The nest-holes of tinkerbirds are generally very small, and the birds will often complete them in a period of about ten days. The entrance to a tinkerbird nest is typically some 2-2.5 cm in diameter, whereas those of most other barbets tend to be around 5 cm across. As the cavity is usually bored into dead or rotten wood that has split, tinkerbird nest-holes can be remarkably deep, sometimes extending up to 1 m. The nest-hole of the Yellow-fronted Tinkerbird tends to be sited about 2-5 m above ground level.

[*Pogoniulus chrysoconus chrysoconus*, Casamance, southern Senegal. Photo: Michael Gore]

for other barbets in the surrounding areas. Such trees normally cannot be defended; feeding barbets from afar often fly to such food sources above the canopy, avoiding challenges from conspecific territorial barbets below them. Those species inhabiting more open forest, woodland and wooded grassland-scrubland habitats often have large, nebulous territories with even larger home ranges. The location of roosting holes and nesting sites can strongly influence the shape of the territory. In near-desert and Sahelian habitats, neighbouring pairs or social groups may be several kilometres apart, rarely meeting one another. Territories along streams in dry country may be linear, following the channel of a watercourse.

Forest-dwelling Afrotropical barbets have territories of 4-20 ha, the size generally being greater in secondary forest. These territory sizes seem to apply also to most tropical Asian barbets, but the bigger species of *Megalaima* are likely to have territories that are somewhat to considerably larger. In the Neotropics, the Toucan-barbet has a territory of less than 20 ha and the Black-spotted Barbet one of under 10 ha; that of the smaller Lemon-throated Barbet is 10-25 ha, and Scarlet-hooded Barbets defend territories of probably 10-20 ha in a larger home range of up to 100 ha.

Among non-forest barbets, about 10 ha is the estimated territory size for the Miombo Pied Barbet. Social Brown-breasted and White-headed Barbets occupy 5-12 ha of woodland per social group, although in more linear, streamside habitat they may occur at intervals of up to 0.5 km. The Black-collared Barbet has territories of 20-50 ha in coastal Kenya and Zambia, but its groups require 80-125 ha in South African farmlands.

Within the genus *Trachyphonus*, Yellow-billed Barbets occupy territories of about 11 ha in primary forest, but of approximately 8 ha in secondary forest in Gabon. Territories of Crested Barbets average some 21 ha in farmland and woodland. The ground barbets have greater requirements, and their territories vary. D'Arnaud's Barbets in Kenya need 20-100 ha, depending upon the habitat, while Yellow-breasted Barbets' territories are 100 ha and more in the Sahel. The third of these terrestrial species, the Red-and-yellow Barbet, has territories as large as 50 ha, but in habitat with lush streamside vegetation it can make do on as little as 4-5 ha, centred on a streambed, and feeding out from this on each side of the watercourse.

Highly social, colonially nesting species of *Gymnobucco* riddle a dead tree with their nests, up to 250 cavities of Naked-faced Barbets (*Gymnobucco calvus*) having been counted in one tree. Pairs and trios defend only the area around their nest-cavity, so that occupied nests may be as close to each other as 1-2 m. The colonies may contain nests of two or three species of *Gymnobucco*, such as Naked-faced, Bristle-nosed (*Gymnobucco peli*) and even Grey-throated Barbets. Occasionally, a pair of Yellow-billed Barbets will excavate a nesting cavity among those of the *Gymnobucco* species. These large, mixed colonies are unique among the Piciformes, whether that order be narrowly defined or broadly inclusive of the jacamars and puffbirds. Brown Barbets in Asia are social and may nest in loose colonies of up to three or four nests, and at times other capitonids nest rather close together, as with White-eared and Whyte's Barbets, but in these cases the pairs or groups forage in opposite directions, away from each other's nest.

The quality of the habitat has direct effects upon population density. In poorer habitats, the territories of barbets are larger and often not contiguous. In such situations, dispersed young birds may "establish" what prove to be ephemeral territories, and they move elsewhere to try again. Young male Yellow-crowned Barbets may be forced to occupy suboptimal territories in peat-swamp-forest. Among social barbets, the quality of the habitat is reflected in the size of the social groups, with poorer habitat harbouring more pairs, rather than groups, and the groups holding three or four individuals, rather than four to seven. This is perhaps most obvious in the case of the very conspicuous Red-and-yellow Barbet. In comparatively lush wooded-bushland, the loud choruses of the group are heard, followed by duets, from several directions. In drier or more degraded rough terrain, however, choruses may not be noticed, a duet may be heard from a dry *lugga*, or ravine, and one has to strain to hear even one distant duet response: the "groups" are mainly pairs.

Although many barbets sing throughout the year, and social, duetting barbets utter duets in all months, the tempo of singing, simultaneous singing of pair-members, countersinging, and duetting increases significantly as breeding commences. More often, one sees a barbet, usually the male, cocking its tail when near its mate. Paired White-mantled and Green Barbets sing simultaneously, while males and females of the Red-fronted and

Rotten or dead wood is usually favoured by tree-nesting barbets because it is soft and easily excavated.

This Red-crowned Barbet has nested in just such a location, reaping the benefits of easy excavation but running the risk of its nest-site toppling over or breaking off.

The nests are sited at varying heights above the ground, sometimes as low as 1 m up for this species, their position being related to the availability of suitable substrates. Given a choice, most barbets tend to nest fairly high up in trees. Barbets do not usually line their nests with any material other than a few wood-chippings from the building phase; most chips are carried away from the nest.

As we can see from this photograph, the head is often the only part of a barbet regularly visible during the breeding season, and this is perhaps one reason why so many species in the family have such striking species-specific markings centred around the bill.

[*Megalaima rafflesii*,  
Sime Forest, Singapore.  
Photo: Ong Kiem Sian]

Acacia Pied Barbets (*Tricholaema leucomelas*) sing back and forth at one another, often one "hoop"-singing and the other "nyah"-singing (see Voice). Lineated and Brown-headed Barbets increase the tempo of songs, and both males and females sing. The chorusing, social barbets go through greeting ceremonies and duets at frequent intervals at the periphery of their territories. Several species will even sing all night on moonlit nights, Red-throated and Lineated Barbets being examples.

Flight displays are part of the breeding ritual of many capitonids. The male Black-spotted Barbet, for example, flutters in flight around the female. White-eared, Whyte's, Anchieta's, Hairy-breasted, Red-fronted, White-headed, Chaplin's, Red-faced, Black-billed and Black-collared Barbets are among those species with a gliding, "floating" display-flight, performed by the male as, with wings stilted or fluttering, he comes to perch beside a female or flies to her. Male Lineated Barbets use a noisy, flopping flight when approaching the female.

Courtship feeding of the female by the male, when the former may pass back the item proffered, almost in teasing fashion, is usually an indication of breeding, yet it is remarkable how infrequently it has been observed. The behaviour occurs in all four species of *Stactolaema*, in the better-known species of *Pogoniulus*, in the Red-fronted Barbet and, among the *Lybius* species, at least in the White-headed, Black-collared, Brown-breasted, Black-backed and Double-toothed Barbets. It is exhibited also by Crested Barbets and ground barbets, by the Asian Lineated, White-cheeked, Red-throated, Flame-fronted, Blue-eared, Crimson-throated and Coppersmith Barbets, and by the American Red-headed (*Eubucco bourcierii*) and Prong-billed Barbets. It seems very probable that virtually all capitonids will be found to engage in courtship feeding. This behaviour may precede copulation. In an observation of courtship feeding by the little Yellow-rumped Tinkerbird, what was presumably the male fed 13 consecutive berries to his mate, and 32 berries in 25 minutes, indicating that a good number of fruits can be held in the oesophagus by the displaying male.

Although roosting holes may be excavated at any time of the year, the excavation of the nesting cavity is another conspicuous feature of the early breeding season. In solitary barbets, the sec-

ond member of the pair is generally evident around the "construction site" when a nest is being excavated, a process in which both male and female usually take part. The cavity, as it is dug, becomes a focal point for courtship activities, and change-over at excavating may be a part of courtship; at times, the male and female replace each other too rapidly to allow either to perform effective excavating. A few barbets are known to tap, really to "drum" in the manner of woodpeckers, at the edge of the cavity entrance. These include several species of *Stactolaema*, and the White-headed Barbet. All capitonids excavate their own nests in trees or posts, or, in the case of the ground barbets, in earthen banks or the ground, while some, such as the Brown and the Black-backed Barbets, dig into arboreal carton-ant nests. Some barbets will occasionally excavate deeper within old nesting or roosting cavities. Further, they sometimes use old woodpecker holes, and rarely they usurp a nest of another species, as did one Crested Barbet pair which took over the hole of a Rufous-necked Wryneck (*Jynx ruficollis*). The Crested Barbet at times uses nestboxes, too; other barbets could probably be induced to use such boxes, but in the tropics nestboxes are all too readily seized upon by bees, snakes and small mammals, if not by other birds.

Excavation of nests may proceed slowly or rapidly. The selected sites are usually at some height above the ground, but a shortage of suitable dead wood may cause the birds to utilize unusually low sites, or fence posts. Even standing logs and broken, hanging branches may be used at times. Smaller barbets often, or perhaps even usually, excavate on the underside of small dead branches. Soft though the tail feathers may be when compared with those of woodpeckers, the barbet, when working in this way, sometimes uses the tail as a prop, the Coppersmith Barbet being one example.

The cavity can be excavated rapidly, in as short a period as ten days in the case of Yellow-rumped Tinkerbirds. This probably reflects the rottenness of the wood, which is sometimes split or harbours a natural cavity within, explaining why a few such tinkerbird nests are as deep as 1 m, while the small Crimson-throated Barbet's nest-chamber can on rare occasions be 1.5 m from the entrance. In general, most barbets for which there are relevant data available take 18-30 days to construct the cavity. The Acacia Pied Barbet, however, can do so in eleven days, whereas the White-eared and White-headed Barbets may take up to six weeks, despite helpers assisting with the excavation. The nests of tinkerbirds have an entrance hole 2-2.5 cm in diameter, that of most barbets being about 5 cm. In the Black-collared Barbet, cavities are excavated to about 48 cm, strictly by the pair, while roosting cavities are about 13 cm deep. The nest of a pair of Black-backed Barbets, when built in a termitarium, may have a 10-cm tunnel leading to a chamber 10 cm in diameter. Usually some wood chips are left at the bottom as a lining; most of the chips produced in excavation are carried away from the nest, except at the start. The Blue-throated Barbet is reported to use a nest lining of grass, or even wool at times.

The Red-and-yellow and Yellow-breasted Barbets excavate horizontally into an earthen bank, usually to a depth of approximately 40 cm, but the latter may burrow to a depth of 1 m. The nest is in a chamber of about 10 cm diameter. D'Arnaud's Barbet digs its tunnel straight into the earth, usually beside a grass tussock, and the tunnel may be 45-90 cm deep. The nest-chamber is not at the bottom of this vertical shaft, but, rather, is excavated to one side off the main tunnel, at a point well above the bottom, allowing rainwater to enter the soil at the bottom and thus, in most cases, preventing flooding of the chamber itself.

Courtship continues during nest-building. Copulation may be preceded by courtship feeding or by allopreening sessions, or it may occur with no preliminary displays. The social barbets usually go through displays involving bowing, swinging of the body, and flipping and cocking of the tail, and flight displays may lead to copulation. In Anchieta's Barbets, grating calls are uttered, and the male glides to the female; the two bow, and the male cocks its tail and courtship-feeds its mate, before mounting her from either side. The *Tricholaema* barbets sometimes copulate with no display other than the soliciting of the female, or the male may glide in or fly over her with stiffened wings, land and cock its tail, and the two birds often swing and bob about; the female crouches,

*While most of the Asian and South American barbets nest in solitary pairs, a few African species are social. Whyte's Barbet, for example, breeds in groups of up to six birds, with helpers assisting the primary pair at the nest. Little is known about the dynamics of this system, but it is likely that helpers are related to the breeding pair. In general, one group member perches almost constantly near the nest, keeping a watchful eye for predators as well as competitors for nest-holes and brood parasites.*

[*Stactolaema whytii* sowerbyi, Marondera, Zimbabwe. Photo: Geoff McIlleron]

Many of the smaller barbets, such as the Coppersmith, tend to nest high in the branches of dead trees, where they are safer from the prying of predators. While snakes, monkeys, squirrels, mustelids and raptors are known to predate the eggs or young, one of the greatest threats to the success of breeding attempts is the belligerence of other barbets. Direct competition between species in this family is evident through regular aggressive encounters, with larger species driving away smaller ones, and through the wrecking of nesting or roosting cavities. Bigger barbets achieve this by enlarging the cavities used by their smaller relatives, such that they are no longer suitable for their use.

[*Megalaima haemacephala indica*,  
Kaeng Krachan  
National Park, Thailand.  
Photo: Bernard van Eiegem]

Territory size varies with species, and also within a particular species it often varies with the nature and quality of the particular habitat type occupied. In poor-quality habitat, the terrestrial Red-and-yellow Barbet may hold a territory of up to 50 ha, but where a stream makes the surrounding vegetation more abundant and productive, a pair can require only 4-5 ha, and at times the species occurs at densities of about 1 pair/200 m. This male is bringing a dragonfly to the nest. At least during the day, the male's contribution to chick feeding and incubation is greater than that of the female.

[*Trachyphonus erythrocephalus erythrocephalus*, Kenya.  
Photo: Alan Root/Oxford Scientific Films]

waggles her wings and fluffs her feathers, and the pair copulates. Black-collared Barbets perform a greeting ceremony in which the whole group participates; the primary male cocks its tail and displays beside the primary female, and the two may touch bills and mate at one side of the group. In Crested Barbets, both sexes erect the crest, the female crouches, the two touch bills, and they then copulate. Red-and-yellow Barbets courtship-feed, and preen each other, and the male cocks its tail and raises its crest, parading before the female until she crouches, trembling, and they mate. Little is known of the behaviour of Asian barbets before and during copulation, other than the fact that courtship feeding may precede it. There may be little in the way of display because pair-bonds are long-term; in captivity, one of the pair, as breeding begins, often kills any additional conspecific caged with them. Copulation may occur twice in rapid succession, each performance lasting 6-7 seconds in the case of White-cheeked Barbets, compared with 10-12 seconds in the Afrotropical Black-backed. Among the American species, the male Black-spotted Barbet will flutter in display over its mate, land beside her, and bounce about with wings fluttering prior to mating. Male Red-headed Barbets courtship-feed, and the male then mounts and treads atop its mate, holding her nape feathers during coition. Displaying male Toucan-barbets cock the tail, fluff the throat and crown feathers, and erect the white superciliary feathers so that they flare out to the sides, before the two birds copulate.

The eggs and, therefore, the clutch sizes of the Capitonidae are incompletely known. The eggs of three-quarters of the Afrotropical species have been described, as have those of half the tropical Asian species and of just over one quarter of the Neotropical barbets. Known clutch sizes range from one to seven eggs; larger barbets, and particularly Asian barbets, tend to lay smaller clutches of two or four, but White-eared and Red-and-yellow Barbets can lay six-egg clutches. The eggs are white, more or less in the form of a long oval, and smooth to slightly rough in texture. They range in weights from approximately 1 g to 18 g, and one egg is laid each day until the clutch is completed.

The parents and any adult helpers have a brood patch, indicating that incubation is shared. Incubation commences when the last or the penultimate egg is laid. Change-overs in duties are

shorter, at intervals of 10-30 minutes, in those species with helpers that incubate, as in the White-eared, White-headed and Green Barbets. Non-social barbets may take turns at up to three-hour intervals. The Flame-fronted Barbet, on returning to the nest, taps at the entrance to signal to its mate to leave. The off-duty mate often perches near the incubating parent, and Green Barbets sometimes sing together, one from within the nest, while incubating. It is not unusual for an adult barbet to sit tightly; in one instance, a nest with eggs was sawed free and carried home, where the collector found a Black-collared Barbet sitting on the clutch.

The incubation period of Afrotropical barbets is 12-19 days, and, so far as is known, that range applies to tropical Asian and American barbets as well. In cases in which the two parents do not roost in the nest together, the female seems to incubate at night, but sometimes, as with the Red-and-yellow Barbet, the male incubates more than the female during the day. In the social barbets of the Afrotropics, a "guard" sometimes perches close by the nest while another incubates inside; indeed, when the nest is first occupied by barbets, one of the adults usually remains near it. This is not only an anti-predator action, but is also necessary to protect the hole from would-be usurpers, usually secondary cavity-nesters. Moreover, the Afrotropical barbets are plagued by one or another of the nest-parasitic honeyguides, especially the Lesser Honeyguide (*Indicator minor*). The honeyguide may monitor the barbets' nests, try to approach them at whatever their stage, and lay in them if they are at the appropriate stage. Lesser Honeyguides will interfere with chorusing and duetting social barbets, and can disrupt a nesting attempt, thereby providing opportunities for a honeyguide to parasitize during the next nesting. In one such instance of disruption, after Lesser Honeyguide interference, two members of a group of Chaplin's Barbets chased the honeyguides, while another group-member entered the nest, carried the four eggs one by one to the entrance and systematically crushed each one, dropping them below. Any successful laying of a honeyguide egg in a barbet nest virtually ensures the destruction of the barbet's eggs or young by the hatchling honeyguide.

On hatching, the naked, blind barbets clearly exhibit the egg tooth with which they crack the shell in order to emerge. They rest in sitting posture on the spiky-scuted hypotarsal tubercles,

The open-country barbets in the genus *Trachyphonus*, including the Red-and-yellow Barbet, nest in freshly made burrows dug into earth banks or termite mounds. The tunnel is generally sited 1-4 m above the surrounding lower ground, and is at least 40 cm deep. A new tunnel is excavated each year. Raising young in the group-living ground barbets is a co-operative affair. Group size in Red-and-yellow Barbets reaches eight, and even in these large groups all individuals help the primary pair to feed insects to the nestlings; it is not yet known whether or not all individuals contribute to excavating the cavity. This picture shows two males perched at the nest entrance.

[*Trachyphonus erythrocephalus erythrocephalus*, Tarangire National Park, Tanzania.  
Photo: Dave Richards]

and on the abdomen. All those species that are sufficiently well known begin feeding the young on insects, or on a mix of insects and fruits. In the socially nesting species, all members of the group feed the young, which are also brooded, mainly by the parents, during cool or wet periods until the feathers appear, at about two weeks of age. Some, and perhaps most, barbets regurgitate food to the nestlings, at least initially. Feeding rates occasionally reach as high as 20 per hour, although the chicks are more usually fed six to 15 times per hour. In some barbet species, a brood-feeding adult remains in the nest until the other parent, or another individual, appears with food, as happens with Fire-tufted Barbets (*Psilopogon pyrolophus*). In social species, except those of *Gymnobucco*, "guard" barbets continue to stay around the nest, and they sometimes feed the young; in one observation, one guard hawked insects by the nest, feeding the young three times in 30 minutes. Gradually, more fruits than insects are brought to the young, but some insects continue to be fed to them, especially by species of *Stactolaema*, ground barbets and the Toucan-barbet. The adults enter the nest to feed the brood until rather late in the nestling period, often up to the last week, after which the young are fed at the entrance.

The nest-cavity remains clean throughout the season, as the barbets remove faecal material from the nest. At first this material may be eaten, but later on in the cycle it is carried away from the site and dropped, usually as a faecal sac, which is sometimes mixed with wood chips. On average, faecal sacs are removed on about every third feeding; Yellow-rumped Tinkerbirds, for example, took away twelve sacs over a period of two hours, during which they fed the young 38 times. Large pits or stones egested into the nest are also removed. Some additional excavation is occasionally carried out in order to provide more wood chips for mixing with the often loose faecal matter, as has been recorded for Prong-billed Barbets.

Snakes, monkeys, squirrels, mustelids and other predators are known to take eggs or young from barbet nests. For the smaller capitonids, however, a greater nuisance can be posed by other, larger barbets, which excavate to enlarge the nest opening, and then clear the cavity of eggs or young, as the White-cheeked Barbet does to nests of the Crimson-throated Barbet. The Plate-

billed Mountain-toucan (*Andigena laminirostris*) frequently usurps the nests of Toucan-barbets. Army ants, often referred to as safari ants, are a predator on nestlings; one "army", having located the nest of a Whyte's Barbet in a tree trunk, killed and dismembered the nestlings and carried off the pieces to their own nest. Human disturbance of nests of all birds in tropical regions, and especially in Africa, where predators have for millennia followed trails of humans as a tactic for locating food, all too frequently leads to the destruction of nestlings, eggs and adults; in some areas, 90% of nests examined closely have "failed", and this makes regular visits to nests to examine their contents very risky indeed. Another source of predation, in this case certainly restricted to Africa, is the African Harrier-hawk (*Polyboroides typus*), the long legs of which have flexible joints; this raptor clings to the bark and reaches its legs far into tree cavities, from which it can extract the eggs and young of any barbets which do not nest in deep hollows. The Neotropical Crane Hawk (*Geranospiza caerulescens*), with a similar leg structure, is possibly also a predator of barbets in America. Finally, but importantly, the Afrotropical honeyguides must be considered a major cause of nest failures, since these birds almost always parasitize the nests of barbets, to the extent that every Afrotropical honeyguide represents a lost barbet clutch.

As with other piciforms, the nestling periods of barbets are rather long and the development of the chicks slow. Tiny tinkerbirds leave the nest at 17-23 days of age, whereas the larger barbets have nestling periods of 25-46 days. Examples of the latter include 28-35 days for species of *Tricholaema*, and, among *Lybius* species, 33-35 days for the Black-collared Barbet and 38-39 days for the larger Double-toothed Barbet; about 42 days for the Fire-tufted Barbet, and 35-38 days for several small to large species of tropical Asian *Megalaima*; and, in the American tropics, 34 days for the Black-spotted Barbet, 31-42 days for the Red-headed Barbet, and 43-46 days for the Toucan-barbet. One female Fire-tufted Barbet, the mate of which died when the nestlings were three weeks old, was able to raise the young successfully by herself.

Nestling barbets develop slowly, but add most of their weight towards adulthood in their first two weeks, after which progress

In pair-living barbets, such as these Brown-headed Barbets in India, change-overs at the nest during the incubation period tend to occur every three hours or so. This contrasts with the situation in the group-living barbets that switch over at the nest every 10-30 minutes. Off-duty pair members are regularly seen perching near the nest-hole, and some species of barbet occasionally counter-sing to each other, one from within the nest-hole and the other outside.

[*Megalaima zeylanica* zeylanica, Delhi Ridge Forests, Dhaula Kuan, Delhi, India. Photo: Ashok Jain/ BBC Natural History Unit]

The courtship behaviour of the Red-fronted Tinkerbird is poorly known, but in many barbet species, including some tinkerbirds, courtship feeding is known to play an important part.

In some cases, pair members will pass food items between them almost teasingly; both courtship feeding and allopreening can be precursors to copulation. Other barbet displays tend to involve posturing by pair or group members, raising of feathers to show off the flashy crown and head patterns, and cocking or flicking the tail.

in eye, muscle and feather development is rapid, although weight gain slows and often ceases in the last week in the nest. The eyes may not open fully until nearly three weeks after hatching. Vocalizations shift gradually, the begging calls of young chicks differing, often considerably, from those of fledglings. At 27 days of age, nestling D'Arnaud's Barbets can utter duet-like notes. The well-feathered young reach the nest entrance within their last week in the nest. As the time for fledging approaches, food is often withheld by the adults, as happens with Brown-headed Barbets, and the adults may hold food conspicuously nearby, enticing the nestlings to leave the cavity. Generally, the young are led back to the nesting cavity for roosting at night. Soon thereafter, the nest is often "handed over" to the fledglings, the adults roosting elsewhere, as in the White-headed Barbet.

Subsequent care of the fledglings varies greatly, even within species, being dependent partly upon whether or not the adults begin a second brood. Fledged Coppersmith Barbets are independent at fledging or within two days of it. Adult White-cheeked Barbets feed their fledglings for just two to four days, roosting with them in the nest; the young are then cast out, and disperse from the territory by ten days of age, by which time the pair is renesting. In social barbets, the young may remain with their parents and group for up to five months or more, as in the case of Black-collared Barbets, but that species will nest up to four times in a year, and its groups rarely number more than four or five individuals, so that numbers of young must disperse. Black-throated Barbets tend to fledge only two offspring, one of which then accompanies each parent daily, the parents foraging in different directions from one another. Fledged Red-fronted Barbets remain a month or two with their parents, and are then driven from the territory. A likely reason why young barbets are able to reach independence as quickly as they do is that the parents can lead them to a fruiting tree and simply let them feed there; after a few days, the juveniles have acquired information which they can then use to locate fruits on their own, especially if nesting has taken place at a time of food abundance.

Crested Barbets in Africa sometimes nest as many as four times in a season. The young remain with the adults for a short period after fledging, and the parents then keep them from returning to the nest. As their parents renest, the young of the ex-

isting brood generally disperse from the territory. Double-brooded Asian barbets include the Great Barbet in China, which can raise three broods in Hong Kong, and the Lineated and Yellow-fronted Barbets; as these species nest strictly in pairs, the young of the first brood must of necessity become independent rather rapidly. Most American barbets are poorly known in terms of the relations between adults and young. In captivity, Black-spotted Barbets sometimes feed their young for about three weeks after fledging, while captive Red-headed Barbets renest after the first nesting, their fledglings being essentially independent. Fledgling Prong-billed Barbets, which lack the bill prong of the adult, accompany their parents back to the nest, and are fed for up to 40-45 days, until they can feed themselves readily. The Toucan-barbet, also prong-billed, raises two or, occasionally, three broods in Colombia. Its juveniles beg for up to four weeks after fledging, and do not have the notch-hook on the bill fully developed until about four months of age. The young of the first brood can act as helpers in raising a second brood.

In studies in southern Colombia, Toucan-barbets were found to raise on average about 1.4 broods per season. Those pairs breeding with helpers successfully reared to fledging an average of 1.1 clutches per year, whereas pairs without helpers fledged only 0.5 clutches per year. The mean age of dispersal of male Toucan-barbets is 10.1 months, and that of females 9 months, indicating that young helpers assisting in the following breeding season may be mainly the survivors of second and third broods of the preceding year.

The data on longevity among barbets are very sparse, and permit little in the way of meaningful comment. Captives of one small and one large species of *Megalaima* are known to have attained an age of nine years. This suggests that at least some barbets may reach ten to twelve or more years of age in the wild, which is about the same as is known for the honeyguides.

## Movements

To put it simply, barbets disperse, but few exhibit any real movements, perhaps none moving 100 km or more. The greatest displacements are those made by the Himalayan species, espe-

cially the Great Barbet, which migrates downslope to the foothills and protected valleys, where it spends the winter. This barbet and others sometimes move locally, from more humid woodland to adjacent dry woodland, to forage for fruits. Other than such mini-migrations, the only movements made by capitonids are those of dispersal, although these may be over rather long distances; those of some dry-region barbets, such as along watercourses, could even be considered emigration.

Droughts can cause large-scale shifts of scrubland barbets, such as Red-fronted Tinkerbirds, into nearby hills and uplands. Dispersal-immigration by Acacia Pied Barbets into dry areas of western and south-western South Africa has occurred within the past century, coinciding with the planting of exotic trees, especially including Australian *Acacia* species, and the planting of fruit trees in formerly treeless areas. Permanent surface water is also more widespread in these areas.

Studies have shown that individual barbets at the fringes of the range regularly disperse about 10-12 km beyond the area in which they are normally found. This distance seems a rather likely one for the dispersal of most species of barbet.

### Relationship with Man

There seem to be few relationships between barbets and man that do not refer directly to conservation (see Status and Conservation). Widespread in the tropics, and very vocal, these birds, as a group, are well known both to birdwatchers and to local inhabitants in general. The colourful ground barbets provide feathers for garments and ornamentation of tribes such as the Samburu and the Maasai in East Africa. Despite their relatively small size, barbets are sometimes hunted for food by children, if not by adults.

Members of the Capitonidae are not held by many aviculturalists on a worldwide basis. In some parts of their ranges, however, they are collected in some numbers to be kept as pets by local people, this practice being particularly prevalent in South American countries. The Toucan-barbet is one species possibly threatened locally by such collecting. Some Asian barbets can

be seen in rather high numbers in Singapore, Bangkok and other bird-marketing places, and some are taken in China as pets. As with many other bird species, barbets are illegally captured in Indonesia to form part of the menu of local restaurants.

In some areas of tropical Asia, and in some gardens and orchards in the Neotropics, these birds are regarded as pests because of their habit of eating, or otherwise damaging, fruits such as papayas and mangos. The Brown-headed, White-cheeked and Yellow-fronted Barbets damage and consume tomatoes, as well as other fruits, and are treated as pests in coffee plantations of India and Sri Lanka.

### Status and Conservation

Currently, only one species of barbet is considered to be globally threatened, namely the White-mantled Barbet, which is listed as Endangered. Nine other capitonids are considered Near-threatened: the Afrotropical Chaplin's and Red-faced Barbets; the Asian Red-crowned, Red-throated, Black-banded and Yellow-crowned Barbets; and the Neotropical Orange-fronted and Five-coloured Barbets and Toucan-barbet. In addition, the so-called White-chested Tinkerbird, now generally treated as a variant form ("makawai") of the Yellow-rumped Tinkerbird (see Systematics), is listed as Data-deficient.

Although these ten species represent only a fairly small percentage of the total of 82 Capitonidae, this is not the time to be sanguine about the future prospects of tropical-forest birds. T. C. Whitmore and others, writing about tropical rainforest in the last decade of the millennium, offer no hope for the saving of major tracts of tropical Asian and most tropical African rainforests. In woodland areas of East Africa, sights that can be seen every day include the cutting of trees, destructive firewood-gathering involving the killing of living trees to be collected some time later, and the conversion to charcoal of patch after patch of remnant primary and secondary woodland. There is no mistaking the fact that the greed of humans and the inexorable pressures of expanding populations pose the most serious threat to forest and woodland barbets. That a few years still remain in which to save substantial tracts of Neotropical and some central African forest

*In seasonal climates, barbets tend to nest during the rains, but where seasons are more constant the timing of breeding is diffuse and can occur virtually all year round. Most barbets can raise more than one brood in a season, while the Crested Barbet has been recorded nesting four times in a season. When their parents renest, young from previous broods tend to disperse away from the natal territory. In some cases this means young birds reaching independence and dispersing within a very few days of fledging.*

*As with other piciform birds, the nestling period in barbets is protracted and the development of chicks is slow. This Acacia Pied Barbet will feed its nestlings for 32-35 days before they fledge, an enormous amount of time for a bird of its size. As cavity nests are less susceptible to predation than open or terrestrial nests, there is less advantage in nestlings becoming independent shortly after hatching. This allows barbets to produce smaller, energetically cheaper eggs, and to rear hatchlings from an earlier stage.*

[*Tricholaema leucomelas leucomelas*,

South Africa.  
Photo: Peter Steyn/Ardea]

Afrotropical barbets are plagued by a family of related brood-parasitic birds, the honeyguides (Indicatoridae), foremost amongst which in terms of its impact on barbet breeding success is the Lesser Honeyguide (Indicator minor).

This species may monitor barbet nests, and lay in them at the appropriate stage. If the stage is too advanced, the honeyguide can disrupt the breeding attempt so that the barbets re-lay, thereby giving the brood-parasite a chance to contribute to the next clutch. Barbets are highly aware of the threat of honeyguides, chasing them away if they approach the nest-site and sometimes responding to the disturbance by crushing their own eggs.

If a Lesser Honeyguide successfully lays an egg in a barbet's nest, the reproductive output of the latter is almost always eliminated, as the honeyguide chick breaks the barbet's eggs and kills its chicks. The parasite's strategy regularly meets with success: this photograph shows an adult Black-collared Barbet feeding a young Lesser Honeyguide.

Reports of the tolerance of barbets to disturbance are somewhat mixed. For example, as well as the honeyguide example above, nesting barbets disturbed in captivity regularly destroy their eggs or young. In contrast, after a Black-collared Barbet nest was sawn from a tree, the nest collector found the adult bird still incubating when he returned home!

Nest cavities are kept clean and hygienic by barbets throughout the breeding cycle. The adults remove faecal material, either as sacs or mixed with woodchips from the base of the nest. Indigestible fruit remains and fruit stones are also gathered up and carried away from the nest, as illustrated by this Coppersmith Barbet. In this way the Capitonidae differ from their relatives the Ramphastidae, which tend to allow a deep layer of fruit stones to gather in the cavity. Also seen here is an adult delivering pulverized and probably regurgitated food into the nestling's gape. Regurgitation is probably the main feeding technique employed by barbets, at least early in the nestling stage. In this instance, however, the nestling is quite mature, as indicated by the advanced development of its feathering, its open eyes, and the fact that it is feeding at the entrance to the cavity, something young barbets only do as they approach fledging.

The two races of the Spot-crowned Barbet occur in Panama and northern Colombia, where they are locally fairly common. Given this fact, the species is not thought to be immediately threatened. Nevertheless, very little is known about its ecological requirements and there are no estimates of its population size or rates of decline. Given its apparent dependence on forested habitat, and the lack of information regarding its status, it would seem to require research and close monitoring in order to assess the impact of rapid deforestation in its range.

[*Capito maculicoronatus rubrilateralis*, Valle, Colombia.

areas is little consolation, given the lack of political will in both developing and developed countries. Of particular concern for barbets is the intensity of the human need for dead wood, the removal of which eliminates nesting sites. Even the selective logging sometimes practised in southern Asia removes the host trees of strangling figs, and thus the figs themselves, a primary barbet food.

Pressure on barbets from the capture of birds for the cagebird market is a lesser problem made significant through even greater removal of the habitat itself. Obviously, as barbets become ever more restricted to smaller fragmented forest patches, the local capturing of them in these remnants becomes significant; and we ought to be able to stop such practices, because they are illegal in the countries in which they occur. The Toucan-barbet and the Fire-tufted Barbet are two species frequently taken for the cagebird trade.

There are some favourable practices that afford assistance to the birds. The planting of fruiting trees attracts barbets to gardens. Moreover, in India, the general antipathy towards the killing of animals, despite the depredations of barbets on fruit trees, has resulted in the presence of forest-edge species in rather open country and in city suburbs. In the Afrotropics, softwood trees, even exotics such as Australian acacias and Neotropical jacarandas, attract barbets by providing sites for roosting and nesting cavities. Such cavities of Yellow-rumped and Moustached Green Tinkerbirds, and also of Spot-flanked and White-headed Barbets, have been found in jacarandas, and it is thought almost certain that forest fragments with jacarandas beside them would attract at least Yellow-billed and Double-toothed Barbets. Nestboxes, which are known to be accepted by at least one species, the Crested Barbet, can be tried on a large scale for other barbets, especially in secondary forest and logged forest in which "firewood" has been gathered. Even though some boxes would be appropriated by other animals, it is likely that several would remain available for barbets.

To judge from the number of species of capitonid and their widespread occurrence in extant forest areas as frugivores, it is apparent that these are important agents for the dispersal of the seeds of certain forest and woodland trees. In maintaining intact forest, attention needs to be paid to the plight of these and other frugivores. There are almost no available data on their signifi-

cance for the health of such forested areas, but studies of frugivores by H. E. McClure and others suggest that the barbets may be of considerable importance.

A few open-habitat species of the Afrotropics, such as the Acacia Pied Barbet and Red-fronted Tinkerbird, have benefited from anthropogenic activities other than locally. Some non-forest barbets, the Double-toothed being an example, may have been

Sharing the subfamily Megalaimatinae with the diverse and familiar Asian genus *Megalaima*, is the associated monotypic genus *Psilopogon*.

This contains the Fire-tufted Barbet, with its long graduated tail and facial bristles arranged in a distinct nasal tuft.

It is endemic to the Sumatra and Peninsular Malaysia EBA, where it remains common in many areas, but it is susceptible to the continuing removal of humid montane forest to supply timber and make room for agricultural expansion.

[*Psilopogon pyrolophus*.  
Photo: Rob & Ann Simpson]

aided by the opening-up of forest. Furthermore, it is possible that some Sahelian species that are arboreal, such as Vieillot's and Bearded Barbets and the Yellow-fronted Tinkerbird, have gained as much through forest clearance in the south, and from the planting of some fruiting trees about homesteads, as they have lost through the felling of Sahelian trees for buildings and firewood. Overall, the three ground barbets may have increased their numbers marginally, although degradation of habitats exploited in the past may have lowered their populations, but there are no firm data to confirm this. Forest barbets have without doubt suffered loss of habitat in the Afrotropics, where forested land is still being cleared by slash-and-burn tactics. Favoured tribes are allowed to encroach upon, settle in and even entirely destroy forest "reserves"; not only does this occur with the knowledge and connivance of leading businessmen and government officials, but some parts of reserves are gifted as favours for political support by those at the highest level. It is a tragedy to see indigenous African "green" movements stifled, and their protagonists' complaints brushed aside. In Kenya, such actions are responsible for, among other things, the fragmenting of the ranges of coastal-forest Green Barbets and Eastern Green Tinkerbirds, and of woodland Black-collared Barbets of the distinctive subspecies *irroratus*.

Wars are not just human tragedies, but also affect wildlife, in most ways adversely. Virtually all recent conflicts have as causal factors the heightened competition for land. In Africa, overpopulated Rwanda has run out of space: except for three or four parks and reserves, every bit of land is under some form of human use. One consequence of the recent and well-publicized civil war there has been the overrunning of the northern half of once grand Akagera National Park that ran along most of the country's eastern border with Tanzania. Settlers moved in with large herds of cattle, cleared trees for building and firewood, burned large areas, and shot out the small to large game. That area covered about one-quarter of the world range of the Red-faced Barbet, the fate of which may now be in doubt.

So far as is known, the tropical Asian barbets have not undergone any expansion or increase in numbers, with the single exception of the non-forest Copper-smith Barbet. Some other species of *Megalaima* have perhaps been buffered by their ability to utilize second-growth forest, but removal of the primary forest which they have occupied historically must surely have prevented their populations from increasing. One can only be chilled by

what must be the terrible effects of the calamity of the fires, smoke and smog of the late 1990's as recorded by N. Brown in Sumatra and Borneo; on top of these are the as yet unknown and unreported effects upon growth and on seasonality of fruiting, and the changed ecology of the forest trees upon the fruits of which the dozen or so barbets of those islands depend. Severe smog effects have spread even over Peninsular Malaysia, where other barbets occur. Thus, the direct effects of the fires upon hundreds of thousands of hectares of forest may be but a small part of the destruction they have wrought on unburned forest; and, what is worse, clearance of forest other than by fire still continues.

Neotropical barbets appear to be under somewhat less threat, but all are forest species, mostly of moist or wet evergreen forest, a habitat that is increasingly threatened. The new road being built from Manaus, on the River Amazon in Brazil, northwards to Venezuela, with huge areas alongside it opened to slash-and-burn colonization, will bisect the northern Amazonian forest and open up far north-western Brazil to exploitive human activities of every type. Understorey species such as the Scarlet-crowned and Scarlet-hooded Barbets, adapted to shifting river-edge and island habitats, may be able to survive quite easily, but there is concern for the canopy-dwelling barbets, particularly those of restricted ranges, such as the Cinnamon-breasted Barbet.

Perhaps the one factor in the barbets' favour that puts them in a somewhat better position for survival than their larger frugivorous cousins the toucans, and others, such as the hornbills, is that the capitonids, owing to their smaller size, require smaller territories and home ranges. A 100,000-ha area of park or reserve in western Amazonia can be expected to hold 2000-4000 pairs of barbets of several species. Even larger forest parks could ensure the survival of these species. Nevertheless, the amount of illegal logging is reckoned to be about 80 % of all logging endeavours in Amazonian Brazil, and an almost exponential increase in logging during the 1990's has been documented by W. F. Laurance and others. These factors give cause to fear that all too soon a point will be reached at which relatively few large areas of protected tropical evergreen forest remain, this before there is full awareness of the need to save intact forest, and before there is sufficient knowledge of the species that require conservation action. Without the political will to make forest reserves sacrosanct and free from any fur-

Although the Banded Barbet has a rather small range, being restricted to woodlands in Ethiopia and Eritrea, it is not considered threatened, as it is locally quite common and tolerant of a fair degree of habitat degradation. As with most tropical species, however, data on its population size, ecology and threats are sparse. Further research needs to aim at providing such information for this and various other poorly known barbets.

[*Lybius undatus leucogenys*, Lake Langano, Ethiopia. Photo: Dick Forsman]

Both members of the aberrant subfamily Semnornithinae have a curious prong on the tip of the upper mandible that fits neatly into a notch in the lower mandible; this feature is unique amongst piciform and near-piciform birds. One of these taxa, the Prong-billed Barbet, is a restricted-range species endemic to the Costa Rica and Panama highlands EBA, a region that is suffering widespread habitat destruction, as a result of burning, logging and conversion to agricultural use.

[*Semnornis frantzii*, Monteverde Cloud Forest Reserve, Costa Rica. Photo: Robert Behrstock]

The Toucan-barbet is so named because it bears a superficial resemblance to some members of the Ramphastidae; in particular, the texture and colour of the plumage resembles the mountain-toucans, one species of which it lives alongside, and indeed competes with, in the humid hill forests of western Andean Colombia and Ecuador. Its population was recently estimated at c. 73,000 individuals, too high for inclusion in the threatened categories at the current rate of decline. However, such is the level of forest destruction in its range, and such is the threat of trapping for the cage-bird trade, that its status might very shortly require re-evaluation; at present it is classified as Near-threatened.

[*Semnornis ramphastinus caucae*,  
Río Nambí, Colombia.  
Photo: Patricio Robles Gil]

ther pressures to exploit them, the consequences will be both tragic and irreversible.

Only eight to ten species of barbet have ever been bred in captivity, and relatively few aviculturalists have experience in maintaining these birds in aviaries. Fortunately, there is perhaps sufficient information available to suggest that most barbets can be maintained relatively easily under appropriate conditions, and

The Brown-throated Barbet is a rather large and dull-coloured species that lives in the mountain forests of Java. The massive devastation of lowland and hill forests on this heavily populated Indonesian island has left few patches of forest standing. Fortunately, although its range is small, this species is quite common at higher altitudes, where several areas of suitable habitat are relatively secure. For this reason it is not classed as a threatened species, pending further developments in the preservation of its remaining forests.

[*Megalaima corvina*,  
Java.  
Photo: Luis Javier  
Barbadillo]

that breeding them poses no major problems. Techniques for the captive-breeding of barbets need to be developed more fully, and broadcast to aviculturalists. Establishing small captive populations from diverse sources will be a task requiring scientific and government assistance. A limitation is the aggression displayed by barbet pairs, particularly of species of *Megalaima*, towards other conspecific individuals in their cages. Perhaps this problem would be minimal in large aviaries. All restricted-range barbets are candidates for captive-breeding. These include species under threat, such as the White-mantled Barbet and the Toucan-barbet in the Americas, and also perhaps the Five-coloured, Orange-fronted and Cinnamon-breasted Barbets in the Neotropics, the Black-banded and Brown-throated Barbets in Java, and the Mountain and Golden-naped and, possibly, the Bornean Barbet, these last three found only in Borneo. Action is needed to determine the number of existing individuals of the recently discovered Scarlet-belted Barbet, and to evaluate the potential threats to it.

The sense of urgency in these matters heightens yearly, as it becomes ever more evident that the current human generation, bridging two millennia, may have the final word on the survival of from 25% to as many as 50% of the existing avian species. What it says will echo down the years, for ever.

## Subfamily TRACHYPHONINAE

### Genus *TRACHYPHONUS* Ranzani, 1821

#### 1. Yellow-billed Barbet

##### *Trachyphonus purpuratus*

**French:** Barbican pourpré **German:** Gelbschnabel-Bartvogel **Spanish:** Barbudo Piquigualdo

**Taxonomy.** *Trachyphonus lurpuratus* [sic] J. Verreaux and E. Verreaux, 1851, Gabon. Often placed in monotypic genus *Trachylaemus*, but morphology, plumage, behaviour and some vocalizations similar to those of *T. vaillantii*, which thus connects present species to *T. erythrocephalus* and others. Four subspecies recognized.

##### **Subspecies and Distribution.**

*T. p. goffinii* (Schlegel, 1863) - Sierra Leone E to Ghana-Togo border.

*T. p. togoensis* (Reichenow, 1892) - extreme E Ghana to SW Nigeria.

*T. p. purpuratus* J. Verreaux & E. Verreaux, 1851 - SE Nigeria E to S Central African Republic, S to N Angola and C Zaire.

*T. p. elgonensis* Sharpe, 1891 - S Sudan and E Zaire E to W Kenya.

**Descriptive notes.** 23-24 cm; 65-100 g (mainly 75-95 g). Nominative race black, red, yellow and white, with silvery-pink throat, yellow bill and facial skin, dark eye, and white scapular mark seen when it moves; red spattered about head; tail quite long; usually spotted yellow below. Differs from similar *Lybius bidentatus* in white scapular mark, darker (less bright red) throat to breast with pink spotting, lack of red bar in wings, and yellow about belly. Immature paler, black lacks gloss, reds duller, no silver on throat. Race *elgonensis* very like nominate, but more red, less silvery, on sides of throat; *togoensis* has brighter red than others and extending to throat, silver-pink streaks broader on throat, plainer underparts, yellow tips on rump feathers, dark facial skin; *goffinii* resembles *togoensis*, but has less red head, more spots of pink (less streaky) on throat, more yellow in rump, and somewhat clearer pale yellow below. **VOICE.** Large repertoire; song low "hoop" notes at 1-2 per second (notes slower in race *goffinii*), in series as long as 5 minutes; duetting infrequent, and female probably utters "wa-hoop" to "wup-oop" in duet; also soft "oop" and chatter "chaa-aa" notes by pair, and in aggressive encounters; soft, irregular "oonk" notes by both of pair in greeting ceremony; soft "ooo-ooo" notes in or at nest; "eh-eh" calls; "toc-toc" as alarm; young chatter noisily, or give rattle-like notes, and loud "yeh-eh—" when fed. Loud wing-fluttering at c. 15 beats per second in interactions.

**Habitat.** Lowland and lower montane forest in understorey, also riverside thickets and forest, forested swamps, old secondary forest, dense forest patches, and adjacent gardens and cultivated areas. Sea-level to 1300 m in W, to 2800 m in E (Kenya).

**Food and Feeding.** Arthropods, including ants and termites, larvae of various insects; also snails; and fruits of avocados, figs, and diverse species of e.g. *Beilschmiedia*, *Heisteria*, *Macaranga*, *Musanga*, *Polyalthia* and *Pycnanthus*, in Sierra Leone especially *Sterculia* fruits. Skulking forest-understorey bird, feeds mainly below 10 m, often below 5 m, to the ground; hops and bounds on ground, and up and along branches, gleaming, picking fruits; flycatches occasionally; often perches quietly.

**Breeding.** Oct-Mar in W; Jan-Jul in Nigeria; Aug-Jan in Cameroon, C Zaire and Angola; probably all year in Uganda and Kenya. Nests mainly or entirely in pairs; very pugnacious, especially to other barbets, able to nest successfully within large colony of *Gymnobucco bonapartei*. Duets and displays, including tail-cocking by presumed male, much bowing, erection of throat and facial feathers, wing-spreading, bill-tapping. Both adults excavate cavity in stub or dead branch, up to 30 m above ground but usually below 8 m; rarely uses old woodpecker cavity; nesting trees include *Ficus* and *Polyscias fulva*. Eggs 2-4; incubation and nestling periods unknown; chicks fed 4-14 times per hour, parents keep nest clean by removing faecal material; at least 1 young may remain with parents up to next breeding period.

**Movements.** Resident, and sedentary.

**Status and Conservation.** Not globally threatened. Densities of 8-13 pairs/km<sup>2</sup> in Gabon, where nests may be as close as 200 m; 5 pairs/km<sup>2</sup> in Liberia. Not uncommon in Sierra Leone. Requires forest with dense undergrowth; after forest clearance, often disappears when forest remnants too small or too far apart. Occurs in several protected areas, e.g. Gola Forests Reserves (Sierra Leone), Korup National Park (Cameroon), Impenetrable Forest National Park (Uganda), Kakamega Nature Reserve (Kenya) and Kibira National Park (Burundi).

**Bibliography.** Allport *et al.* (1989), Bannerman (1933, 1953), Bates (1930), Britton (1980), Brosset & Éraud (1986), Brown & Britton (1980), Cave & Macdonald (1955), Chapin (1939), Cheke & Walsh (1996), Christy & Clarke (1994), Colston & Curry-Lindahl (1986), Dean (2000), Dowsett (1989b, 1990), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Field (1999), Friedmann & Williams (1971), Fry *et al.* (1988), Gatter (1997), Grimes (1987), Lewis & Pomeroy (1989), Lippens & Wille (1976), Louette (1981b), Mackworth-Præd & Grant (1957, 1962, 1970), Nikolaus (1987), Pinto (1983), Rand *et al.* (1959), Serle (1950, 1954, 1965), Short *et al.* (1990), Snow (1978), Thiollay (1985a), Zimmerman (1972), Zimmerman *et al.* (1996).

#### 2. Crested Barbet

##### *Trachyphonus vaillantii*

**French:** Barbican promépie **German:** Haubenbartvogel **Spanish:** Barbudo Crestado  
**Other common names:** Levallant's Barbet

**Taxonomy.** *Trachyphonus Vaillantii* Ranzani, 1821, south-east Cape Province.

Forms a link between forest-dwelling *T. purpuratus* and typical ground barbets such as group including *T. erythrocephalus* and *T. darnaudii*, being intermediate in bill morphology and some plumage

features. Racial differentiation difficult to evaluate, owing to mosaic evolution (correlated with rainfall, birds being paler in more xeric areas) and individual variation; proposed race *nobilis*, known from single specimen from Botswana, now included within nominate. Two subspecies recognized.

##### **Subspecies and Distribution.**

*T. v. suahelicus* Reichenow, 1887 - C Angola, S & E Zaire and SW Uganda to N Tanzania, S to Zambia, N Zimbabwe, Malawi and C Mozambique.

*T. v. vaillantii* Ranzani, 1821 - S Angola, NE Namibia, N & E Botswana, S Zimbabwe, and from S Mozambique S to E South Africa.

**Descriptive notes.** 22-23 cm; 57-85 g. Distinct crest and unique white, yellow, red and black colour pattern. Nominative race has black and white area around ear opening, yellow and red head, black crest, yellow and white marks on black back, white inner wing-covert stripe, red-tipped uppertail-coverts, white spot-bars on tail; shiny black "shield" on breast has silver-pink to white spots (variable, some have none), and red markings on yellow below. Female similar overall but generally somewhat duller and paler. Immature duller, paler, with dark bill (yellow in adult). Race *suahelicus* tends to have narrower breast shield broken up by pinkish markings, more yellow underparts, less white marks on back, more red on crown. **VOICE.** Distinctive trilling "di-di-di-" song with 10-17 notes per second for up to 5 minutes, resembles shorter songs of *Lybius bidentatus* and Scaly-throated and Spotted Honeyguides (*Indicator variiegatus* and *I. maculatus*); pair-members loosely sing together, only parts of songs overlap ("duet"); also alarm rattle "kek-kek-kek-", much like *T. erythrocephalus*, at 10-11 per second, given also by 2-week-old young; single or double "kik" notes when adults close together, grating "a-a-a-a" notes at 30 per second, begging "zweep", and "tirr-tirr" of nestlings are other calls. Audible bill-wiping near nest or roost apparently distinct for each pair.

**Habitat.** Woodland and thickets, especially where there are termite mounds, also plantations, including pines, streamside vegetation in dry areas, often amid palms (*Phoenix*); often common in *Brachystegia* and mopane (*Colophospermum mopane*) woods with termite mounds. Usually at 200-1800 m, but down to sea-level in E, and rarely to 2250 m.

**Food and Feeding.** Fruits and seeds, including those of guavas, figs and berries; also insects, such as grasshoppers and locusts, various beetles, wasps, roaches, termites, and larvae of numerous insects; also snails, worms; takes suet at feeders, and pirates eggs and nestlings of small birds. Hops on ground, mainly under bushes, and along branches, probes into bark crevices and lichens, tears at debris in trees or on ground, clings to and even hangs from leaves to reach insects.

**Breeding.** Sept-Mar in all areas; earlier, to Aug, in South Africa; up to 4 broods in a season in S. Courtship feeding and bill-touching with much duetting occur when copulating frequently. Nest usually excavated by both adults in stump, dead tree, underside of dead branch, or in sisal stalk; occasionally usurps nesting cavity of Rufous-necked Wrynecks (*Jynx ruficollis*), or uses old woodpecker hole or nestbox, or old swallow (Hirundinidae) or weaver (Ploceidae) nest; nest 1-4 m up, rarely to 18 m, entrance c. 3-8 by 6-4 cm, cavity 15-100 cm deep, deeper when re-nesting or using old cavity. Eggs 2-5, laid at daily intervals; female incubates at night, both parents by day, period 13-17 days; young fed 104-120 times a day, mainly on insects, adults remove faecal material; young reach entrance at c. 14 days; nestling period 17-30 or more days; juveniles stay with parents, but driven from nest (though remaining on territory) if pair re-nests. Nests parasitized by Lesser Honeyguide (*Indicator minor*).

**Movements.** Typically sedentary; may sometimes move some distance, and disperse along water-courses in arid areas.

**Status and Conservation.** Not globally threatened. Generally common; density can reach c. 5 pairs/100 ha in some woodland areas. Adaptable, aggressive barbet where not persecuted; some individuals are taken as cagebirds. Present in Mikumi National Park (Tanzania), South Luangwa National Park (Zambia), Vwaza Marsh and Liwonde National Parks (Malawi) and Kruger National Park (South Africa).

**Bibliography.** Benson & Benson (1977), Benson *et al.* (1971), Britton (1980), Brown & Britton (1980), Chapin (1939), Clancy (1964, 1974b, 1993, 1996), Dean (2000), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Earle & Grobler (1987), Evans *et al.* (1994), Fry *et al.* (1988), Ginn *et al.* (1989), Harrison *et al.* (1997), Herholdt & Earle (1987), Irwin (1981), Kopij (1998), Lewis (1982), Lippens & Wille (1976), Liversidge (1991), Mackworth-Præd & Grant (1957, 1962, 1970), Maclean (1993), McFarlane (1991), van Niekerk (1993), Parker (1999), Penry (1994), Pinto (1983), Prozesky (1966), Rushforth (1999), Rutgers & Norris (1977), Short *et al.* (1990), Snow (1978), Sothike (1984), Stenhouse (1993), Steyn (1996), Tarboton (2001), Tarboton *et al.* (1987), Thompson (1998), Ward (1986, 1989), Zimmerman *et al.* (1996), Van Zyl (1987, 1989, 1994).

#### 3. Red-and-yellow Barbet

##### *Trachyphonus erythrocephalus*

**French:** Barbican à tête rouge **German:** Flammenkopf-Bartvogel **Spanish:** Barbudo Cabecirrojo

**Taxonomy.** *Trachyphonus erythrocephalus* Cabanis, 1878, Ukamba, south-west Kenya.

Forms a superspecies with *T. margaritatus*, with which sometimes thought conspecific; both rather closely related to *T. darnaudii*, less so to *T. vaillantii*. Proposed races *gallarum* (SC Ethiopia) and *jacksoni* (S Ethiopia to NC Kenya) probably represent intergrades of races *shellei* and *versicolor*. Three subspecies currently recognized.

##### **Subspecies and Distribution.**

*T. e. shellei* Hartlaub, 1886 - SE Ethiopia to NW & S Somalia.

*T. e. versicolor* Hartlaub, 1883 - NE Uganda and SE Sudan to S & CE Ethiopia and N Kenya.

*T. e. erythrocephalus* Cabanis, 1878 - C Kenya to NE & NC Tanzania.

**Descriptive notes.** 20-23 cm; 40-75 g. Very distinctive barbet. Male nominate race has black cap and slight crest, and black throat patch; spotted and streaked red, yellow, white and black, with long, pointed orange or red bill; white "half-moon" about ear opening, surrounded by black and red; black upperparts, marked yellow and white, with red tips of uppertail-coverts; tail with large yellowish spot-bars; yellow with some spotting and marks below, and red undertail-coverts. Distinguished from *T. darnaudii* by larger size, brighter appearance, different head pattern, larger and brighter bill; from *T. margaritatus* by much more red in plumage, black and red edge to white ear-covert marks. Female red-

yellow on crown, rarely with a little black; more commonly has small black bib. Immature more yellow and brown, dull. Races vary mainly in brightness and intensity of colour: *versicolor* slightly smaller than nominate, with less red on head and body and none on uppertail- or undertail-coverts, rather more yellow overall; *shellei* considerably smaller, with even less red and orange, more yellow, belly yellow-white. Voice. Songs "erupt" from greeting ceremony and chorus of all group-members, but only primary pair sings synchronized duet with overall sound of "red'n yell-ow" as repeated duet set; male 3 whistled notes dropping in pitch, female

3-5 higher-pitched, shorter whistles, these fitting together, at about 2 sets every 3 seconds, repeated over and over for up to 2 minutes; pre-duet chorus of "tik", "tik-it" and "chowp" notes, though birds arriving to join start with loud, rattling "kuk" series; other calls a soft "chuk" by adults coming to feed young, sharp "kik-kik" alarm, and begging, chattering notes.

**Habitat.** Uneven terrain with outcrops, steep stream channels, or termite mounds in open woodland, wooded grassland, scrubland, and edges of deserts with lush streamside vegetation. Rarely to sea-level (Somalia), and up to 1820 m, occasionally 1980 m, rarely 2130 m.

**Food and Feeding.** Figs, other fruits and their seeds, as well as spiders, various insect larvae, beetles, mantids, grasshoppers, locusts, harvestmen, termites and ants; also eats lizards, centipedes, small birds and birds' eggs; takes all kinds of household refuse, including bread, cereal, hamburger, chicken bones, bananas, melon, in fact any food discarded by humans. Forages in group, sometimes very loosely, moving over ground, under or near bushes and trees; will search walls and roofs of buildings and probe tyres and radiators of cars for insects.

**Breeding.** Feb-Jul in N, also in S, where may breed Sept-Jan; mainly during and after rains. Male of group hops about primary female, male tail cocked, female's swinging, both with head feathers erect, may allopreen, male feeds mate at times; in duets, other group-members actively keep below duetting male and female. Nest dug in bank or termite mound 1-4 m from ground, tunnel 40 cm or more deep, diameter of nest-chamber c. 11.2 cm; new tunnel excavated yearly, unknown whether helpers assist in digging; territories often large, but along well-wooded stream sometimes c. 1 pair/200 m. Eggs 2-6; incubation period unknown; in captivity, male incubates, feeds young more than does female; all group-members (up to 8) feed insects and other arthropods to chicks, removing legs and wings from larger ones, feeding rate 2.5-12 times per hour; nestling period unknown; fledged young move with group, beg from all members.

**Movements.** Mainly sedentary, but wanders; occurs casually S to SC Tanzania, and wanders into range of *T. margaritatus* in N Somalia.

**Status and Conservation.** Not globally threatened. Generally common throughout range. Group size probably reflects relative health of populations. Dominant over other barbets, including *T. darnaudii* of flatter, drier country (where latter may outcompete present species), and also over woodpeckers. In some parts of range, children dig out nests; feathers used in adornment by some tribes; this species is also taken to be kept as cagebird. Present in several protected areas, e.g. Samburu Reserve, and Tsavo East and Tsavo West National Parks (Kenya), and Serengeti National Park (Tanzania).

**Bibliography.** Archer & Godman (1937-1961), Ash & Miskell (1983, 1998), Benson (1946), Britton (1980), Brown & Britton (1980), Cave & Macdonald (1955), Clarke (1985), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), England (1973b), Friedmann (1930a, 1930b), Fry *et al.* (1988), Jackson & Slater (1938), Lewis & Pomeroy (1989), Mackworth-Præd & Grant (1957), Nikolaus (1987), Reynolds (1974), de Ruiter (1997), Schmitt & Lyvere (1980), Short & Horne (1980b, 1985a), Short *et al.* (1990), Snow (1978), Stevenson & Fanshawe (2001), Zimmerman *et al.* (1996).

## 4. Yellow-breasted Barbet

### *Trachyphonus margaritatus*

**French:** Barbican perlé

**German:** Perlenbartvogel

**Spanish:** Barbudo Perlado

**Taxonomy.** *Bucco margaritatus* Cretzschmar, 1826, Sennar, east-central Sudan.

Forms a superspecies with *T. erythrocephalus*, and the two are sometimes considered conspecific; both are related rather closely to *T. darnaudii*, less so to *T. vaillantii*. Validity of subdivision into races perhaps questionable; also, NE Sudan birds, described as race *kingi*, and those from C Sudan, as *berberensis*, both considered indistinguishable from nominate. Two subspecies currently recognized.

**Subspecies and Distribution.**

*T. m. margaritatus* (Cretzschmar, 1826) - E Mauritania E to Chad, C & NE Sudan, N Ethiopia, and Eritrea.

*T. m. somalicus* Zedlitz, 1910 - E Ethiopia and Djibouti to N Somalia.

male rather similar but lacks black throat patch. Race *somalicus* slightly paler, has whiter belly, is smaller than nominate, although freshly moulted specimens not distinguishable from latter. Voice. Very like that of *T. erythrocephalus*, with duet "tew-choo-to-" similar, songs slightly higher-pitched and notes a trifle faster; chorus and ceremony similar, with "chevp" and "tik" notes; also rattling call in alarm, or by barbet coming in to join chorus, and "cheh-cheh" calls.

**Habitat.** Rough terrain such as along streams or wadis, in sandy *Acacia* wooded grassland, in hilly scrub, or stabilized sand dunes near coast, in irrigated gardens and around habitations, especially ruins. Sea-level to 1800 m.

**Food and Feeding.** Omnivorous; eats berries and fruits such as figs and *Salvadora persica*, and centipedes, grasshoppers, locusts, mantids, beetles and other insects and their larvae; probably takes eggs and young of small birds; captives survived well on diet of eggs and meat. Forages in noisy groups, on ground and in bushes and trees.

**Breeding.** May-Jun in all areas; also Mar and Aug-Oct in Niger, Feb-Jun in Chad, to Jul in Sudan, Feb-Nov in Ethiopia, also Feb and Apr in Somalia; possibly 2 broods per season in some places. Groups excavate tunnel in bank, cliff edge, wall, well with earthen sides, or old building, tunnel up to 1 m long and c. 5 cm in diameter, entrance within 3 m of ground; territories irregular and large, probably dictated by habitat. Eggs 3-6; no information on incubation and nestling periods, or on general breeding biology.

**Movements.** Largely resident, and sedentary; probably wanders somewhat at times.

**Status and Conservation.** Not globally threatened. Uncommon, but widespread. Considerable variety of habitats used suggest that species is secure for present. Occurs in several protected areas, e.g. Air et Ténéré National Park (Niger), Ouadi Rimé-Ouadi Achim Reserve (Chad) and Awash National Park (Ethiopia).

**Bibliography.** Archer & Godman (1937-1961), Ash & Miskell (1983, 1998), Bannerman (1933, 1953), Bates (1930), Cave & Macdonald (1955), Cheesman & Slater (1935), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Fairon (1975), Friedmann (1930a), Fry *et al.* (1988), Giraudeau *et al.* (1988), Lamarche (1980, 1988), Mackworth-Præd & Grant (1938, 1957, 1970), Newby (1980), Nikolaus (1987), Rutgers & Norris (1977), Short & Horne (1985a), Smith (1957), Snow (1978), Tilahun *et al.* (1996), Urban & Brown (1971), Zinner (2001).

## 5. D'Arnaud's Barbet

### *Trachyphonus darnaudii*

**French:** Barbican d'Arnaud **German:** Ohrfleck-Bartvogel **Spanish:** Barbudo Capuchino

**Other common names:** Maasai/Masai/Usambiro Barbet (*usambiro*)

**Taxonomy.** *Micropogon darnaudii* Prévost and Des Murs, 1850, Kordofan, south Sudan.

Related to the *T. margaritatus* superspecies, but not very closely. Race *usambiro* sometimes considered a full species on basis of vocal and other differences, but one of two duet roles is identical to those of other races, and *usambiro* is no more distinct than are they. Nominate includes proposed race *zedlitzii* (L Baringo, Kenya). Four subspecies normally recognized.

**Subspecies and Distribution.**

*T. d. darnaudii* (Prévost & Des Murs, 1850) - SE Sudan and SW Ethiopia S to NE Uganda and WC Kenya.

*T. d. boehmi* Fischer & Reichenow, 1884 - S & E Ethiopia and S Somalia S to EC & SE Kenya and NE Tanzania.

*T. d. usambiro* Neumann, 1908 - SW Kenya to CN Tanzania.

*T. d. emini* Reichenow, 1891 - NC Tanzania (E to Dar es Salaam suburbs).

**Descriptive notes.** 16-19 cm; 17-39 g (*darnaudii*, *boehmi*), 32-51 g (*usambiro*, *emini*). Rather distinctive. Nominate race brown, black, yellow and orange, speckled and streaked; white spots on brown back and tail, speckled head with some orange; small black throat patch extending to upper breast, black half-band across breast, mainly yellow underparts with red vent; bill rather short, brownish. Most similar to *T. erythrocephalus* and *T. margaritatus*, but considerably smaller, with black spots on head, less orange and red in plumage, shorter and brown bill. Sexes alike. Immature duller, less yellow. Race *boehmi* has

unmarked black cap, and bill often rather dark; *emini* similar but yellower, with stronger black throat patch, whiter below, yellower bill; *usambiro* has crown spots yellower, more distinct breastband, usually more dark belly bars, on average darker bill. **VOICE.** Complex repertoire, duet varies within and between races; 2 duet roles not absolutely assignable sexually, role A used by immatures, some of which later adopt role B of duet, single adults sing only A or B and, if recordings of one played back at different speeds, adult with other role responds at matching speed; song A usually of 1 long and 2 (or 3) shorter notes in a set; song B with different long initial note and 2 or 3 other, short notes, with first note synchronously set between first and second A notes; in race *usambiro*, A song reduced to 3-7 grating notes, B like that of other races; overall effect in most races "ker-ka-tee-too-tle-.", sets repeated for up to 3 minutes; all group-members chorus in preliminary greeting ceremony before duets; if duet removed, replaced within 1-2 minutes by another group-member, always singing song of missing duet, so possible that adult can switch songs from A to B or vice versa. Pre-duet notes mainly "tik-et, tik-et", also used in aggressive encounters; alarm a loud "tik" or chirp to aerial predator, repeated noisy "shreee-eek" to terrestrial predator; also hissing "ch-ch-ch" notes from pair; begging is soft "dddddd" trill at 45 elements per second, clustered in sets of c. 0-2 seconds, repeated loud notes of same type when fed by adult; chattering call by fledged young, also by food-soliciting female. Loud bill-wiping; and wing-rustling or wing-fluttering at 15-25 beats per second by barbets flying to join group.

**Habitat.** Open areas, wooded grassland, open woods, bushland, degraded shrubby grassland and pasture, favouring old "manyattas" (bomas, Maasai camps) that have been abandoned; frequently forages about camps and facilities in parks. Where *T. erythrocephalus* or *T. margaritatus* present, frequents flatter areas, away from streambeds used by these larger relatives. Generally at 200-1900 m, reaches coast in Somalia; race *usambiro* and, in part, *emini* at 1600-2100 m.

**Food and Feeding.** Omnivorous; diverse fruits and berries, including *Grewia*, and their seeds, also insects of many kinds (ants, termites, grasshoppers, larvae and eggs of these and others). Feeds low or on ground, in loose groups, moving to nearest bush at sign of danger. Flycatches in jump-hops upwards, for termites. Birds gradually work around territory, pausing to chorus or, if response heard, to duet.

**Breeding.** Feb-Aug and Oct in Sudan and Ethiopia to NE Tanzania; all months but Mar and May in SW Kenya and rest of Tanzania, greatly dependent on flooding, most breeding just before or immediately after rains; gonads of all group-members somewhat enlarged throughout year. Most groups of 3 birds, sometimes as many as 5 adults. Primary pair duets with crown, facial and upperpart feathers erected, head bobbing; tail spread and that of 1 bird (often female, sometimes both) cocked and waved, or flicked closed and then spread, or both held tail down; any group-member other than pair driven down in bush if it starts singing. Nest-tunnel dug straight into ground, often in open, sometimes beneath grass tuft, to depth of 45 cm or to 90 cm; chamber off to one side, well above bottom of shaft (avoiding flooding to some extent), lined with grass; territory c. 100 ha, patrolled by foraging group with periodic duets along borders, where any counter-duetting singers attacked by duetting pair if they come too close. Eggs 2-4; incubation and nestling periods unknown, as is role of helpers, but pair seemingly performs most of incubation and brood-feeding; fledged young follow adults, begging loudly, return early in the evening to roost in nest, leaving in late morning, also return to nest during inclement weather. Apparently only 1 or 2 young survive, and probably

remain in the group until next breeding season; captive young sing at 27 days of age. Longevity to 13 years in captivity.

**Movements.** Resident and sedentary, with local movements only.

**Status and Conservation.** Not globally threatened. Not uncommon throughout range; often common, even around villages, where frequently observed seeking food. Present in several protected areas, e.g. Samburu Reserve, and Tsavo East and Tsavo West National Parks (Kenya), and Tarangire and Serengeti National Parks (Tanzania).

**Bibliography.** Albrecht & Wickler (1968), Anzenberger (1974), Archer & Godman (1937-1961), Ash & Miskell (1983, 1998), Benson (1946), Britton (1980), Brown & Britton (1980), Cave & Macdonald (1955), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Fernald (1973), Friedmann (1930a, 1930b), Friedmann & Loveridge (1937), Fry *et al.* (1988), Kalas (1973), Lewis & Pomeroy (1989), Mackworth-Præd & Grant (1957), Nikolaus (1987), Payne (1971), Schmidl (1982), Seibt & Wickler (1977), Short & Horne (1980b, 1983b, 1984b, 1985a), Short *et al.* (1990), Snow (1978), Stevenson & Fanshawe (2001), Tyroler (1974), Ward (1972a), Wickler (1973), Wickler & Uhrig (1969), Zimmerman *et al.* (1996).

## Subfamily LYBIINAE

## Genus *GYMNOBUCCO* Bonaparte, 1850

### 6. Grey-throated Barbet

#### *Gymnobucco bonapartei*

**French:** Barbican à gorge grise **German:** Trauerbartvogel **Spanish:** Barbudo Gorgigrís  
**Other common names:** Bonaparte's Barbet

**Taxonomy.** *Gymnobucco Bonapartei* Hartlaub, 1854, Gabon.

W populations of *cinereiceps* formerly separated as race *intermedius*. Two subspecies currently recognized.

**Subspecies and Distribution.**

*G. b. bonapartei* Hartlaub, 1854 - W Cameroon and Gabon E to SW & EC Zaïre.

*G. b. cinereiceps* Sharpe, 1891 - Central African Republic, S Sudan and E Zaïre, S to N Angola, Burundi, W Kenya and NW Tanzania.

**Descriptive notes.** 16.5-19 cm; 45-75 g. Nominate race with forehead and forecrown greyish-black with yellowish streak-like spots, hindcrown, nape, neck sides and ear-coverts grey-brown, brownish bristly tufts about blackish bill; throat grey; body brown with buffish spots and streaks; wings and tail dark brown; eyes brown. Distinguished from congeners by combination of fully feathered head, dark bill, grey throat, darker bristly nasal tufts. Sexes alike. Immature sootier, more streaky, bill paler, nasal tufts short and soft, not bristly. Race *cinereiceps* larger, more contrasting pale spots on forehead, throat to breast paler grey, back

greyer, head grey, longer nasal tufts with buff bases, eyes cream to yellow. Voice. Loud "whew", "whee-ew" or "peek"; rattling, buzzy and nasal "chaaa"; loud wing sounds.

**Habitat.** Primary, secondary and riverine forest, forest patches, overgrown plantations, pastures near forest, and around villages with fruiting trees. In lowlands and, towards E, up to 2450 m.

**Food and Feeding.** Diverse fruits and berries, such as figs, and those of *Musanga*, *Prunus*, and *Rauwolfia*; also arthropods, including stick-insects, wasps, beetles, dragonflies, grasshoppers and others, including larvae. Feeds in groups; aggressive at fruiting trees.

**Breeding.** Lays Jan-Aug in Cameroon, Nov-Feb in Gabon, Sept-Jul in forest area of Congo and W Zaïre, Mar-Dec in S Zaïre, Nov to as late as May in Sudan and Uganda, and Oct-Mar in W Kenya. Social, in small to large colonies, sometimes with other *Gymnobucco*; nests as close as 1 m. Nest in cavity in dead tree, 2 m or more up. Eggs 3-5, cared for sometimes by other group-members than the pair; incubation period not known; hatchling naked, orbit flesh-coloured, yellow bill with black tip, eyes grey-brown when opened; no information on nestling period or care of young.

**Movements.** Resident; dependent largely on fruiting trees, moves some distance to them.

**Status and Conservation.** Not globally threatened. Widespread, somewhat adaptable, and relatively abundant. Threats involve removal of dead trees, and isolation of fruiting trees from forest as habitat is opened up, but wide range and abundance within habitat indicate that it is less threatened than others of its genus. Present in Impenetrable Forest National Park (Uganda) and Kakamega Nature Reserve (Kenya).

**Bibliography.** Bannerman (1953), Baranga & Kalina (1991), Britton (1980), Brosset & Énard (1986), Brown & Britton (1980), Cave & Macdonald (1955), Chapin (1939), Christy & Clarke (1994), Dean (2000), Dowsett (1989b, 1990), Dowsett & Dowsett-Lemaire (1991, 1993), Dowsett & Forbes-Watson (1993), Friedmann (1978a), Friedmann & Williams (1971), Fry *et al.* (1988), Lewis & Pomeroy (1989), Lippens & Wille (1976), Louette (1981b), Mackworth-Præd & Grant (1957, 1970), Nikolaus (1987), Pinto (1983), Serle (1950, 1954), Short & Horne (1985a), Snow (1978), Stevenson & Fanshawe (2001), Taylor (1983), Zimmerman (1972), Zimmerman *et al.* (1996).

### 7. Sladen's Barbet

#### *Gymnobucco sladeni*

**French:** Barbican de Sladen **German:** Rußbartvogel **Spanish:** Barbudo de Sladen  
**Other common names:** Zaïre Barbet

**Taxonomy.** *Gymnobucco sladeni* Ogilvie-Grant, 1907, Mawambi, Zaïre.

Forms a superspecies with *G. peli*, both also rather closely related to *G. calvus*. Monotypic.

**Distribution.** C & E Zaïre (E to near borders of Uganda and Rwanda); reported also SW Central African Republic.

**Descriptive notes.** c. 17 cm. Dark brown barbet with bare face, pale tufts about bill; throat grey to brownish-grey; bill blackish. Differs from *G. bonapartei* in bare head, less streaky appearance;

from *G. peli* in darker, less streaky plumage, dark bill. Sexes alike. Immature paler-billed, shows feathers on head, has darker tufts, paler below. Voice. Soft "pyew" notes, also rattling and chattering notes; similar to *G. peli*.

**Habitat.** Forest, often together with *G. bonapartei*, but details lacking.

**Food and Feeding.** Poorly known; feeds on *Musanga* and other fruits, and also takes insects; few details available.

**Breeding.** Probably lays Jan-Sept, inferred from dates of juveniles. Nest and eggs not known; associates with *G. bonapartei*, presumably nests in their colonies.

**Movements.** Sedentary.

**Status and Conservation.** Not globally threatened. Very poorly known species; even basic data are needed for this barbet, as details of distribution and habits uncertain owing to confusion with similar but much commoner *G. bonapartei*. Available data considered insufficient to establish true status; apparently uncommon at best, and potentially rare. In view of absence of information, conservation status of this species probably merits reassessment. No readily perceived threats except those that are facing all hole-nesters in forest, especially fragmentation of habitat and removal of dead trees.

**Bibliography.** Chapin (1939), Dowsett (1989b), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Fry *et al.* (1988), Germain & Cornet (1994), Lippens & Wille (1976), Mackworth-Præd & Grant (1970), Pedersen (2000), Schouteden (1962), Short & Horne (1983b, 1985a, 1988b), Snow (1978).

### 8. Bristle-nosed Barbet

#### *Gymnobucco peli*

**French:** Barbican à narines emplumées **German:** Borstenbartvogel **Spanish:** Barbudo de Pinceles

**Taxonomy.** *Gymnobucco Peli* Hartlaub, 1857, Dabocrom, Ghana.

Forms a superspecies with *G. sladeni*, both also rather closely related to *G. calvus*. Monotypic.

**Distribution.** S Sierra Leone E to S Cameroon, W Zaïre and S to Gabon and Cabinda (N Angola).

**Descriptive notes.** c. 17 cm; 41-63 g. Male brown, with bare blackish-grey head; pale bristly tufts around base of bill; secondaries and tertials narrowly edged yellowish; bill yellow to light brown. Distinguished from *G. bonapartei* by pale bill, bare face, and lack of grey on neck; from *G. calvus* by smaller bill, indistinct yellowish-buff edges to wing feathers, and bristly tufts above bill; from *G. sladeni* by paler, more yellow-brown coloration, more yellow on wings, paler bill. Female like male. Immature has feathered brown head, soft darker tufts about head, and darker bill than adult. Voice. Series up to 5 seconds long of soft hoots;

"pyew" notes pitched higher than those of *G. calvus*; "yee" chatters or rattles.

**Habitat.** Primary and dense secondary forest and nearby fruiting trees, riverine swamps in high forest, also logged forest and plantations. In lowlands to 1100 m.

**Food and Feeding.** Fruits and insects. Hangs in manner of tit (Paridae) to secure fruits. Feeds in fruiting trees with often more common *G. bonapartei* and, especially, *G. calvus*.

**Breeding.** Apparently Sept-Jan in Liberia, Nov-Dec in Ghana, May-Jun in Nigeria, most of year but especially in dry season in Cameroon, and Oct-Apr in Gabon. Nests colonially, either alone or with *G. calvus* and to lesser extent *G. bonapartei*. Nest and eggs undescribed, but holes of this species observed at 10-35 m in trees.

**Movements.** Resident, and sedentary.

**Status and Conservation.** Not globally threatened. Status uncertain. Little known, and possibly overlooked; easily confused with *G. calvus* and *G. bonapartei*; further information required, especially since it is usually less common than those 2 species; may have special requirements, as yet unidentified, so possible that any pressures on it remain to be elucidated. Favoured, at least temporarily, by forest clearance. Known to occur in Gola Forests Reserves (Sierra Leone) and Taï Forest National Park (Ivory Coast).

**Bibliography.** Allport *et al.* (1989), Bannerman (1933, 1953), Bates (1930), Bowden (2001), Brosset & Énard (1986), Chapin (1939), Cheke & Walsh (1996), Christy & Clarke (1994), Demey & Fishpool (1994), Dowsett (1989b), Dowsett & Dowsett-Lemaire (1991, 1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Farmer (1979), Field (1999), Fry *et al.* (1988), Gatter (1997), Grimes (1987), Lippens & Wille (1976), Louette (1981b), Mackworth-Præd & Grant (1970), Pinto (1983), Rodewald *et al.* (1994), Sargeant (1993), Serle (1950), Short & Horne (1985a), Snow (1978), Thiollay (1985a).

### 9. Naked-faced Barbet

#### *Gymnobucco calvus*

**French:** Barbican chauve **German:** Glatzenbartvogel **Spanish:** Barbudo Calvo

**Taxonomy.** *Bucco calvus* Lafresnaye, 1841, Ashanti, Ghana.

Apparently related rather closely to *G. sladeni* and *G. peli*. Birds from Mt Cameroon S to Gabon formerly separated from nominate, as race *major*. Three subspecies currently recognized.

**Subspecies and Distribution.**

*G. c. calvus* (Lafresnaye, 1841) - Sierra Leone E to Cameroon and Gabon.

*G. c. conigicus* Chapin, 1932 - W Congo (Brazzaville) and W Zaïre S to NW Angola.

*G. c. vernayi* Boulton, 1931 - WC Angolan uplands.

**Descriptive notes.** c. 18 cm; 47-67 g. Male nominate race with crown and face unfeathered, blackish to blue-grey; buff to dull brown bristly tufts on chin and at lateral base of lower mandible, short hair-like feathers on forehead and lores; upperparts dark brown with thin pale streaks; underparts brown to grey-brown with fine pale streaks; bill yellow to pale brownish. Differs from *G. bonapartei* in pale bill and naked face; from *G. sladeni* in less dark plumage, pale bill, paler bristle tufts; distinguished from similar *G. peli* by larger bill, deeper brown rump, darker and less conspicuous nasal tufts. Sexes alike. Immature paler, with less prominent pale shaft streaks on body, looser plumage. Race *conigicus* very like nominate, but slightly larger, with broader streaks, throat paler

greyish-white, has small more yellowish-buff tufts also at nostrils; *vernayi* like *congius*, but slightly darker above, still more broadly pale-streaked below with pale throat, and lacks tuft on chin of other races. VOICE. Song soft "poo" notes in series; "kyew" call longer, pitched lower than in *G. pelli*; variable rattling notes, and chittering begging calls of young.

**Habitat.** Primary and adjacent secondary forest, into wooded grassland, and nearby plantations, farms and villages with fruiting trees. Occurs at up to 1820 m.

**Food and Feeding.** Eats diverse wild and cultivated fruits, including those of species of fig,

*Enantia*, *Harungana*, *Musanga*, *Parinari*, *Rauvolfia*, *Trema*, papayas, and others; also feeds on arthropods, including crickets, beetles and other insects; also on nectar, such as that of *Bombax*. Feeds in manner of tit (Paridae) in foliage and along branches. Highly social at all times; nearly always in groups; quarrelsome and aggressive at food sources, chases off other barbets.

**Breeding.** Breeds Mar-Dec in W Africa, also Jan-Feb in Ghana and Nigeria; most of year in Cameroon, Oct-Apr in Gabon and Congo; year-round roosting in nest-holes may distort reports of apparent breeding. Colonial, often with sympatric congeners, in colonies of up to 250 pairs. Nest in cavity excavated in dead tree, at 8-40 m above ground; hole used also for roosting. Eggs 2-5, usually 3; details of incubation, fledging, feeding rates, and other information meagre, insufficient to indicate factual data.

**Movements.** Resident; shifts foraging sites as different fruiting trees come into fruit.

**Status and Conservation.** Not globally threatened. Generally common throughout range. Seems less affected by fragmenting of forest than are *G. sladeni* and *G. pelli*; nevertheless, its social habits and colonial nesting mean that it requires suitable dead trees for roosting and breeding. Further research needed on breeding biology. Present in Gola Forests Reserves (Sierra Leone) and Mount Kupe National Park (Cameroon).

**Bibliography.** Allport *et al.* (1989), Bannerman (1933, 1953), Bates (1930), Bowden (2001), Brosset & Énard (1986), Chapin (1939), Cheke & Walsh (1996), Christy & Clarke (1994), Colston & Curry-Lindahl (1986), Dean (2000), Demey & Fishpool (1994), Dowsett (1989b), Dowsett & Dowsett-Lemaire (1991, 1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Farmer (1979), Field (1999), Fry *et al.* (1988), Gatter (1997), Grimes (1987), Lippens & Wille (1976), Louette (1981b), Mackworth-Praed & Grant (1962, 1970), Pinto (1983), Rand (1951), Rand *et al.* (1959), Serle (1950, 1954), Short & Horne (1985a), Snow (1978), Stahl (1998), Thiollay (1985a).

PLATE 7

## Genus *STACTOLAEMA*

C. H. T. Marshall & G. F. L. Marshall, 1870

### 10. White-eared Barbet

#### *Stactolaema leucotis*

**French:** Barbican oreillard **German:** Weißohr-Bartvogel **Spanish:** Barbudo Orejiblanco

**Taxonomy.** *Megalama leucotis* Sundevall, 1850, Natal.

Sometimes placed in monospecific genus *Smilorhis*. Kenyan population sometimes separated as race *kenyae*, but normally considered inseparable from *kilimensis*. In past, race *bocagei* of *Lybius torquatus* erroneously listed as a race of present species. Three subspecies normally recognized.

**Subspecies and Distribution.**

*S. l. kilimensis* (Shelley, 1889) - CE & SE Kenya to NE Tanzania.

*S. l. leucogrammica* (Reichenow, 1915) - highlands of C & S Tanzania.

*S. l. leucotis* (Sundevall, 1850) - Malawi and Mozambique S to Swaziland and Natal.

**Descriptive notes.** c. 18 cm; 48-63 g. Dark brown woodland barbet with white belly and dark head. Nominat race has black head with white stripe behind eye, white on rump and uppertail-coverts; bill blackish. Differs from *S. whytii* in having no white in wings, and different head pattern. Sexes alike. Immature blacker than adult. Races differ mainly in plumage darkness, and amount of white on head: *leucogrammica* with more white on head, extending also under eye, dark rump; *kilimensis* dark, with rump generally whiter than in nominate. Voice. Various harsh "skreek" calls, and "whew" calls (resembling those of *Gymnobucco*); grating, buzzy notes and trills; also taps at nest entrance, wipes bill and flutters wings noisily during encounters; nestlings give piping "wi" notes and trills.

**Habitat.** Moist primary and secondary forest, forest edge, also nearby gardens and plantations where fruiting trees present, and where dead trees and limbs are available for excavation. Attains elevations of up to 2600 m in N, often on forested slopes.

**Food and Feeding.** Diet made up of fruits, including figs, guavas, pawpaws, mangoes, juniper and other berries; insects, including hornets, wasps, roaches, dragonflies, crickets, moths, grasshoppers and locusts; and spiders. Uses special sites as "anvils" for killing and disarming insects. Gleans, works over bark, and flycatches for termites and other aerial insects. Aggressive and dominant at food sources.

**Breeding.** Lays Jun-Jan in all areas, in N after main rains. Social nester. Courtship feeding occurs; paired birds give flight displays. Nest 5-18 m up, in tree cavity c. 50-75 cm deep; in Kenya, area defended by group c. 8 ha. Eggs 2-6; helpers assist in incubating, period 14-18 days, also in feeding young; typically 1 barbet remains as "guard" while other adults forage, chicks fed 8-20 times an hour; nest kept clean; nestling period c. 39 days; most young that survive remain with group for a year or more.

**Movements.** Resident, and sedentary.

**Status and Conservation.** Not globally threatened. Little information on status: apparently common at least in NE Tanzania, but local and uncommon in Kenya; said to occur in Taita Hills in SE Kenya, but no confirmed records and possibly absent there. Present in Mtunzini and Umlalazi Nature Reserve (South Africa). Disappearing in some highland parts of its range in N; habitat increasingly fragmented, with dead trees being cleared away. Species should be monitored, especially as its range is discontinuous.

**Bibliography.** Benson & Benson (1975, 1977), Britton (1980), Brooks *et al.* (1998), Brown & Britton (1980), Clancey (1964, 1971a), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Earle & Grobler (1987), Fry *et al.* (1988), Ginn *et al.* (1989), Harrison *et al.* (1997), Irwin (1981), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957, 1962), Maclean (1993), Moreau & Moreau (1937), Oatley (1968), Priest (1934, 1948), Short & Horne (1984a, 1985a), Short *et al.* (1990), Skutch (1987), Snow (1978), Stevenson & Fanshawe (2001), Steyn (1996), Tarboton (2001), Waiyaki & Bennun (2000), Yates (1975), Zimmerman *et al.* (1996).

### 11. Whyte's Barbet

#### *Stactolaema whytii*

**French:** Barbican de Whyte **German:** Spiegelbartvogel **Spanish:** Barbudo Especulado  
**Other common names:** Sowerby's Barbet (*sowerbyi*)

**Taxonomy.** *Smilorhis whytii* Shelley, 1893, Zomba, Malawi.

Forms a superspecies with *S. anchietae*. Six subspecies recognized.

**Subspecies and Distribution.**

*S. w. whytii* (Shelley, 1893) - SC Tanzania to Mozambique and SE Malawi.

*S. w. stresemanni* (Grote, 1934) - SW corner of Tanzania and adjacent NE Zambia.

*S. w. terminata* Clancey, 1956 - highlands around Iringa, in S Tanzania.

*S. w. angoniensis* (Benson, 1964) - E Zambia to SW Malawi.

*S. w. sowerbyi* Sharpe, 1898 - E Zimbabwe to extreme S Malawi.

*S. w. butoni* (C. M. N. White, 1945) - NC Zambia; almost certainly also extreme S Zaire.

**Descriptive notes.** c. 19 cm; 51-62.5 g. Brown woodland barbet with white chin and 2 white wing patches. Nominat race has top of head black, spotted with white, white line below eye, yellow restricted to nasal tufts; whitish lower belly and vent. Separated from *S. leucotis* by white wing patches; from *S. anchietae* by whiter wing patches, and generally darker head with white chin. Sexes alike. Immature darker and less spotted, with yellow on head reduced. Races differ from nominate in having more yellow on head: *sowerbyi* with yellow on forehead and over eye, and as spots over crown to nape; *terminata* has yellow of crown more golden, dark central part of fore-

head, throat to breast black below white chin; *angoniensis* heavily marked yellow over crown, to nape; *butoni* yellow instead of white under eye, only spotted yellow on forehead and crown, and white chin patch small; *stresemanni* fully yellow to mid-crown, more white in wings, yellow under eye. Voice. Song is soft series of "hoo" notes, 0.7-1 per second, faster than that of *S. anchietae* (these low-pitched songs like those of *Gymnobucco*), and probably by paired birds only, sometimes as duets; trill calls in chases of Lesser Honeyguide (*Indicator minor*) and *Lybius torquatus*; soft buzzy grating by adults around nest; soft "eh-eh-ehh"

in courtship feeding; "yek" calls (as in *S. leucotis* and some *Gymnobucco* species) in conflicts, including with *S. anchietae* and other barbets, more "yeek"-like in persistent chasing of honeyguides; squawking, shrieking notes, longer in alarm as against snakes. Mechanical sounds include wing-fluttering at 25 beats per second in conflicts, bill-wiping at 20 per second in encounters, bill-tapping at 2-10 (rarely up to 20) per second inside or at nest entrance.

**Habitat.** *Brachystegia* woodland, partly cleared woods, riverside woods, and gardens, at 750-2500 m. Found in same woodland as *S. anchietae* near Ndola, in N Zambia.

**Food and Feeding.** Eats berries, and fruits such as figs, masuku (*Uapaca kirkiana*) and others; also insects, including ants, termites, grasshoppers, dragonflies and others. Forages in groups for fruits, even going to ground to pick them up; often forages solitarily for insects, obtained by gleaning and by flycatching. Regularly uses "anvil" to break up large insects, especially armoured ones. Probes into lichens, hangs like tit (Paridae); flies strongly and directly from site to site.

**Breeding.** Aug-Jan, mainly Oct-Dec. Nests in groups, with helpers, group containing up to 6 birds, nests sometimes as close together as 100 m. Courtship-feeds, displays with cocked tail, swinging and spreading of tail, bowing and swinging of body and head; in aggression within group, or against *S. anchietae*, facial and crown feathers spread, head bobbed, wings flicked, and bill-wiping. Cavity excavated at 2-20 m in dead tree, or on underside of dead branch in living tree; from completion, a "guard" barbet usually perches near it; group territory as small as 5 ha, very aggressive to all other barbets in nest area. Eggs 2-5; incubation period unknown; young fed insects at first, then gradually more fruit, until fruits are main item; up to 24 feeds per hour; nestling period c. 40 days; helpers, parents and fledged young roost in nest, young incorporated into group, with which they remain for unknown period. Nests parasitized by Lesser Honeyguide (*Indicator minor*). One nest preyed on by army ants, which killed and removed young in tiny pieces.

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. Somewhat adaptable, can exist in patches of woodland where considerable clearance has been carried out, so long as trees that are suitable for nesting and roosting remain. Nonetheless, more data needed about its specific requirements, as woodland is being cleared rapidly in many areas.

**Bibliography.** Benson (1964), Benson & Benson (1977), Benson *et al.* (1971), Britton (1980), Clancey (1995, 1996), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Fry *et al.* (1988), Ginn *et al.* (1989), Goodwin (1964), Harrison *et al.* (1997), Irwin (1981, 1998), Mackworth-Praed & Grant (1957, 1962), Maclean (1993), Marshall (1996), Newman (1996), Priest (1934, 1948), Short & Horne (1985a), Short *et al.* (1990), Sinclair *et al.* (1993, 1997), Snow (1978), Stevenson & Fanshawe (2001), Tarboton (2001).

### 12. Anchieta's Barbet

#### *Stactolaema anchietae*

**French:** Barbican à tête jaune **German:** Strohkopf-Bartvogel **Spanish:** Barbudo de Anchieta  
**Other common names:** Yellow-headed Barbet

**Taxonomy.** *Buccanodon anchietae* Bocage, 1869, Caconda, south-west Angola.

Forms a superspecies with *S. whytii*. Three subspecies recognized.

**Subspecies and Distribution.**

*S. a. katangae* (Vincent, 1934) - NE Angola, S Zaire, and NW, NC & EC Zambia.

*S. a. rex* (Neumann, 1908) - WC Angola.

*S. a. anchietae* (Bocage, 1869) - SC Angola E to near Zambian border.

**Descriptive notes.** 18-19 cm; 36-54 g. Brown woodland barbet with yellow markings on head. Nominat race with pale yellow forehead, crown, face and chin, blackish-brown hind-crown and nape with fine white or yellow-white spots; white wing patch; upper breast black with yellowish streaks, lower belly whitish; dark brown eyes, black orbital skin. Distinguished from *S. whytii* by more extensive yellow, including chin, only single white wing patch. Sexes alike. Immature duller brown, has yellow in bill, and yellow orbital skin. Races weakly defined: *rex* with unspotted black hindcrown and nape, grey-brown to pale brown

eyes; *katangae* shows richer yellow on face than nominate, with larger breast spots, whiter belly, brown eyes. Voice. Soft song of "hoo" notes, slightly higher-pitched than in *S. whytii* and usually slower with longer notes, but can be fast; grating calls less buzzy than those of *S. whytii*, more like *S. leucotis* and *S. olivacea*; also fast, wavering grating "aaAAaaaaa", soft "kooi" and associated "ek" notes, chattering "nyaaak" calls, "yee", "keew" and other calls; shrieks longer, lower-pitched than in *S. whytii*; nestlings give three different calls. Mechanical sounds of wing-rustling, bill-wiping, and bill-tapping at nest.

**Habitat.** *Brachystegia* woodland, wooded clearings, riverine woods, and edges of forest, always where there are fruiting trees, at 900-2440 m. Found in same woodland as *S. whytii* near Ndola, in N Zambia.

**Food and Feeding.** Eats fruits, including figs, *Uapaca kirkiana* and *U. nitida*, and others; also termites, grasshoppers such as rare *Xenocotantops parazermyi*, locusts, wasps, beetles and flies.

On following pages: 13. Green Barbet (*Stactolaema olivacea*); 14. Speckled Tinkerbird (*Pogoniulus scolopaceus*); 15. Eastern Green Tinkerbird (*Pogoniulus simplex*); 16. Moustached Green Tinkerbird (*Pogoniulus leucomystax*); 17. Western Green Tinkerbird (*Pogoniulus coryphaeus*); 18. Red-rumped Tinkerbird (*Pogoniulus atroflavus*); 19. Yellow-throated Tinkerbird (*Pogoniulus subsulphureus*); 20. Yellow-rumped Tinkerbird (*Pogoniulus bilineatus*); 21. Red-fronted Tinkerbird (*Pogoniulus pusillus*); 22. Yellow-fronted Tinkerbird (*Pogoniulus chrysoconus*).

Gleans. probes for insects, especially where mosses and lichens occur, and flycatches from perch. Special notches in branches or depressions in bark used as "anvils" to kill and dismember insects. Drinks water from lichen "cups". Flies fast and directly to fruiting trees and bushes, usually in groups. Aggressive at fruiting trees.

**Breeding.** Jul-Nov; in S Zaire nests in rainy season, Jan-Jun. Social, groups of up to 6 at a nest. Nest excavated at 2-10 m in stub, dead tree or dead branch, depth 25 cm or more; always 1 barbet on "guard" after excavation completed; attacks any bird close to nest, any other barbet that chances to sing nearby, and leads in mobbing predators such as mongooses (Viverridae). Eggs 2-5; incubation and nestling periods unknown; eggshells carried away from nest, as is faecal material; chicks fed 3-17 times an hour, by all group-members; adult once caught 3 insects in 30 seconds, fed them singly to nestlings. Frequently parasitized by Lesser Honeyguide (*Indicator minor*); in one observation, nestling honeyguide was fed at entrance but, as soon as it left nest, was instantly driven away 300 m and more by members of the group.

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. No reliable details on numbers, but appears to be locally common. Seems tolerant of some clearing of woodland, but dependence on dead wood and fruits suggests that monitoring is necessary.

**Bibliography.** Anon. (1998a), Aspinwall & Beal (1998), Benson *et al.* (1971), Chapin (1939), Clancey (1995), Dean (1974a, 2000), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Fry *et al.* (1988), Horne & Short (1988), Lippens & Wille (1976), Mackworth-Præd & Grant (1962, 1970), Payne (1967b), Pedersen (2000), Pinto (1983), Robertson (1998b), Short & Horne (1985a), Snow (1978), Traylor (1963).

### 13. Green Barbet

#### *Stactolaema olivacea*

**French:** Barbican olivâtre    **German:** Olivbartvogel    **Spanish:** Barbudo Oliváceo  
**Other common names:** African Green Barbet, Olive Barbet; Woodward's Barbet (*woodwardi*)

**Taxonomy.** *Barbatula olivacea* Shelley, 1880, Rabai, south-east Kenya.

Sometimes placed in monospecific genus *Cryptolybia*, but differences in morphology, plumage and some vocalizations are minimal and generally considered quite insufficient to warrant generic separation. Race *woodwardi* sometimes treated as full species, but its features are shown to some degree in other races, and they are vocally identical. Proposed race *hylophona* included within *woodwardi*, though tending towards N races. Five subspecies recognized.

**Subspecies and Distribution.**

*S. o. olivacea* (Shelley, 1880) - SE Kenya and NE Tanzania.

*S. o. howelli* (Jensen & Stuart, 1982) - Udzungwe and Mahenge Mts, in C Tanzania.

*S. o. rungweensis* (Benson, 1948) - highlands of SW Tanzania and N Malawi.

*S. o. woodwardi* Shelley, 1895 - disjunctly in SE Tanzania (Rondo Plateau) and Natal (Ngoye Forest).

*S. o. belcheri* (W. L. Sclater, 1927) - NW Mozambique (Mt Namuli) and S Malawi (Mt Thyolo).

**Descriptive notes.** 17-18 cm; 40-60 g. Generally olive-green, unpatterned barbet. Nominative race has forehead to nape blackish-brown, ear-coverts greyer; hint of yellow-green area behind eye; eyes dull reddish. Differs from superficially similar *Pogoniulus simplex* in much larger size, lack of wing markings. Sexes alike. Immature somewhat duller than adult. Races *rungweensis* and *howelli* more bronzy (golden-green) above and darker-headed than nominate, *howelli* blackish on crown, and *rungweensis* with black to nape, buffish-olive behind eye, more greyish-olive below; *belcheri* more contrasting in colours, with greener, even

yellow-green, ear-coverts, darker brownish or blackish rest of head, blackish throat and breast, darker green back; *woodwardi* green like nominate, but area behind eye more yellow and patch-like, dark forehead and lores, base of culmen more keel-like. **Voice.** Song up to 30 loud "chomp" notes introduced by "chuk", by either or both of pair together, occasionally as true duet; soft "ooo-ooo" series sometimes follow "chomp" songs, these slow notes resembling songs of *S. whytii* and *S. anchietae*; also squawking "shreek" calls, possibly alarm, used sometimes against honeyguides (Indicatoridae); other calls include interactive "kek", soft "ah", also grating, buzzy notes at 35-48 per second or faster; chatter and grating-churring notes from nestlings. Also bill-wiping and wing-fluttering displays.

**Habitat.** Wet to dry forest and dense to open woodland, and in Kenya *Brachystegia* woodland, using canopy to lower understorey, wherever fruits are found. Occurs in lowlands and hills to c. 2000 m. Interactions with other barbets suggest that those such as *S. leucotis* and *Lybius torquatus* could affect utilization of habitat.

**Food and Feeding.** Takes fruits such as figs, *Flagellaria guineensis* and many others, including berries of diverse types; also arthropods, including beetles, roaches, termites, moths, and the slug *Limax flavus*. Regurgitates larger fruit stones and hard insect parts. Flycatches and gleans for insects. Moves in groups of up to 6, more usually 3 or 4 when feeding. May join mixed-species foraging flocks of orioles (Oriolidae), starlings (Sturnidae), helmetshrikes (*Prionops*), flycatchers (*Muscicapra*) and drongos (Dicruridae).

**Breeding.** Sept-Apr generally, mainly Sept-Jan in S. Social, nests in groups of up to 8. Displays include courtship feeding, spreading of rump, face and crown feathers, and various postures; countersinging, used also against other barbets, e.g. *Lybius torquatus*. Excavates hole at 3-22 m in tree, usually on underside of dead branch of live tree but also in stub of dead tree, cavity to c. 60 cm deep, entrance c. 5 cm, nest-chamber c. 15 cm; 1 barbet "guards" hole during day. Eggs 3-6; changeovers in incubating duties at c. 30 minutes, incubation period c. 18 days; all adults feed young, c. 3 times per hour, at first insects, then mainly fruits, up to 4 figs in 1 feed; chamber may be enlarged as young grow, wood chips with faecal matter carried away by adults; nestling period c. 35 days. Post-fledging details lacking. Nests parasitized by Lesser Honeyguide (*Indicator minor*).

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. Common in coastal Kenya, where shows some adaptation to *Brachystegia* forest adjacent to wet forest; locally common in NE Tanzania, for example in E Usambaras. Suffers some pressure from other barbets, woodpeckers and honeyguides in form of nest-cavity and other competition, and brood parasitism by honeyguides. S races *belcheri* and *woodwardi* appear to be much rarer, need monitoring; other populations may remain to be discovered in C Mozambique; South African population of *woodwardi* may number only c. 1000 individuals (c. 300 pairs or groups). Continued forest clearance could place entire species under threat.

**Bibliography.** Barnes (2000), Belcher (1930), Benson (1948), Benson & Benson (1977), Britton (1980), Brooke (1984), Brown & Britton (1980), Chittenden *et al.* (1998), Clancey (1958c, 1964, 1979a, 1979c, 1985b, 1989b), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Dowsett-Lemaire & Dowsett (1987), Evans & Anderson (1992), Fry *et al.* (1988), Ginn *et al.* (1989), Harrison *et al.* (1997), Holliday & Tait (1953), Holsten *et al.* (1991), Irwin (1981), Jensen & Stuart (1982), King (1978/79), Lewis & Pomeroy (1989), Liversidge (1991), Mackworth-Præd & Grant (1957, 1962), Maclean (1993), Priest (1948), Ripley & Heinrich (1969), Schönwetter (1967), Short & Horne (1979, 1980a, 1985a), Short *et al.* (1990), Snow (1978, 1979), Tarboton (2001), Zimmerman *et al.* (1996).

## Genus *POGONIULUS* Lafresnaye, 1844

### 14. Speckled Tinkerbird

#### *Pogoniulus scolopaceus*

**French:** Barbion grivelé    **German:** Schuppenbartvogel    **Spanish:** Barbudito Escolopáceo  
**Other common names:** Spectacled Tinkerbird/Tinkerbarbet

**Taxonomy.** *Xylobucco scolopaceus* Bonaparte, 1850, Ashanti, Ghana.

No close relatives. Forms described as *aloyisii* from Kenya and Uganda and *flavior* from N Angola considered synonyms of *flavissquamatus*. Three subspecies recognized.

**Subspecies and Distribution.**

*P. s. scolopaceus* (Bonaparte, 1850) - Sierra Leone and SE Guinea E to S Nigeria.

*P. s. stellatus* (Jardine & Fraser, 1852) - Bioko I (Fernando Póo).

*P. s. flavissquamatus* (J. Verreaux & E. Verreaux, 1855) - S Cameroon E to Uganda, S to N Angola and S Zaire.

**Descriptive notes.** c. 12 cm; 11-18 g. Rather large for a tinkerbird, with scaly markings above. Nominative race has blackish-olive crown feathers broadly edged and tipped with yellow; upperparts blackish-grey with broad yellow fringes, rump yellow; underparts light yellow-buff with darker mottling. Sexes alike. Immature similar to adult, with markings yellower, base of bill yellow, often barred throat. Race *flavissquamatus* larger than nominate, more marked and thus darker below, crown especially darker than in other races; *stellatus* largest, more olive-green above, paler below. **Voice.** Variable, diverse, song-like series

of single to 6-part "tikikik" notes, and loud, typically tinkerbird-like "tok-tok-"; also toad-like, nasal "bbbbtt", fast piping "titi-" trills resembling those of *P. simplex* superspecies, and loud, high-pitched "hyet" notes in series.

**Habitat.** Occupies primary forest at edges, in clearings, and also secondary forest and plantations of trees; requires dead wood for excavating hole; enters gardens. Occurs up to 1300 m in W Africa, up to 1800 m farther E.

**Food and Feeding.** Diet of fruits and arthropods (mainly insects). Fruits include those of figs, and species of *Coelocaryon*, *Heisteria*, *Macaranga*, *Rauwolfia* and others; ants, termites, beetles, flies and earwigs among insects eaten. Gleans from foliage and branches, and flycatches from perch. Forages in vines, bushes and trees, but mainly in canopy and subcanopy. May join mixed-species foraging flocks.

**Breeding.** Long season, or possibly re-nests: most months in W Africa, but especially Sept-Feb; in Apr-Jun on Bioko; in Oct-Mar in Cameroon and Gabon, Feb-Aug in Zaire, and probably Aug-Jan and May in Uganda. Breeds in pairs, sometimes trios; once 4 adults seen feeding nestlings. Nest excavated at 0.5-22 m, often higher, in dead tree, stub, even hanging dead branch; territory at least 6-8 ha in primary forest, up to c. 33 ha in secondary forest, maintained throughout year. Eggs 2-4; no data on incubation, fledging, or feeding of young, but groups or families of up to 5 roost together.

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. Widespread, and somewhat adaptable. Population in Liberia estimated at 1,200,000 pairs; estimates of 12-15 pairs/km<sup>2</sup> in Gabon secondary forest; common in Sierra Leone. No longer occurs in W Kenya, but may never have been common there. Present in several protected areas, e.g. Gola Forests Reserves (Sierra Leone), Korup National Park (Cameroon) and Kibale Forest National Park (Uganda).

**Bibliography.** Allport *et al.* (1989), Bannerman (1933, 1953), Bates (1930), Britton (1980), Brosset & Éard (1986), Brown & Britton (1980), Chapin (1939), Cheke & Walsh (1996), Christy & Clarke (1994), Colston & Curry-Lindahl (1986), Dean (2000), Dowsett (1989b), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Field (1999), Fry *et al.* (1988), Gatter (1997), Germain & Cornet (1994), Grimes (1987), Lewis & Pomeroy (1989), Lippens & Wille (1976), Louette (1981b), Mackworth-Præd & Grant (1957, 1962, 1970), Pérez del Val (1996), Pérez del Val *et al.* (1994), Pinto (1983), Rand *et al.* (1959), Serie (1950, 1957, 1965), Short & Horne (1985a), Short *et al.* (1990), Snow (1978), Thiollay (1985a), Zimmerman *et al.* (1996).

### 15. Eastern Green Tinkerbird

#### *Pogoniulus simplex*

**French:** Barbion vert    **German:** Schlichtbartvogel    **Spanish:** Barbudito Sencillo  
**Other common names:** Green(!)/African Green Tinkerbird/Tinkerbarbet

**Taxonomy.** *Barbatula simplex* Fischer and Reichenow, 1884, Pangani River, north-east Tanzania. Forms a superspecies with *P. leucomystax* and *P. corpyphaeus*, all three having in past been placed in separate genus *Viridibucco*. Birds of S Malawi and Mozambique sometimes separated as race *hylodytes*. Monotypic.

**Distribution.** SE Kenya (S from Arabuko-Sokoke Forest) to NE Tanzania, and S disjunctly to SE Malawi and S Mozambique (Sul do Save); also Zanzibar.

**Descriptive notes.** c. 9 cm; 7-10.5 g. Tiny, active green barbet lacking distinctive head markings. Both sexes olive-green above, with yellow rump; wings blackish with much yellow; underparts light olive-yellow to greyish-yellow. Differs from similar *P. leucomystax* in less dark upperparts,

lack of white malar line; from other *Pogoniulus* species in lack of patterning. Immature with yellow basal half of bill. Voice. Song of 2 types, a "pop-trill" very like that of sympatric race *fischeri* of *P. bilineatus* but higher-pitched, faster and shorter, and a variable piping trill, slow to fast (20-30 notes per second); also grating "ggggg", noisier long grating notes, and "prit" notes.

**Habitat.** Occupies dense undergrowth in primary forest, also in forest thickets and edges, as in coral rag bush; occasionally occurs in mangroves; rarely enters *Brachystegia* woods adjacent to forest. Occurs from sea-level up to

300 m in N, but up to 900 m in Usambara Mts in NE Tanzania, there overlapping with *P. leucomystax*, which generally replaces it at higher elevations; but where *P. leucomystax* is absent, as E of Rift Valley in S Malawi, present species occurs up to 1525 m.

**Food and Feeding.** Diet largely unknown, but apparently mainly fruits, especially mistletoe berries (*Loranthus*); also gleans for insects. Flits about rapidly; seems to move constantly, calling as it does so. Occasionally joins mixed-species foraging flocks.

**Breeding.** Aug-Sept in Kenya, also Dec-Mar in Tanzania, and Oct-Dec in Zanzibar. Very little known: 1 nest with young 2 m up in thin dead tree in Kenya; sings generally below 7 m, so nests probably low; eggs and other details undescribed.

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. Uncommon and local in N of range; no details available from elsewhere. Relatively poorly known species; other populations may remain to be discovered in C Mozambique; much research required in order to uncover details of its ecology and breeding behaviour.

**Bibliography.** Benson & Benson (1977), Britton (1980), Clancey (1971a, 1984d, 1985b, 1996), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Evans & Anderson (1992), Fry *et al.* (1988), Ginn *et al.* (1989), Harrison *et al.* (1997), Holsten *et al.* (1991), Horne & Short (1988), Jackson & Selater (1938), Lewis & Pomeroy (1989), Mackworth-Præd & Grant (1957), Maclean (1993), Mlingwa (2000), Newman (1996), Pakenham (1979), Short & Horne (1985a), Short *et al.* (1990), Sinclair *et al.* (1993, 1997), Snow (1978), Stevenson & Fanshawe (2001), Stuart & Jensen (1981), Waiyaki & Bennun (2000), Zimmerman *et al.* (1996).

## 16. Moustached Green Tinkerbird

### *Pogoniulus leucomystax*

**French:** Barbion à moustaches **German:** Bergbartvogel **Spanish:** Barbudito Bigotudo  
**Other common names:** Whiskered Green Tinkerbird, Moustached Tinkerbird/Tinkerbarbet

**Taxonomy.** *Barbatula leucomystax* Sharpe, 1892, Sotik, west Kenya.

Forms a superspecies with *P. simplex* and *P. coryphaeus*, all three having in past been placed in separate genus *Viridibucco*. Populations of present species show slight clinal increase in size towards S, but no constant geographical colour differences to warrant subspecific differentiation; birds from Chyulu Hills (Kenya) formerly separated as race *chyulu*. Monotypic.

**Distribution.** Extreme E Uganda (Mt Elgon) and C Kenya, S in highlands to Malawi mountains W of Rift Valley.

**Descriptive notes.** c. 9.5 cm; 8-14.5 g. Active small, green barbet. Both sexes dark olive-green above, with bright yellow rump; distinctive white malar stripe and dark lores; wings blackish with broad yellow wingbars, yellow feather edges; underparts light greyish-yellow, darker on breast. Distinguished from *P. simplex* by white malar mark, darker green crown and back. Immature has half or more of basal bill yellow. Voice. Song, by male or female, a short to long piping trill at 6-20 notes per second, slow to faster, or tempo varying; also short, fast trills, often with varying number of notes in each set within series; other calls are sharp "pit" or "pit-it", grating "grrrr" notes, chatter "chaaaa" series, and rattling "griiiiik"; slow "ti-ti-ti" to fast "peep-eep" calls from nestlings.

**Habitat.** Generally in forest with dense undergrowth in mountains, but ranges from small remnant patches of forest to gardens and dense thickets; seems often to require presence of mistletoe (*Loranthaceae*) for breeding. Usually at 900-2500 m, rarely up to 3000 m, and in Usambara and Uluguru Mts, in Tanzania, down to 450 m. Known to overlap with *P. simplex* only at 450-900 m in W Usambaras, and replaces that species at higher elevations.

**Food and Feeding.** Eats fruits and berries, especially mistletoe berries (*Loranthaceae*, including *Engleria inaequilatera*); also flycatches for insects, but no details of species taken. Regurgitates fruit stones, often sticks those of mistletoe around nest entrance. Moves rapidly, feeding mainly at 2-8 m. Subordinate to *P. bilineatus* at food sources.

**Breeding.** May-Jun and Aug-Jan in N, thus in either of 2 rainy seasons; mainly Oct-Nov in S; in Malawi, 2 broods in a year, with 2-month interval between. Nests in pairs, but only 1 sleeps in nest at night. Nest, excavated by both adults, 3-7 m up in tree or stub, often in jacaranda in suburban areas, with entrance c. 2 cm; territories in suburban Nairobi 4-20 ha, but as small as 0.2 ha in Nyika Plateau, in Malawi; male sings just before roosting and after leaving nest in morning, as well as sporadically in bursts. Eggs 2-3; incubation period not known; both adults feed chicks, nestling period 32-34 days.

**Movements.** Resident; largely sedentary, with local dispersal and perhaps shifts to breeding areas (forest patches) from non-breeding locations.

**Status and Conservation.** Not globally threatened. The most widespread member of its superspecies, and the only one showing some adaptability. Locally common; fairly common to scarce in Kenya; less common than sympatric *P. bilineatus*; known to occur in Tsavo East and Tsavo West National Parks. On Nyika Plateau, in Malawi, 2 breeding pairs in forest patch as small as 1.2 ha, but densities lower in intact forest.

**Bibliography.** Aspinwall & Beel (1998), Atkins (1985), Belcher (1930), Benson & Benson (1977), Benson *et al.* (1971), Britton (1980), Brooks *et al.* (1998), Brown & Britton (1980), Clancey (1971d), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Dowsett-Lemaire (1983a), Fry *et al.* (1988), Horne & Short (1988), Jackson & Selater (1938), Johnston-Stewart & Heigham (1982), Lewis & Pomeroy (1989), Mackworth-Præd & Grant (1957, 1962), Moreau & Moreau (1937), Ripley & Heinrich (1969), Short & Horne (1985a, 1988b), Snow (1978), Stevenson & Fanshawe (2001), Zimmerman *et al.* (1996).

## 17. Western Green Tinkerbird

### *Pogoniulus coryphaeus*

**French:** Barbion montagnard **German:** Gelbrücken-Bartvogel **Spanish:** Barbudito Coronado  
**Other common names:** Green(!)/Western Tinkerbird/Tinkerbarbet

**Taxonomy.** *Barbatula coryphaea* Reichenow, 1892, Buea, Mount Cameroon.

Forms a superspecies with *P. simplex* and *P. leucomystax*, all three having in past been placed in separate genus *Viridibucco*. Races poorly defined, but widely separated geographically. Three subspecies recognized.

**Subspecies and Distribution.**

*P. c. coryphaeus* (Reichenow, 1892) - E Nigeria and adjacent W Cameroon uplands.

*P. c. hildamariae* (W. L. Selater, 1930) - E Zaire, SW Uganda and W Rwanda.

*P. c. angolensis* (Boulton, 1931) - WC Angola.

**Descriptive notes.** c. 9-10 cm; 8-13 g. A rather distinctive, small montane barbet. Both sexes of nominate race with broad golden-yellow band from forehead to rump, bordered black on each side; white malar stripe; wings black and gold; and greyish-olive underparts. Easily distinguished from both *P. simplex* and *P. leucomystax* by general coloration and pattern, but voice similar. Immature duller than adult, base of bill yellow. Race *hildamariae* slightly smaller, more yellow, less golden; *angolensis* still paler yellow, duller and greyer, less olive, below. Voice. Main vocalization fast to slow piping trills in series, much like those

of *P. leucomystax*, 5-12 notes per second; other calls little known.

**Habitat.** Usually montane forest in dense undergrowth, also edges, clearings, riverine thickets and dense secondary forest; occasionally forages into adjacent woodland and *Eucalyptus* plantations, and visits fruiting trees in the open. Occurs at 900-3030 m, mainly 1900-2500 m.

**Food and Feeding.** Eats fruits and berries, including figs and mistletoe berries (*Loranthaceae*); also beetles and probably other insects, but data are sparse. Feeds mainly 2-10 m up in trees; clings like tit (*Paridae*) to fruits. Moves about rapidly.

**Breeding.** Oct in Cameroon, Jun-Aug and Nov-Jan in E Zaire, Apr-May in Uganda, and May-Jun in Angola. Non-social breeder, strongly territorial. Nest excavated at 0.6-5 m in dead stub or small dead tree; 1 was 80 cm deep and up to 50 mm wide, with entrance hole 2 cm across and with sprouting seeds stuck around it. Eggs 3; no information on incubation and nestling periods, or on role of sexes.

**Movements.** Mainly resident; post-breeding downslope movement occurs, rarely down to c. 50 m, bringing it into range of several lowland tinkerbirds.

**Status and Conservation.** Not globally threatened. Appears to be generally uncommon and local, but no detailed data on population numbers. Little known also about its breeding biology and general ecology. Requirement for further information on this species considered of some importance, particularly in view of its small fragmented range. Present in several protected areas, e.g. Gashaka-Gumti Reserve (Nigeria), Mount Kupé National Park (Cameroon) and Impenetrable Forest National Park (Uganda).

**Bibliography.** Ash *et al.* (1989), Bannerman (1953), Britton (1980), Chapin (1939), Dean (2000), Dowsett (1989a, 1990), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Fry *et al.* (1988), Jackson & Selater (1938), Larson *et al.* (2000), Lippens & Wille (1976), Louette (1981b), Mackworth-Præd & Grant (1957, 1962, 1970), Pedersen (2000), Pinto (1983), Prigogine (1971), Serle (1950, 1964, 1965), Short & Horne (1985a), Short *et al.* (1990), Snow (1978), Stevenson & Fanshawe (2001), Stuart & Jensen (1986).

## 18. Red-rumped Tinkerbird

### *Pogoniulus atroflavus*

**French:** Barbion à croupion rouge **German:** Rotbürzel-Bartvogel **Spanish:** Barbudito Culirrojo

**Taxonomy.** *Bucco atro-flavus* Sparrman, 1798, Sierra Leone.

Rather isolated member of genus, perhaps near to *P. bilineatus* and the superspecies formed by *P. pusillus* and *P. chrysoconus*. "*P. erythronotus*" is a synonym. Monotypic.

**Distribution.** Senegambia E in forested areas to S Cameroon, thence to SE Central African Republic and W Uganda, and S to Cabinda (N Angola), R Congo and CE Zaire.

**Descriptive notes.** c. 12-13 cm; 14-21.5 g. Relatively large tinkerbird with distinctive pattern. Both sexes glossy black above, with yellow wingbar and red rump; side of head with 2 yellow stripes, broader malar stripe; throat yellow, rest of underparts pale greyish-olive. Distinguished from all other *Pogoniulus* by red rump. Immature duller, more sooty and less black, base of bill yellow. Voice. Song an unbroken series of "pop" notes at 1.3 per second; also fast "bdddtt" trill series 3-4 seconds long with 29 notes per second, and higher-pitched, shorter, slower trills with notes c. 16 per second.

**Habitat.** Primary and secondary forest, including some mature mangrove forest, edges, adjacent clearings, forest-grassland mosaic, plantations and other cultivated areas; extends into open floodplains in S Sierra Leone. Usually below 800 m, but occasionally to 1550 m in W Africa, to 1800 m in Cameroon and to 2400 m in NE Zaire.

**Food and Feeding.** Eats mainly fruits, including figs, and species of *Allophylus*, *Musanga*, *Rauvolfia* and others, especially *Loranthus*; also undetermined insects and spiders. Forages at all levels, in forest mostly in canopy.

**Breeding.** Nov-May and Aug in W Africa, May-Jun in Central African Republic, Jun-Feb in Uganda. Other data very sparse: territorial, sings all year, singers depress tail, erect and spread red rump feathers; presumably excavates hole in dead tree, but no details; eggs 2-3.

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. Estimated 300,000 pairs in Liberia, where density of 5-8 pairs/km<sup>2</sup>; common in Sierra Leone. Usually uncommon, however, and considered the least common lowland tinkerbird, perhaps because of competition with larger barbets and woodpeckers for

nesting and roosting sites; such competition possibly more likely owing to this species' comparatively large size for a tinkerbird. Further data needed on all aspects of its biology. Present in several protected areas, e.g. Tai Forest National Park (Ivory Coast) and Korup National Park (Cameroon).

**Bibliography.** Allport *et al.* (1989), Bannerman (1933, 1953), Barlow *et al.* (1997), Bates (1930), Britton (1980), Brosset & Énard (1986), Chapin (1939), Chappuis (1981), Cheke & Walsh (1996), Christy & Clarke (1994), Clancey (1984c), Colston & Curry-Lindahl (1986), Dean (2000), Dowsett (1989b), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Field (1999), Friedmann (1978a), Fry *et al.* (1988), Gatter (1997), Grimes (1987), Lippens & Wille (1976), Louette (1981b), Mackworth-Præd & Grant (1970), Morel & Morel (1990), Pinto (1983), Rand *et al.* (1959), Serle (1950, 1965), Short & Horne (1985a), Short *et al.* (1990), Snow (1978), Thiollay (1985a).

## 19. Yellow-throated Tinkerbird

### *Pogoniulus subsulphureus*

**French:** Barbion à gorge jaune **German:** Gelbkehl-Bartvogel **Spanish:** Barbudito Gorgigualdo

**Taxonomy.** *Bucco subsulphureus* Fraser, 1843, Bioko.

Closely related to *P. bilineatus* and the superspecies formed by *P. pusillus* and *P. chrysoconus*. Three subspecies recognized.

#### Subspecies and Distribution.

*P. s. chrysopygus* (Shelley, 1889) - Sierra Leone and SE Guinea E to S Ghana.

*P. s. flavimentum* (J. Verreaux & E. Verreaux, 1851) - Togo E to S Central African Republic and S Uganda, and S to C Zaïre.

*P. s. subsulphureus* (Fraser, 1843) - Bioko I (Fernando Póo).

**Descriptive notes.** c. 9.5 cm; 7.5-13 g. Tiny, black, yellow and white tinkerbird. Both sexes with glossy blue-black crown to back; nominate race with yellow rump and yellow throat; pale yellow supercilia, thin yellow line across forehead extending into whiter moustachial stripe; flight-feathers with whitish inner webs, pale yellowish edges; underparts pale yellowish, greying at sides. Distinguished from *P. bilineatus* by smaller size, yellow throat; from *P. atroflavus* by smaller size, yellow rump. Immature duller, upperpart feathers edged yellowish, base of bill yellowish. Race *flavimentum* less grey below, more olive-yellow.

low, flanks buffy; *chrysopygus* greyish yellow below, with whiter throat, broader and more golden-yellow wing markings, and facial stripes white, not yellow. **VOICE.** Resembles that of *P. bilineatus*, but paused popping song higher-pitched, with sharp "pyop" as first note, song sets normally with 2-4 notes each; popping may be uttered in accelerating series for several seconds; also yipping, piping notes at 5-6 per second in paused series; and single "pyip" notes woven with multiple "yi-yi-yi" notes into varying series; nestlings give piping, tinkling notes.

**Habitat.** Primary and old secondary forest, streamside forest, forest borders, and submontane forest; enters gardens. Possibly excluded from more open habitats by larger *P. bilineatus*, but co-occurs with it in open forest, forest-savanna mosaic and areas of palms in parts of Sierra Leone. Occurs from sea-level to 2100 m; on Bioko generally below *P. bilineatus*, up to 800-1000 m.

**Food and Feeding.** Diet of diverse fruits, such as figs and species of *Allophylus*, *Heisteria*, *Macaranga*, *Trema* and others; also takes insects from around such flowers as *Bombax*, and consumes others such as ants and termites, as well as wood-boring beetle larvae. Most foraging is in dense canopy and subcanopy above 20 m, making it difficult to observe.

**Breeding.** Mainly Jan-Jul but as early as Sept in Sierra Leone, Liberia and Guinea; Dec-Jan in Ivory Coast and Ghana; all year in Nigeria and probably Cameroon; Sept-Mar in Gabon, Congo and Zaïre; Feb-May on Bioko; and May-Jun and Dec-Jan (following both rainy seasons) in Uganda. Nest usually at c. 4 m, few other details (but a roosting hole once only 8 cm deep in stub 5 cm thick); territory 9-10 ha in Gabon. Eggs 2-3; no information on incubation and fledging periods; chicks fed at intervals of 1-13 minutes, by both parents.

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. Together with *P. bilineatus* is a characteristic bird of forest in W & C Africa; usually appears to be less numerous than the larger *P. bilineatus* but is also mistaken for it. Estimated population in Liberia 700,000 pairs, with densities of up to 15 or more/km<sup>2</sup>, and greatly outnumbers *P. bilineatus* in that country; common throughout S Sierra Leone. Also suggested to occur in SW Senegal, on basis of vocal record; this would represent significant range extension, but confirmation required. Usually requires more dense cover than *P. bilineatus*, or is physically kept from edge habitats by that species. More information is needed about its ecology and population dynamics. Present in several protected areas, e.g. Gola Forests Reserves (Sierra Leone) and Korup National Park (Cameroon).

**Bibliography.** Allport *et al.* (1989), Bannerman (1933, 1953), Barlow *et al.* (1997), Bates (1930), Britton (1980), Brosset & Énard (1986), Brown & Britton (1980), Chapin (1939), Chappuis (1981), Cheke & Walsh (1996), Christy & Clarke (1994), Colston & Curry-Lindahl (1986), Demey & Fishpool (1994), Dowsett (1989b), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Field (1999), Fry *et al.* (1988), Gatter (1997), Grimes (1987), Lippens & Wille (1976), Louette (1981b), Mackworth-Præd & Grant (1970), Morel & Morel (1990), Pérez del Val (1996), Pérez del Val *et al.* (1994), Pinto (1983), Rand *et al.* (1959), Serle (1965), Short & Horne (1985a), Short *et al.* (1990), Snow (1978), Thiollay (1985a).

## 20. Yellow-rumped Tinkerbird

### *Pogoniulus bilineatus*

**French:** Barbion à croupion jaune **German:** Goldbürtzel-Bartvogel **Spanish:** Barbudito Culigualdo

**Other common names:** Golden-rumped Tinkerbird/Tinkerbarbet; Lemon-rumped Tinkerbird/Tinkerbarbet (*leucolaimus*); White-chested Tinkerbird/Tinkerbarbet ("makawai")

**Taxonomy.** *Megalaima bilineata* Sundevall, 1850, Natal.

Appears to be most closely related to *P. subsulphureus* and the superspecies formed by *P. pusillus* and *P. chrysoconus*; possibly fairly close to *P. atroflavus*. Yellow-rumped races *mfumbiri*, *leucolaimus* and *poensis* have been thought to represent a separate species, *P. leucolaimus*, but they intergrade with the three golden-rumped races in E Zaïre, Rwanda and Burundi; also, vocal evidence suggests that *leucolaimus* is conspecific with present species. In view of similarity and intergradation between these two groups, other described forms considered untenable: thus, *sharppei* (S Ghana),

*togoensis* (Gambia to S Nigeria) and *nyansae* (W shore L Victoria) regarded as synonymous with *leucolaimus*; *urungeni* (S shore L Tanganyika) with *mfumbiri*; *alius* (C Kenya) with *jacksoni*; *pallidus* (Sokoke Forest) and *concoloratus* (Uluguru Mts) with *fischeri*; and *rovumensis* (SE Tanzania), *deceptor* (E Zimbabwe), *riparium* (S Mozambique, NE South Africa) and *orenesus* (Malawi) with nominate *bilineatus*. In addition, single specimen from NW Zambia originally described as separate species, "*P. makawai*", on basis of plumage differences and bigger bill, but now generally considered no more than aberrant individual of present species. Six subspecies recognized.

#### Subspecies and Distribution.

*P. b. leucolaimus* (J. Verreaux & E. Verreaux, 1851) - Senegambia E to S Cameroon, S Central African Republic and W Uganda, S to N Angola, and S Zaïre.

*P. b. poensis* (Alexander, 1908) - highlands of Bioko I (Fernando Póo).

*P. b. mfumbiri* (Ogilvie-Grant, 1907) - SW Uganda and E Zaïre to W Burundi, W Tanzania and E & NC Zambia.

*P. b. jacksoni* (Sharpe, 1897) - E Uganda and C Kenya S to E Burundi and N Tanzania.

*P. b. fischeri* (Reichenow, 1880) - coastal Kenya S to NE Tanzania; also Zanzibar, and Mafia I (off E Tanzania).

*P. b. bilineatus* (Sundevall, 1850) - E Zambia and S Tanzania S to E South Africa.

**Descriptive notes.** 10-12 cm; 11-18.5 g, but *fischeri* 8-12.5 g, and *leucolaimus* 7-14 g. The epitome of a tinkerbird, with contrastingly marked face, strong bill, rather short tail. Both sexes of nominate race black above, with golden rump, golden-yellow in wings; white supercilia, white line across forehead and down to neck side, white throat; underparts pale olive-yellow, more olive laterally. Distinguished from similar *P. subsulphureus* by larger size, white throat, more golden rump, from very similar white-throated race *chrysopygus* of latter also more safely by voice. Immature duller, greener, less black than adults, with yellow

base of bill. Races differ mainly in coloration of pale areas of plumage, forming two groups according to rump colour: *jacksoni* and *fischeri* golden-rumped like nominate, former smaller, greyer and less olive below, and paler generally; *fischeri* very small, with whiter throat, yellower rest of underparts, larger gold rump, and becoming clinally paler to N; other three races all yellower-rumped, *mfumbiri* large and with buff on sides and flanks, *leucolaimus* small and brighter yellow, with even less olive, and *poensis* paler yellow on rump and underparts and with whiter breast. **VOICE.** Usual song paused popping, series of "pop" notes at c. 3 per second, in sets generally of 2-6, more in some situations, first and last sets with fewest notes; N birds of race *fischeri* substitute "pop-trill" for paused popping, more S individuals of same race employ both songs; occasional nasal "honk", lacking overtones, within popping song; also pure "honk" calls in series, especially at start of and after breeding, also so-called "frog" call "driii-driii", with burry "rrrrrr" perhaps a version of it; also "pop-op" calls in series, sharp "chip" notes, rattling "bdddttt" in interactions, common "zddddd" grating calls with elements at c. 90 per second, and begging "di-di-di". Mechanical signals include wing-fluttering, bill-tapping at or in cavity.

**Habitat.** Forested highlands and lowlands, especially at edges, about clearings, in forest clumps left over after clearing, in thickets, riverine forest, moist parts of drier woods, tree plantations, and gardens. In coastal Kenya, shares forest habitat with *P. simplex*, more open wooded habitats with *P. pusillus*; in C & W Africa less often in dense forest than is smaller *P. subsulphureus*, but occurs with it and with *P. atroflavus* and *P. scolopaceus*. On Bioko, is a highland species generally occurring above *P. subsulphureus*; elsewhere, may impinge on highland *P. leucomystax* and *P. coryphaeus*. Occurs from sea-level to 1800 m in W Africa, to 2600 m in C Africa and on Bioko (where usually above 800-1000 m), to 3000 m in E Africa, c. 1600 m in Zimbabwe and 600 m in South Africa.

**Food and Feeding.** Fruits essential, including especially mistletoe berries (*Loranthus*, *Tieghemia*, *Sulphurea*, *Viscum*), also *Ficus*, and species of *Allophylus*, *Clausenia*, *Ekebergia*, *Macaranga*, *Maesa*, *Ochna*, *Ocotea*, *Polyscias*, *Prunus*, *Psychotria*, *Trema* and others; insects also taken, including termites, ants, noctuid moths and other Lepidoptera, Homoptera, curculionid and galericid beetles, among others. Discards epicarp of mistletoe berries as fruits eaten, cellulose layer is digested, pectin layer over seeds passes through digestive system and egested with seed; small berries swallowed, regurgitated in courtship feeding. Insects caught by gleanings and flycatching, even in exotic trees. Isolated fruiting trees may be defended by a single bird.

**Breeding.** Nov-Apr in W Africa; all year in Cameroon, Apr-Nov and Jan in Gabon, Congo and Zaïre; May-Jun in Uganda; Jan-Mar and Aug in W Kenya, Mar-Jul and Sept-Jan in coastal Kenya and Tanzania, May-Aug and Nov-Feb (during and after rains) in C Kenya and EC Tanzania; Apr-May and Sept-Dec on Mafia I and Zanzibar; Oct-Jan in Angola to Zambia and Malawi, and eggs in Sept-Dec in South Africa; sometimes 2 broods in a season. Singer erects rump feathers, puffs throat, flicks tail with each note, turns head side to side in almost vertical posture; courtship feeding of up to 32 berries in 25 minutes, sometimes followed by copulation (e.g. 3 times in 25 minutes). Nest, excavated by both adults, 1-10 m up in dead tree, stump, post or dead branch; entrance diameter 2-5 cm, cavity 2-5 cm into branch, 40-100 cm deep, nest-chamber 3-5 cm by 5 cm, lined with wood chips; territory c. 4 ha. Eggs 2-5, usually 3; incubation c. 12 days, by both adults; chicks fed insects at first, later also fruit, at rates of up to 19 feeds per hour; nestlings' faecal material eaten at first by parents, later young present anal area to adult, which then carries away faecal sac, in one instance 12 sacs removed after 38 feeds in 2-hour period; fledging at 17-20 days; few data on post-fledging period, but occurrence sometimes of second brood suggests rapid independence. Up to 4 young fledge; nests parasitized by Least (*Indicator exilis*) and Scaly-throated Honeyguides (*I. variegatus*), and also recorded by Pallid Honeyguide (*I. meliphilus*); 1 tinkerbird pair enlarged cavity entrance apparently to facilitate exit of large young honeyguide.

**Movements.** Resident, and largely sedentary, but dispersal up to 20 km.

**Status and Conservation.** Not globally threatened. Form "*makawai*" officially considered Data-deficient. Widespread, and common throughout range; generally commonest tinkerbird wherever it occurs, although in Liberia far less numerous than *P. subsulphureus*. Adapts to various habitat changes. Despite searches having been carried out, "*makawai*", now thought almost certainly to be variant of present species, not recorded in the 35 years since first discovered, in 1965. Present in several protected areas, e.g. Abuko Nature Reserve (Gambia), Kakamega Nature Reserve (Kenya), Kruger National Park and Mkuzi Reserve (South Africa).

**Bibliography.** Anon. (1998b), Bannerman (1933, 1953), Barlow *et al.* (1997), Bennun (1991), Benson & Benson (1977), Benson & Irwin (1965a, 1965b), Benson *et al.* (1971), Britton (1980), Brosset & Énard (1986), Brown & Britton (1980), Cave & Macdonald (1955), Chapin (1939), Cheke & Walsh (1996), Christy & Clarke (1994), Clancey (1971c, 1985c), Collar & Andrew (1988), Collar & Stuart (1985), Collar *et al.* (1994), Colston & Curry-Lindahl (1986), Day (1981), Dean (2000), Dowsett (1979a, 1980, 1990), Dowsett & Dowsett-Lemaire (1980, 1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Field (1999), Friedmann (1930a, 1978a), Fry *et al.* (1988), Gatter (1997), Ginn *et al.* (1989), Goodwin (1965), Gore (1990), Grimes (1987), Harrison *et al.* (1997), Irwin (1981), Lewis

## 21. Red-fronted Tinkerbird

### *Pogoniulus pusillus*

**French:** Barbion à front rouge **German:** Feuerstirn-Bartvogel **Spanish:** Barbudito Frentirrojo  
**Other common names:** Red-fronted Tinkerbarbet

**Taxonomy.** *Bucco pusillus* Dumont, 1816, Sunday River, east Cape Province.

Forms a superspecies with *P. chrysoconus*, which it meets marginally in Ethiopia and South Africa with no apparent hybridizing; both are also closely related to *P. bilineatus* and *P. subsulphureus*, and perhaps fairly close to *P. atroflavus*. Populations to E and S of L Victoria formerly separated as race *eupterus*. Three subspecies currently recognized.

**Subspecies and Distribution.**

*P. p. uropygialis* (Heuglin, 1862) - Eritrea and N & C Ethiopia to N Somalia.

*P. p. affinis* (Reichenow, 1879) - SE Sudan, SE Ethiopia and S Somalia S to SE Tanzania.

*P. p. pusillus* (Dumont, 1816) - S Mozambique and E South Africa.

**Descriptive notes.** 9.5-11.5 cm; 6-12.5 g. Tiny, short-tailed tinkerbird with black, gold-yellow and white streaky and spotted pattern, and red forehead. Both sexes of nominate race with golden wing-covert patch coalescing with golden-yellow edges to flight-feathers; yellowish streaks on back, yellow rump; throat yellow, rest of underparts light olive-greyish with yellow tinge. Distinguished from very similar *P. chrysoconus* by red forehead. Immature lacks red patch on head. Race *affinis* smaller than nominate, is less gold with more of a yellow wingbar (not patch), white-streaked rather than yellow-streaked above, with more orange-red

forehead, occasional red tips to rump feathers, whiter throat; *uropygialis* close to *affinis*, but yellower streaks dorsally, still less gold in wings, and frequently shows red in rump. **VOICE.** Song slow "pop" notes unbroken by pauses, to 20 minutes at 109-140 per minute in S Africa, generally 110-130 but also 45-200 per minute in Kenya; also trills in series, often starting with 1 note as singles, to double notes, then up to 8 notes in a set, "pip-ip-ip-ip"; low "wee" note after courtship feeding; other calls include interactive grating series with 60-180 elements per second, piping that is high-pitched and faster than comparable calls of *P. chrysoconus*, when breeding honking nasal series at c. 90 notes per minute and pitched higher than in *P. bilineatus*, and frog-like snore 0.5 seconds long with 90 elements per second. Responds equally to playback of *P. chrysoconus* voice.

**Habitat.** Various dry woodland, bushland, riverine bush in desert, scrubland, cut-over forest and gardens. Invades opened forest as at Arabuko-Sokoke Forest, in Kenya, where meets *P. simplex*. Occurs in more moist woods than does *P. chrysoconus* in S Africa, but in drier bushed areas than that species in Ethiopia. Strong interactions among tinkerbirds, and between this species and larger barbets such as *Tricholaema diademata*, suggest that these barbets impinge on one another. Found from sea-level to 2000 m, even 2200 m where *P. bilineatus* absent, but below 1550 m in Ethiopia.

**Food and Feeding.** Diverse fruits and berries, mainly mistletoe berries (Loranthaceae); also unspecified insects (including beetles) and spiders. Flies directly to food sources, keeping in denser clumps amid sparse vegetation; forages over branches and trunks at times, much as warblers (*Sylvietta*); pecks or taps to get at insects under bark.

**Breeding.** Feb-Sept, occasionally Oct, in N, and Oct-Dec in S. Singer erects rump, throat and red frontal feathers, flips tail at each pop; responds to countersingers with faster song, grating and displaying, swinging head, and chasing off. Nest excavated at 1-6 m in tree such as *Acacia* or *Commiphora*, usually on underside of dead branch, entrance c. 2 cm, chamber to 55 cm deep and 30-50 cm in diameter; territory up to 10 ha, territories not always abutting, nor occupied every year, defended against *P. chrysoconus* as well as own species, but can overlap with *P. bilineatus* territory and even using same songposts at different times. Eggs 2-4, usually 3; both sexes incubate, period c. 12 days, and feed nestlings as well as carry away faecal material; nestling period c. 23 days.

**Movements.** Some movements suggested by disappearance from some sites after breeding; in uplands numbers fluctuate from year to year.

**Status and Conservation.** Not globally threatened. Common in most of range; fairly common in Kenya. The commonest tinkerbird along with *P. chrysoconus* and *P. bilineatus*. More precise data on habitat requirements are needed. Present in several reserves, e.g. Awash National Park (Ethiopia), Mikumi National Park (Tanzania) and Mkuzi Reserve (South Africa).

**Bibliography.** Archer & Godman (1937-1961), Ash & Miskell (1998), Benson (1946), Britton (1980), Brown & Britton (1980), Cave & Macdonald (1955), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Friedmann (1930a, 1930b), Fry *et al.* (1988), Ginn *et al.* (1989), Harrison *et al.* (1997), Heuglin (1861), Jackson & Selater (1938), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957, 1962), Maclean (1993), Miskell (1989), Monadjem *et al.* (1994), Ross (1970), Schmidl (1982), Short & Horne (1985a, 1988b), Short *et al.* (1990), Skead (1944, 1945), Smith (1957), Snow (1978, 1979), Steyn (1996), Tarboton (2001), Ward (1989), Zimmerman *et al.* (1996), Zinner (2001).

## 22. Yellow-fronted Tinkerbird

### *Pogoniulus chrysoconus*

**French:** Barbion à front jaune **German:** Gelbstirn-Bartvogel **Spanish:** Barbudito Frentigualdo  
**Other common names:** Yellow-fronted Barbet(!)/Tinkerbarbet

**Taxonomy.** *Bucco chrysoconus* Temminck, 1832, Senegal.

Forms a superspecies with *P. pusillus*, overlapping very narrowly in Ethiopia and E South Africa and apparently not hybridizing; both are also closely related to *P. bilineatus* and *P. subsulphureus*, and perhaps fairly close to *P. atroflavus*. Proposed races *schubotzi* (WC Niger to SW Sudan), *zedlitzii* (E Sudan) and *centralis* (NE Zaire and Uganda) regarded as synonyms of *chrysoconus*; *schoanus* (C Ethiopia) included in *xanthostictus*; and *rhodesiae* (SW Zaire to Malawi) and *mayri* (S Zaire to NE Angola) in *extoni*. Three subspecies currently recognized.

**Subspecies and Distribution.**

*P. c. chrysoconus* (Temminck, 1832) - SW Mauritania and Senegal E to NW Ethiopia, S to N edge of forest in C Cameroon, N & NE Zaire, Burundi and NW Tanzania.

*P. c. xanthostictus* (Blundell & Lovat, 1899) - highlands of C & S Ethiopia.

*P. c. extoni* (E. L. Layard, 1871) - Angola and S Zaire E to S Tanzania, S to NC Namibia, N Botswana, Transvaal and S Mozambique.

**Descriptive notes.** c. 10.5-12 cm; 8-20 g. Small, strong-billed, short-tailed tinkerbird with yellow-gold, black and white spotted and striped pattern, and yellow to orange forehead. Both sexes of nominate race with fine black band above bill, golden-yellow (rarely, more orange) forehead, hindcrown streaked white on black; yellowish-white back streaks, yellow wing markings; lemon-yellow throat and breast. Distinguished from very similar *P. pusillus* by forehead colour. Immature lacks yellow patch on black forehead. Race *xanthostictus* has smaller forehead patch, narrower white streaks on crown, green-yellow dorsal

streaks, more gold in wings, is paler yellow with greenish tinge below; *extoni* larger, with broader black band in front of orange to gold frontal patch, and greyer underparts than N races. **VOICE.** Nearly identical to *P. pusillus*; song long series of "pop" notes (occasional "honk" notes interjected) at 80-120 per minute for up to 11 minutes; piping trills of 5-8 notes per second for up to 20 seconds, also variable multiple piping trills each 1 second long and having 2-15 notes (either trill can switch to popping song, or used in response to latter); intermediate piping-popping calls also occur; common interactive call a grating "dddzzh", intense interactions marked by fast, very high-pitched barrage of grating calls longer and slower than in *P. pusillus*; also single "dit" notes in loose series. Loud wing-fluttering during interactions.

**Habitat.** Occupies dry scrub, Sahelian woodland and wooded grassland, and riverine woods; also montane evergreen forest in Ethiopia; also found around pasture and remnant forest patches. Woodlands include those with *Acacia*, *Brachystegia*, *Combretum*, *Terminalia* and other trees. Occurs from sea-level up to c. 1500 m, but up to 1800 m in Malawi, and in Ethiopia above *P. pusillus* at 1600-3000 m.

**Food and Feeding.** Diverse fruits, especially mistletoe berries, figs, fruits of *Uapaca nitida*; fruit stones are regurgitated. Also flycatches for diverse insects, including beetles, and gleans for their larvae in foliage and on branches at all levels. Feeds alone or in pairs; very aggressive towards other tinkerbirds and small barbets. Joins mixed-species foraging flocks.

**Breeding.** May-Aug and Dec in Gambia and Mali, Feb-Nov in Nigeria; Mar-Oct in Sudan, Ethiopia and Uganda; Sept-Dec in W Kenya, Mar-Jun and Oct-Nov in Zaire; Aug-Jan, also May, in Zambia, Zimbabwe, Angola and South Africa. Male sings with forehead and rump feathers erected, tail flicked in time with notes; encounters with much wing-fluttering, erected frontal patch, side-to-side swinging with head high, emphasizing throat, or head low, emphasizing forehead patch, and may cock tail. Nest excavated 2-5 m up in dead stub or branch, often on underside, in tree such as fig, frangipani, *Acacia* or *Terminalia*, entrance c. 2 cm. Eggs 2-3; incubation by both parents, for c. 12 days; both adults feed young, which egest fruit stones inside nest; nestling period c. 3 weeks.

**Movements.** Generally resident; some seasonal movement suspected in Nigeria.

**Status and Conservation.** Not globally threatened. Widespread, and common; locally common in W Kenya. Along with *P. pusillus* and *P. bilineatus* is the commonest tinkerbird. In some woodland areas, densities may reach up to 30-35 pairs/km<sup>2</sup>. Seems to be fairly adaptable. Present in numerous national parks, e.g. W (Niger), Comoé (Ivory Coast), Bénoué (Cameroon), Murchison Falls and Lake Mburo (Uganda), Akagera (Rwanda), Ruvuvu (Burundi) and Mikumi (Tanzania).

**Bibliography.** Bannerman (1933, 1953), Barlow *et al.* (1997), Bates (1930), Benson & Benson (1977), Benson *et al.* (1971), Britton (1980), Brown & Britton (1980), Cave & Macdonald (1955), Chapin (1939), Cheke & Walsh (1996), Clancey (1974a), Cocker (2000), Curzon & Curzon (1996), Dean (1974a, 2000), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Friedmann (1930a, 1930b, 1978a), Fry *et al.* (1988), Ginn *et al.* (1989), Giraudeau *et al.* (1988), Gore (1990), Grimes (1987), Harrison *et al.* (1997), Horne & Short (1988), Irwin (1981), Lewis & Pomeroy (1989), Lippens & Wille (1976), Liversidge (1991), Louette (1981b), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Milstein (1995), Monadjem *et al.* (1994), Penry (1994), Pinto (1983), Ross (1970), Short & Horne (1985a, 1988b), Short *et al.* (1990), Snow (1978, 1979), Tarboton (2001), Thiollay (1985a), Zimmerman *et al.* (1996).

## Genus *BUCCANODON* Hartlaub, 1857

### 23. Yellow-spotted Barbet

#### *Buccanodon duchaillui*

**French:** Barbican à taches jaunes **German:** Gelbfleck-Bartvogel **Spanish:** Barbudo Pintado  
**Other common names:** (Duchaillu's) Yellow-spotted Tinkerbird/Barbet

**Taxonomy.** *Barbatula Duchailui* Cassin, 1855, Moonda River, Gabon.

Genus related both to *Pogoniulus* and to *Tricholaema*; larger than former, similar in size to latter but lacks bill "teeth", and vocally distinct from both genera. No close relatives. Birds from S Congo described as race *gabrielae*, but now considered indistinguishable; populations at higher elevations are larger, but insufficient difference to warrant any racial separation. Monotypic.

**Distribution.** Sierra Leone and Guinea E to Ghana; and SW Nigeria E to W Kenya, and S to Cabinda (N Angola), C Zaire, W Rwanda and NW Tanzania.

**Descriptive notes.** 15.5-17 cm; 37-50 g. Larger and chunkier than a tinkerbird. Both sexes glossy black, with yellow spots above and, below black upper breast, yellow and black barring to undertail area; distinctive orange-red forehead and forecrown, and yellow supercilia; orbital skin black, bill black. Immature lacks red on head, has pinkish orbital skin, and yellow bill with dark tip. Voice. Distinctive purring "brrrr-t" of up to 3 seconds, notes at 38-45 per second, in loose series to 30 minutes, up to 5 songs per minute; possibly also soft hooting song (Ivory Coast), nearly as in *Tricholaema hirsuta*; also grating calls to 0.5 seconds, and soft "bdaa-aa-" calls, during encounters.

ing calls, with nasal version, chattering "chchch" all during encounters.

**Habitat.** Inhabits forest, including old secondary forest, forest patches, edges, overgrown clearings and tree plantations; also in riverine forest with surrounding forest. Occurs from lowlands up to c. 2250 m.

**Food and Feeding.** Eats many small fruits, such as those of *Allophylus*, *Ficus*, *Heisteria*, *Musanga* and *Vismia*, and oil palm (*Elaeis guineensis*) nuts; also insects such as termites, and snails. Clings, grasps thin branchlets, gleans fruits or insects; small figs taken at 3 per minute; occasionally flycatches. Forages at heights of 8-30 m. Sometimes congregates in groups of up to 12 at trees laden with ripe fruits, where attacked by species of *Gymnobucco*. Joins mixed-species foraging flocks.

**Breeding.** Aug-Apr in Liberia, Ivory Coast and Ghana; Nov-Mar and May-Jun in Nigeria; probably all year in Cameroon and Gabon (especially Jan-Sept), Feb-Sept in Zaire; Aug-Mar in Uganda and W Kenya. Singer appears as fluffy ball, tail projecting, then leans head forward, points bill down in "bow", erects head and rump feathers, sings, then resumes upright posture; responds to playback of song with rapid wing-flicking, tail-twitching, intense peering. Nest in cavity, once 15 m up, but no other information; territory c. 10 ha in Gabon. Clutch size, incubation and fledging periods, and other details of breeding, undescribed.

**Movements.** Resident and sedentary; moves only locally to fruiting trees.

**Status and Conservation.** Not globally threatened. Reasonably common; in Sierra Leone, common in E but less so in W; local and uncommon in Kenya. Estimated 300,000 pairs in Liberia, where over 10 pairs/km<sup>2</sup>, and as many as 3 males singing in 16-ha forest patch. Generally, however, does not persist in small patches of forest, disappears as forest becomes fragmented. Relatively little-known species; additional information is required in relation to its habitat and breeding requirements, and its breeding biology. Occurs in several protected areas, e.g. Tai Forest National Park (Ivory Coast), Korup and Mount Kupé National Parks (Cameroon) and Kakamega Nature Reserve (Kenya).

## Genus *TRICHOLAEMA*

J. Verreaux & E. Verreaux, 1855

### 24. Hairy-breasted Barbet

#### *Tricholaema hirsuta*

**French:** Barbican hérissé **German:** Fleckenbartvogel **Spanish:** Barbudo Hirsuto  
**Other common names:** Hairy-breasted Toothbill; Spot-headed Barbet (*flavipunctata*)

**Taxonomy.** *Pogonias hirsutus* Swainson, 1821, Ghana.

No close relatives. Exact delimitation of races difficult owing to intergradation: nominate and race *flavipunctata* hybridize over an extensive zone, roughly from Ghana to S Nigeria; proposed races *hybrida* (Niger Delta) and *chapini* (SE Cameroon E to C Zaire) considered indistinguishable from, respectively, nominate and *ansorgii*. Four subspecies currently recognized.

#### Subspecies and Distribution.

*T. h. hirsuta* (Swainson, 1821) - Sierra Leone E to SC Nigeria (Niger Delta).

*T. h. flavipunctata* J. Verreaux & E. Verreaux, 1855 - from at least SE Nigeria through Cameroon (except SE) to C Gabon.

*T. h. ansorgii* Shelley, 1895 - SE Cameroon E to W Kenya, S to E Congo, C Zaire and NW Tanzania.

*T. h. angolensis* Neumann, 1908 - S Gabon and S Congo S to NW Angola and S Zaire.

**Descriptive notes.** 17-18 cm; 43-63 g. Yellow, blackish and white forest barbet. Male nominate race black above with yellow spots, yellow edges to wing feathers; white superciliary and sub-moustachial marks; throat black, throat and breast feathers with hair-like tips, rest of underparts yellow with black spots. Differs from *Buccanodon duchaillui* in head pattern, no red on crown, larger bill. Female differs from male in more golden markings above, brighter tone below; white tips to feathers of chin and throat. Immature pale-billed, duller, with lax plumage, lacks adult's "tooth" on bill. Race *flavipunctata* with head spotted and lacking

white stripes, browner above, brown markings below; *ansorgii* dark-headed with very narrow white facial stripes, streaked white chin and throat, yellow spots onto nape or crown, and brown-black ground colour above and markings below; *angolensis* like *flavipunctata* but browner, overall dull and not cleanly patterned, crown brownish, face with pale streaky spots, brownish-white throat with darker bars, vaguely brown markings below. Voice. Song a series of "oop" or "oork" notes at c. 1 per second for up to 20 seconds, but varies, may be short with fast notes, perhaps averages faster in nominate race; also a croaking "oo-o-o-oork", interactive grating calls, and "wuk" notes. Wipes bill audibly and flips wing during encounters.

**Habitat.** The most forest-adapted *Tricholaema*. Inhabits lowland primary and adjacent dense secondary forest and edges, infrequently riverine forest. Usually below 1000 m, reaching 1800 m in W Uganda.

**Food and Feeding.** Fruits and arthropods: eats berries, and drupes of such plants as *Ficus*, *Morinda*, *Musanga*, *Pachypodanthium*, *Pycnanthus*, *Rauwolfia*, *Solanum* and *Trema*; also beetles, lepidopteran larvae and others. Insect prey larger than that taken by *Buccanodon duchaillui*. Probes into lichens, mosses and bark crevices, hovers at times to seize insect or fruit; often smashes insect against bark to remove limbs. Feeds mainly above 20 m, sometimes lower, occasionally pursuing insects through undergrowth. At fruiting trees rarely in numbers; aggressive to smaller *Buccanodon duchaillui* and tinkerbirds, also small woodpeckers, but submissive to social *Gymnobucco bonapartei*. Sometimes joins mixed-species foraging flocks.

**Breeding.** Aug-Feb, possibly from Jun. in W Africa; Apr-May in Cameroon, Feb-Mar in Gabon and Congo, most months in Zaire; Feb-Jul and Sept in Uganda and W Kenya. Both sexes sing throughout year, singer spreads hair-like breast feathers apron-like, puffs throat, erects rump feathers and turns head from side to side; gliding flight displays with wings fixed. Nest and eggs inadequately described; seen at holes high in trees, and 1 nest in Sierra Leone c. 30 m up in underside of sloping branch; territory estimated at 13-20 ha in Liberia, 5-10 ha in W Kenya. Possibly parasitized by Least Honeyguide (*Indicator exilis*).

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. Population in Liberia estimated at 250,000 pairs; not uncommon but very local in Sierra Leone; rare in Kenya. Appears to be rather strictly tied to intact, large forest blocks, more so than is *Buccanodon duchaillui*. Poorly known species; study required of its ecology and breeding behaviour. Occurs in several protected areas, e.g. Gola Forests Reserves (Sierra Leone), Tai Forest National Park (Ivory Coast), Korup National Park (Cameroon) and Kakamega Nature Reserve (Kenya).

**Bibliography.** Allport *et al.* (1989), Bannerman (1933, 1953), Barlow *et al.* (1997), Bates (1930), Britton (1980), Brosset & Énard (1986), Cave & Macdonald (1955), Chapin (1939), Chappuis (1981), Cheke & Walsh (1996), Christy & Clarke (1994), Colston & Curry-Lindahl (1986), Dean (2000), Dowsett (1989b), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Field (1999), Fry *et al.* (1988), Gartshore (1989), Gatter (1997), Grimes (1987), Jackson & Selater (1938), Lewis & Pomeroy (1989), Lippens & Wille (1976), Louette (1981b), Mackworth-Præd & Grant (1957, 1962, 1970), Morel & Morel (1990), Pinto (1983), Serle (1950, 1965), Short & Horne (1985a), Short *et al.* (1990), Snow (1978), Thiollay (1985a), Zimmerman *et al.* (1996).

### 25. Red-fronted Barbet

#### *Tricholaema diademata*

**French:** Barbican à diadème **German:** Diadembartvogel **Spanish:** Barbudo Diademado

**Taxonomy.** *Pogonorhynchus diadematus* Heuglin, 1861, Upper White Nile, Ethiopia.

Forms a superspecies with *T. frontata* and *T. leucomelas*, and all three have in the past been considered conspecific; all respond strongly to playback of each other's song. Fairly closely related also to *T. lacrymosa*. Races weakly differentiated; birds from NE Uganda E to Mt Kenya, described as race *musta*, now considered inseparable from nominate. Two subspecies currently recognized.

#### Subspecies and Distribution.

*T. d. diademata* (Heuglin, 1861) - SE Sudan and NC Ethiopia S to SE Uganda and C Kenya.

*T. d. massaica* (Reichenow, 1887) - SC Kenya S to SW & C Tanzania.

**Descriptive notes.** 16-17 cm; 22-25 g. Small, short-tailed barbet with black, white and yellow plumage, prominent notch on bill tomtia. Male of nominate race has red forehead, yellow supercilia, white throat, yellow streaks on back, yellow rump; whitish below, with few blackish spots on flanks. Distinguished from *T. leucomelas* by whitish, not black, throat and upper breast; from similar *Pogoniulus pusillus* by larger size, differences in head pattern. Female averages less red on forehead. Immature duller, with lax plumage, red on forehead smaller or lacking, no "tooth" on bill. Race *massaica* differs from nominate in having, on average, more spots or spot-streaks ventrally, though variation great. Voice. Primary song slow to fast series of up to 20 "hoop" notes, usually 4-6 per second; fast "hoop" songs by paired birds mark early breeding season; secondary song "nyah" or "yeah" notes given singly or in series at 1-1.5 per second; occasionally "nyah" notes interjected into "hoop" song; interactive, chattery, fast "yeh" notes in series; also grating "chaaa" calls, low "di-di-" notes, higher "tik-tik-" calls. Also wing-rustling.

**Habitat.** Occupies woodland such as *Acacia* and *Combretum* woods, but also wooded grassland and pastures with bushes; generally found in drier situations than is *T. lacrymosa*, and in more moist sites than those favoured by *T. melanocephala*. Occurs at 600–2100 m.

**Food and Feeding.** Eats fruits such as those of *Carissa edulis*, *Euclea*, *Grewia* and others, also tendrils of vines and thistle-like seeds; in addition, in captivity, will feed on foods such as lettuce, apples and carrots; also takes insects, including termites, grasshoppers and ants, and captives accepted egg yolk, fly maggots, mealworms and locusts. Egests pellets of fruit stones, seeds and insect parts. Gleans from branches and foliage; goes to ground to take termites, and also breaks into tunnels on trees to eat them.

**Breeding.** Jan–Sept in most areas, also Nov–Mar in N Tanzania. Singing posture with bill pointing down, rump and throat feathers erected; crown and forehead feathers erect during encounters; aerial display by male to female, but little or no display before copulation. Nest, excavated by both adults, at 1–8 m in stub or branch of tree, euphorbia or sisal stem; territory large, with irregular borders, size uncertain. Eggs 2–4; incubation period uncertain, over 12 days, individual sessions of up to 3 hours, off-duty adult guards nest; adults tap, perhaps enlarging chamber, while incubating; chicks fed by both adults, at intervals of 5–30 minutes, nestling period c. 28 days; young leave territory c. 2 months after fledging. Nests parasitized by Lesser Honeyguide (*Indicator minor*).

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. Uncommon in Kenya and N Tanzania. Numbers seem to be stable. Species is somewhat adaptable, as it frequents degraded habitats that retain potential nesting and roosting sites. Range sometimes reported as extending to NW Somalia, but this requires confirmation. Occurs in several protected areas, e.g. Lake Nakuru National Park (Kenya) and Serengeti National Park (Tanzania).

**Bibliography.** Benson (1946), Britton (1980), Brown & Britton (1980), Cave & Macdonald (1955), Clancey (1984b), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), England (1973a), Friedmann (1930a, 1930b), Friedmann & Loveridge (1937), Fry *et al.* (1988), Grant & Mackworth-Præd (1946), Jackson & Schiater (1938), Lewis & Pomeroy (1989), Mackworth-Præd & Grant (1957), Rutgers & Norris (1977), Schmidt (1982), Short & Horne (1985a, 1988b), Short *et al.* (1990), Snow (1978), van Someren (1956), Stevenson & Fanshawe (2001), Taylor (1983), Vincent (1946), Zimmerman *et al.* (1996).

## 26. Miombo Pied Barbet

### *Tricholaema frontata*

**French:** Barbican du miombo **German:** Miombobartvogel **Spanish:** Barbudo del Miombo  
**Other common names:** Miombo Barbet

**Taxonomy.** *Pogonorhynchus frontatus* Cabanis, 1880, Angola.

Forms a superspecies with *T. diademata* and *T. leucomelas*, and all three have in the past been considered conspecific; all respond strongly to playback of each other's song. Known to hybridize occasionally with *T. leucomelas* in S Zambia. Fairly closely related also to *T. lacrymosa*. Monotypic.

**Distribution.** S Zaire to SW Tanzania and S to C Angola, S Zambia and W Malawi.

**Descriptive notes.** c. 16 cm; c. 25 g. Black, white and yellow barbet. Both sexes have red spot in central part of forehead, pale yellow supercilia, brown ear-coverts, brown bill, and scaly malar area; nape is spotted white, upperparts black with yellow spots; breast yellow, rest of underparts whiter, all usually with black spotting. Distinguished from *T. leucomelas* by very spotted underparts, lack of black throat patch; hybrids are intermediate. Immature lacks red on crown, has no "tooth" on bill. **VOICE.** Primary song 6–30 "hoop" notes at c. 2 per second, songs at 3–5 per minute; secondary "nyeh" song or call,

singly, or in series of up to 12 notes at 1–1.5 per second, notes shorter than in *T. diademata*; also grating calls, and "yeh" calls in interactions, and 2 calls of young when begging. Loud wing-rustling during interactions.

**Habitat.** Inhabits woodland, usually of *Brachystegia*; generally found in more wooded habitats than *T. diademata* and *T. leucomelas*, but occurs in some degraded woodland patches and clearings in Zambia and also patchy woods in Angola. Generally observed at 500–1100 m, but at 900–1520 m in Malawi.

**Food and Feeding.** Eats fruits and insects, but diet not known in detail. Certainly takes figs, and consumes some termites and beetles; possibly takes nestling birds or bird eggs. Inconspicuous, usually solitary, gleans in leaf clusters and on bark; flycatches occasionally. Drives away foraging *Pogonius chrysocornis*.

**Breeding.** Sept–Dec, rarely Jul–Mar. Male sings with throat puffed, bill down, turning head side to side. Nest 1–15 m up in dead branch, often on underside, of tree such as *Brachystegia* or *Acacia polyacantha*; hole dug horizontally to c. 7.5 cm, then vertically to as much as 30.5 cm; territory c. 10 ha. Eggs 2–3; incubation and nestling periods unknown; both adults provision young, at 2–10 feeds per hour, insects fed at first, with fruits predominating later on; adults remove faecal material regularly.

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. No data on numbers, but appears to be locally common. Populations presumably becoming more fragmented with continuing clearance of woodland. More information needed on species' ecology and breeding biology, as well as on its numerical status.

**Bibliography.** Anon. (1998a), Aspinwall & Beel (1998), Belcher (1930), Benson & Benson (1977), Benson *et al.* (1971), Britton (1980), Chapin (1939), Dean (2000), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Fry *et al.* (1988), Johnston-Stewart & Heigham (1982), Mackworth-Præd & Grant (1962, 1970), Pearson (1983), Pedersen (2000), Pinto (1983), Ripley & Heinrich (1966), Short & Horne (1985a, 1988b), Short *et al.* (1990), Snow (1978), Stevenson & Fanshawe (2001), Traylor (1960, 1965).

## 27. Acacia Pied Barbet

### *Tricholaema leucomelas*

**French:** Barbican pie **German:** Rotstirn-Bartvogel **Spanish:** Barbudo Pío  
**Other common names:** Pied Barbet

**Taxonomy.** *Bucco leucomelas* Boddaert, 1783, Cape of Good Hope.

Forms a superspecies with *T. diademata* and *T. frontata*, and the three have in the past been treated as conspecific; all respond strongly to playback of each other's song. Occasionally interbreeds with *T. frontata* in S Zambia. Fairly closely related also to *T. lacrymosa*. Species name sometimes erroneously spelt *leucomelan*, *leucomelaena* or *leucomelaina*, but original *leucomelas* must stand, as being non-Latinized Greek. Proposed race *namaqua* (W South Africa) included within *leucomelas*, *nkatiensis* (N Botswana) within *centralis*, and *zuluensis* (SE Zimbabwe S to Natal) within *affinis*. Three subspecies currently recognized.

**Subspecies and Distribution.**

*T. l. centralis* (Roberts, 1932) – Angola, extreme SW Zambia and W Zimbabwe, S to S Namibia, N Cape Province and W Natal.

*T. l. affinis* (Shelley, 1880) – E Zimbabwe and SW Mozambique, S to E Cape Province, E & N Lesotho and N Natal.

*T. l. leucomelas* (Boddaert, 1783) – C, S & SW Cape Province.

**Descriptive notes.** c. 17 cm; 23–45 g. Small, chunky, black, yellow and white barbet. Both sexes of nominate race with red forehead, yellow-white supercilia, and black chin, throat and upper breast; upperparts brownish-black with yellow spots and streaks, rump yellow, wings brown; belly whitish, flanks washed yellow, usually some black spots below. Distinguished from *T. diademata* and *T. frontata* by black throat and upper breast; from *Pogonius pusillus* additionally by larger size. Immature like adult but duller, with lax plumage, no red on head, no "tooth" on bill. Race *centralis* blacker, less brown, than nominate,

often lacking ventral spots; *affinis* usually more yellowy white below than *centralis*, more spotted and even streaked black below than nominate. **VOICE.** Main vocalizations, "hoop" and "nyah" series, nearly identical to those of *T. frontata* and *T. diademata*, with "hoop" song slightly faster than in former and slower than in *T. diademata*.

**Habitat.** Woodland, including *Acacia* and *Baikiaea* woods, especially where open, also streamside woods, scrubland, gardens, farms, parks, even in exotic wattle (*Acacia*) plantings; occurs in deserts and parks where suitable nesting trees present. From sea-level or, more usually, 400 m to 1500 m.

**Food and Feeding.** Omnivorous: takes fruits such as those of lantana and *Salvadora persica*, seeds from pods of *Sophora*, occasionally nectar; also suet from feeders; and also various grasshoppers, beetles, wasps and other insects. Forages at all levels in bushes and trees, even isolated trees; will cling or hang to reach fruits.

**Breeding.** As long as Sept–Jun in Angola; farther E & S mainly Aug or Sept–Jan, but Aug–Oct in far SW; sometimes nests 2–4 times in a season. Nests strictly in pairs. Displays involve spreading of forehead and throat feathers, side-to-side swinging of head and body, tail-flicking. Both adults excavate nesting cavity in tree or stump, entrance c. 4 cm, depth to 16 cm or more, base lined with wood chips; occasionally uses old nest of swallow (Hirundinidae). Eggs 1–4, average 2.9 in South Africa; incubation 14–16 days, by both parents; young fed by both adults, which keep nest clean by removal of faecal material, often mixed with wood bits; nestling period 32–35 days; fledglings can feed themselves by 6 days, independent within 2 months.

**Movements.** Resident, and generally sedentary.

**Status and Conservation.** Not globally threatened. No figures on numbers or densities available, but species appears to be common throughout much, if not all, of its range. Reasonably adaptable, and tree-planting activities have been major factor in this species' expansion of range towards SW. Occurs in several national parks, e.g. Etosha and Waterberg Plateau (Namibia), Rhodes Matopos and Hwange (Zimbabwe) and Upington to Augrabies Falls and Kruger (South Africa).

**Bibliography.** Benson *et al.* (1971), Clancey (1958c), Curio (1978a, 1978b), Dean (2000), Dedeckind (1997), Dowsett (1989c), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Earlé & Grobler (1987), Fry *et al.* (1988), Ginn *et al.* (1989), Goodwin (1964), Harrison *et al.* (1997), Herholdt & Earlé (1986), Hoersch (1957), Irwin (1981), Liversidge (1991), Macdonald (1983, 1984, 1986), Mackworth-Præd & Grant (1962), Maclean (1993), Morris (1988), Parker (1999), Peck (1983), Penny (1994), Pinto (1983), Poley (1973), Priest (1934), Rutgers & Norris (1977), Short & Horne (1985a, 1988b), Snow (1978), Steyn (1996), Tarboton (2001), Tarboton *et al.* (1987), Ward (1989), Willows (1989).

## 28. Spot-flanked Barbet

### *Tricholaema lacrymosa*

**French:** Barbican funèbre **German:** Tränenbartvogel **Spanish:** Barbudo Lacrimoso  
**Other common names:** Spotted-flanked Barbet

**Taxonomy.** *Tricholaema lacrymosa* Cabanis, 1878, Athi River, central Kenya.

Closely related to *T. melanocephala*, but the two are considered not close enough to form a superspecies. Apparently quite closely affiliated also with the superspecies that includes *T. diademata*, *T. frontata* and *T. leucomelas*. Species name sometimes misspelt as *lachrymosa*. Races only weakly differentiated; proposed race *narokensis*, from Doinyo Narok (Kenya), included within nominate; birds from EC Tanzania, described as race *ruahae*, now considered inseparable from *radcliffei*. Two subspecies currently recognized.

**Subspecies and Distribution.**

*T. l. lacrymosa* Cabanis, 1878 – NE Zaire to S Sudan and C Kenya, and S to C Uganda and NE Tanzania.

*T. l. radcliffei* Ogilvie-Grant, 1904 – E Zaire and S Uganda to WC Kenya, S to Burundi, NE Zambia and SW Tanzania.

**Descriptive notes.** 13–14 cm; 18–27 g. Small black, white and yellow barbet. Male nominate race with white supercilia, blackish upperparts, brown rump with yellow streaks; wing feathers with yellow edges; chin and throat to central upper breast black, rest of underparts whitish to creamy, flanks with large black spots, undertail-coverts yellowish with black spots; eyes creamy to orange. Distinguished from *T. melanocephala* by unspotted back, spotted flanks. Female like male, except

for brown eyes. Immature duller, without bill 'tooth' of adult. Race *radeliffei* differs from nominate only in having smaller, more circular spots on sides and flanks, and paler iris. VOICE. Song "hoop" notes in series at 1-2 per second, in interactions to 4 per second; also "nya" or "ch" notes in series, grating calls, low double-noted calls, and "wup" or "pop" series. Non-vocal signals include loud wing-rustling during interactions, bill-wiping, and slow signal tapping at nest.

**Habitat.** Inhabits wet woodland, wetter areas in dry woodland, also riverine woods, patches of forest and gardens; found in wetter areas than

is *T. melanocephala*. Occurs at 600-2100 m in Kenya and Tanzania.

**Food and Feeding.** Feeds on fruits of many kinds, e.g. mistletoe (*Loranthus*) berries, *Ficus* and *Cordia*; also takes various types of insect, including ants and beetles; possibly also nectar. Flies rapidly from site to site, working through foliage and moving over branches and trunks, when taking insects.

**Breeding.** Generally Sept-May, or Jul, usually in dry period before or after rains. Usually in pairs, occasionally trios. Male cocks tail, and pair-members call and answer frequently. Nest, excavated by both adults, often on underside of dead branch, or in trunk of dead tree, 2-18 m up, cavity to c. 33 cm deep, nest-chamber 6-7-6 cm, lined with wood chips; interacts strongly with similar-sized hole-nesters, defends cavity against these. Eggs 2-4; both adults incubate and feed young; incubation and nestling periods unknown; adults sleep with young in nest at night. Probably parasitized by Lesser Honeyguide (*Indicator minor*).

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. No information on numbers or densities: locally common in Kenya and Tanzania. Where competition from larger barbets is intense, nests in thin stubs too small for those, thus indicating need for preserving dead trees and stubs for this and similar small species in woodland. Precise limits of range in S require confirmation. Occurs in several protected areas, e.g. Masai Mara Reserve (Kenya), Akagera National Park (Rwanda), Ruvuvu National Park (Burundi) and Tarangire and Ruaha National Parks (Tanzania).

**Bibliography.** Aspinwall (1973), Aspinwall & Beel (1998), Britton (1980), Brown & Britton (1980), Cave & Macdonald (1955), Chapin (1939), Dowsett (1989c), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), England (1977), Friedmann (1930a, 1930b), Friedmann & Loveridge (1937), Fry *et al.* (1988), Gaugris *et al.* (1981), Goodwin (1964), Jackson & Selater (1938), Lewis & Pomeroy (1989), Lippens & Wille (1976), Mackworth-Praed & Grant (1957, 1970), Nikolaus (1987), Ripley & Heinrich (1969), Schouteden (1966), Short & Horne (1985a, 1988b), Short *et al.* (1990), Snow (1978), Stevenson & Fanshawe (2001), Zimmerman *et al.* (1996).

## 29. Black-throated Barbet

### *Tricholaema melanocephala*

**French:** Barbican à tête noire **German:** Schwarzkopf-Bartvogel **Spanish:** Barbudo Cabecinegro  
**Other common names:** African Black-throated Barbet, Brown-throated Barbet; Yellow-cheeked Barbet (*flavibuccalis*)

**Taxonomy.** *Pogonius melanocephala* Cretzschmar, 1826, north Ethiopia.

Closely related to *T. lacrymosa*, but not so close as to form a superspecies. Races moderately distinctive; *flavibuccalis*, known from few NC Tanzanian specimens, sometimes considered a separate species, or a megasubspecies, though it could actually be no more than a morph. Four subspecies currently recognized.

### Subspecies and Distribution.

*T. m. melanocephala* (Cretzschmar, 1826) - N & C Ethiopia, Djibouti and NW Somalia.

*T. m. stigmatothorax* Cabanis, 1878 - SE Sudan, S Ethiopia and S Somalia, S to C Tanzania.

*T. m. blandi* E. L. Phillips, 1897 - CN & NE Somalia.

*T. m. flavibuccalis* Reichenow, 1893 - NC Tanzania (Seronera region and Wembere steppes).

**Descriptive notes.** 12-13 cm; 17-25 g. Small black and white barbet. Both sexes of nominate race with white supercilia, glossy black above with yellow spots and streaks, wing feathers edged yellow; black chin to breast and in band to upper belly, rest of underparts white. Distinguished from *T. lacrymosa* by yellow spots above, no spots below; from various *Pogonius* species by somewhat larger size, black throat. Immature paler, duller, plumage lax, no bill "tooth". Race *stigmatothorax* differs from nominate in lacking gloss on black areas, with head and ventral dark areas browner, less black, and often has orange spot

on lower breast; *blandi* more brown and paler than *stigmatothorax*, has buff to yellow spots on chin, throat, forehead, often also on crown; *flavibuccalis* resembles nominate, but pale head stripes are yellow, centre of back to tail base yellow, and black bib ends on breast, not belly. VOICE. Very vocal, large repertoire: has "kaaa" instead of "hoop" song, and "ptaa" or "ptaw" song-like call, both 3-4 notes long; simultaneous singing occurs, both birds using "kaaa" or one using "ptaw" song; harsh "nyah" calls become grating at times; also rattling calls, chatter calls, single or double "da-dit" calls; "chehchaa" to "chrrr" begging calls, shorter and louder when adult approaches. Fluttering wing sounds accompany interactions, along with grating, rattle-like chatter and "ptaw" calling.

**Habitat.** Very dry woodland, brushland, scrubland, including desert with some cover; in drier areas at lower elevations (to 1820 m) than *T. lacrymosa*. Where co-occurs with latter species, it is found in drier sites, whereas *T. lacrymosa* prefers areas around streamsides.

**Food and Feeding.** Insects, including various larvae, flies and termites; also fruits, as of *Ficus*, *Grewia*, *Salvadora* and *Sanseveria*, and buds of some *Acacia* species. Insects taken by flycatching, hovering, gleaning, and probing along bark and into flowers.

**Breeding.** Feb-Jun in Ethiopia, Somalia, Kenya, Tanzania; also Jul-Aug and Nov-Dec in parts of Kenya and Tanzania. Breeds in pairs, rarely in trios. Singer erects head and throat feathers, perches upright, tail down and twitching in time to notes, and turns head from side to side; interactions marked by much calling, bobbing and swinging of head and body, hair-like tips of spread black ventral feathers hanging as apron over white ones. Nesting cavity often in underside of thin, dead branch, details of nest undescribed; cavity vigorously defended against barbets and woodpeckers throughout year; territory irregular, sometimes linear such as 1 km along streambed in very dry areas. Clutch unknown, estimated at 2-3 from observations of fledged young; usually 1 juvenile seen, or 2 (1 with each parent).

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. No information on numbers, but appears at least locally common; fairly common in Kenya and Tanzania; very uncommon in NE Somalia. May benefit from degradation of more wooded habitats, and from some desertification. Present in several protected areas, e.g. Fôret du Day National Park (Djibouti) and Tsavo East and Tsavo West National Parks (Kenya).

**Bibliography.** Archer & Godman (1937-1961), Ash & Miskell (1983, 1998), Benson (1946), Britton (1980), Brown & Britton (1980), Cave & Macdonald (1955), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Énard (1976), Friedmann (1930a, 1930b), Friedmann & Loveridge (1937), Fry *et al.* (1988), Jackson & Selater (1938), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957), Nikolaus (1987), Rutgers & Norris (1977), Short & Horne (1985a, 1988b), Short *et al.* (1990), Smith (1957), Snow (1978), Stevenson & Fanshawe (2001), Zimmerman *et al.* (1996).

# Genus *LYBIUS* Hermann, 1783

## 30. Banded Barbet

### *Lybius undatus*

**French:** Barbican barré

**German:** Wellenbartvogel

**Spanish:** Barbudo Etíope

**Taxonomy.** *Pogonias undatus* Rüppell, 1837, Simien Province, central Ethiopia.

Not particularly closely related to others of genus; may represent connecting link between genera *Tricholaema* and *Lybius*. Races rather well marked for a species with small range. Proposed races *senafensis* in NE of range, *gardullensis* in W & SW, and *squamatus* in E considered untenable. Four subspecies recognized.

#### Subspecies and Distribution.

*L. u. thiogaster* Neumann, 1903 - far NE Ethiopia and Eritrea.

*L. u. undatus* (Rüppell, 1837) - NW to C Ethiopia.

*L. u. leucogenys* (Blundell & Lovat, 1899) - SC to SW Ethiopia.

*L. u. salvadorii* Neumann, 1903 - SE Ethiopia.

**Descriptive notes.** 16-17.5 cm; 35-5-42 g. Small barbet with red forehead. Both sexes of nominate race with black head, upper mantle and breast, white line behind eye, red forehead; upperparts brown-black with pale edgings, rump barred yellow; underparts below breast evenly barred blackish-brown and white. Differs from *Tricholaema* species in lacking bold head patterning and hair-tipped throat feathers. Immature much duller, lacks or has but trace of red on forehead. Race *leucogenys* has barring uneven in centre of underparts, also very variable, some individuals almost entirely black, and others with patchy white to fully

white head other than forehead, also red or orange on forehead can be present also on face, chin and throat, and belly yellowish or even orange; *salvadorii* like nominate, but wedge-shaped white marks on throat, white spots on sides of neck, wavy barring on breast to belly; *thiogaster* browner than *salvadorii*, with brown wedge-streaks on yellow-white throat, face and breast, and streaky marks from breast to belly. **VOICE.** Only vocalizations reported are "gr-gr-grgr-gr" notes and "tock" or "took" series as song, latter resembling that of *Megalaima haemacephala*.

**Habitat.** Woodland, bushland, and streamside trees, at 300-3040 m.

**Food and Feeding.** Fruits, including figs, and insects, including beetles and cockchafers, have been noted. Flycatches for insects; moves through trees and bushes in foliage and on branches, gleaning insects and fruits, sometimes clinging upside-down, like a tit (Paridae).

**Breeding.** Probably Jan-Jun. Birds encountered in pairs only, likely to be territorial throughout year. Nest a cavity in branch or stub of tree, details not known. Eggs undescribed, and no information on other aspects of breeding.

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. Very poorly known, and few data on populations; thought to be commoner in S of range. Probably competes with similarly sized *L. guifsobalito* and *Tricholaema diademata*, but no available information. Further research required on population numbers, ecology and breeding behaviour.

**Bibliography.** Benson (1946), Cheesman & Sclater (1935), Desfayes (1975), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Francis & Shirihai (1999), Friedmann (1930b), Fry *et al.* (1988), Goodwin (1964), Heuglin (1861), Macdonald (1938), Mackworth-Præd & Grant (1957), Ryan (2001), Shirihai & Francis (1999), Short & Horne (1985a, 1988b), Smith (1957), Snow (1978), Tlahun *et al.* (1996), Urban (1980), Urban & Brown (1971).

## 31. Vieillot's Barbet

### *Lybius vieilloti*

**French:** Barbican de Vieillot

**German:** Blutbrust-Bartvogel

**Spanish:** Barbudo Sangrante

**Taxonomy.** *Pogonius vieilloti* Leach, 1815, Ethiopia.

Not very closely related to congeners, probably closest to the group comprising *L. leucocephalus*, *L. chaplini* and *L. rubrifacies*. Races ill-defined, with some mosaic variation, and clinal variation in colour intensity. Three subspecies recognized.

#### Subspecies and Distribution.

*L. v. buehanani* Hartert, 1924 - S Mauritania and Mali E to S Chad, and S to S Sahel region (E to NC Nigeria).

*L. v. rubescens* (Temminck, 1823) - Sahel fringe from Gambia and Sierra Leone E to C Nigeria, N Cameroon, Central African Republic and NC Zaire, reaching coast from Ivory Coast to Nigeria.

*L. v. vieilloti* (Leach, 1815) - C Sudan and NW Ethiopia S to NE Zaire, S Sudan and W Ethiopia.

**Descriptive notes.** c. 16 cm; 31-43 g. Distinctive red, brown and yellow barbet with strong bill and short-tailed, dumpy appearance. Both sexes of nominate race with red head, blackish back with pale spots, yellow rump and uppertail-coverts; yellow with red spots below; notched bill blackish. Immature duller and much less red, browns greyer, bill paler without notch. Race *buehanani* paler than nominate; *rubescens* averages darker above, with red spots below larger, but very variable. **VOICE.** Song by 1 or 2 of group an "ope-ope-" at intervals of c. 1-4 seconds, others of group chatter; noisy choruses like those of some races of *L.*

*leucocephalus*; also snarling alarm note, soft "cwa" call and interactive "pew" call.

**Habitat.** Wooded grassland, forest-grassland mosaic, open woods, streamside trees, forest edges and cultivation, including plantations and gardens. Occurs from sea-level to c. 1500 m.

**Food and Feeding.** Eats fruits, such as those of *Ziziphus mauritiana*, gourds (*Coccinea grandis*), *Butyrospermum*, mistletoe (*Loranthus*) berries, and figs; also insects, including termites, ants and caterpillars. Feeds in groups, from ground to canopy, in foliage and along bark of branches.

**Breeding.** Apr-Sept generally; also later in year in W (after rains); also Jan in Liberia. Nest excavated in dead branch or stub, often in isolated tree in open, 1-8 m above ground, entrance 3-4 cm; variably sized territory defended throughout year. Eggs 2-3; incubation and fledging periods unknown, and data lacking on most aspects of breeding, including degree of help by group-members other than primary pair.

**Movements.** Resident; largely sedentary, but post-breeding groups sometimes move around beyond usual territory, up to 8 km.

**Status and Conservation.** Not globally threatened. Locally common; common in Sierra Leone; in Liberia, 20-35 pairs/km<sup>2</sup>, with inselbergs cleared for agriculture holding single pairs. Loss of habitat owing to degradation and desertification perhaps offset by new areas being made available to this species by cutting and clearing of forest. Research needed on social aspects of lifestyle, as species often occurs in groups, not only in pairs. Present in several protected areas, e.g. Air et Ténéré National Park (Niger), Ouadi Rimé-Ouadi Achim Reserve (Chad), Dinder National Park (Sudan), Comoe National Park (Ivory Coast), Falgore Reserve (Nigeria) and Bénoué National Park (Cameroon).

**Bibliography.** Allport *et al.* (1989), Bannerman (1933, 1953), Barlow *et al.* (1997), Bates (1930), Cave & Macdonald (1955), Chapin (1939), Cheke & Walsh (1996), Colston & Curry-Lindahl (1986), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Field (1999), Friedmann (1930b), Fry *et al.* (1988), Gatter (1997), Giraudoux *et al.* (1988), Goodwin (1964), Gore (1990), Grimes (1987), Lamarche (1980), Lippens & Wille (1976), Louette (1981b), Mackworth-Præd & Grant (1957, 1970), Morel & Morel (1990), Newby (1980), Nikolaus (1987), Quantrell & Quantrell (1998), Rodwell (1996), Short & Horne (1985a), Snow (1978), Thiollay (1985a).

## 32. White-headed Barbet

### *Lybius leucocephalus*

**French:** Barbican à tête blanche

**German:** Weißkopf-Bartvogel

**Spanish:** Barbudo Cabeciblanco

**Other common names:** White-bellied Barbet (*leucogaster*)

**Taxonomy.** *Laimodon leucocephalus* de Filippi, 1853, White Nile in extreme south Sudan.

Related to *L. chaplini* and *L. rubrifacies*, though not very closely; all three fairly close also to *L. vieilloti*. Races *albicauda* and *leucogaster* have sometimes been considered separate species; former interbreeds with other races wherever they meet, but latter is isolated geographically. Proposed race *usukumae* (SE of L Victoria) possibly recognizable; represents populations intermediate between *albicauda* or *lynesi* and nominate *leucocephalus*. Birds from N Tanzania described as race *parensis* considered inseparable from *albicauda*. Six subspecies currently recognized.

#### Subspecies and Distribution.

*L. l. adamauae* Reichenow, 1921 - N & C Nigeria E to S Chad, W Central African Republic and NW Zaire.

*L. l. leucocephalus* (de Filippi, 1853) - possibly E Central African Republic, and S Sudan and NE Zaire to NW Tanzania and WC Kenya.

*L. l. senex* (Reichenow, 1887) - C & SC Kenya.

*L. l. albicauda* (Shelley, 1881) - SW & S Kenya to N Tanzania.

*L. l. lynesi* C. H. B. Grant & Mackworth-Præd, 1938 - C Tanzania.

*L. l. leucogaster* (Bocage, 1877) - highlands of SW Angola.

**Descriptive notes.** 18-19.5 cm; 45-81 g. Distinctive large-bodied, white-headed barbet with much white elsewhere in plumage. Both sexes of nominate race white, apart from blackish back and tail, brown lower breast and belly with white streaks, and blackish wings, latter spotted white; black bill with large "tooth". Immature with lax plumage, more grey or brown in white areas of adult, bill paler with "tooth" obscure or absent. Race *adamauae* like nominate, but ventral brown-black restricted to lower down belly and flanks, underwing-coverts white, spotted with black; *albicauda* with tail mainly white (very base may be

brown), belly and flanks blackish-brown with white spots, underwing-coverts dull black with white streaks; *senex* all white below, wings and back more brown, with white of wing limited to scapulars; *lynesi* like *albicauda*, but less blackish-brown on belly and flanks, tail base brown-black; *leucogaster* resembles nominate and *adamauae*, but with only white in wings being on inner wing-coverts, and no black on underparts. **VOICE.** Group "greeting ceremonies" with and without ensuing song, varying racially, with chirping, chattering usually by pair only in *senex*, noisy slower notes in *albicauda*, clearer, more melodic notes in *leucocephalus*, similar but faster and lower-pitched in *adamauae*; "duet" portion of chorus not synchronous, songs more or less simultaneous; also grating calls, low "pew" notes, chatter and rattle calls (with loud versions used against honeyguides), "kerr-rek" call, and "pzheeeet" call. Mechanical signals are loud wing-rustling, comb-scraping like bill-wiping, and tapping or side-to-side whacking of bill against cavity entrance.

**Habitat.** Open woodland, streamside trees, bushland with trees, open areas with fig or other fruiting trees, cultivated areas and gardens; often near water. Usually above 600 m, to 2300 m.

**Food and Feeding.** Diverse fruits, including cultivated guavas and others, and figs, Cape lilac, and berries; also insects, including termites, flies, ants and others. Groups fly to fruit trees, also individually work over bark of trees and foliage, though clumsy. Opens tunnels of arboreal termites; takes dung beetles on ground at times, although usually a bird of the canopy.

**Breeding.** Feb-Jun in N, also Aug-Dec in Kenya (before and after rainy seasons), Sept-Feb in Angola, Dec-Mar in parts of Tanzania and Uganda, Oct-Nov in Cameroon. Nests in groups of up to 8, but pair may prevent "helpers" from roosting in nest. Elaborate greeting calls, songs, tapping at nest, courtship feeding by male, floating flight displays, bobbing, wing-flicking and other displays. Nest excavated in fig, jacaranda or other soft-wooded tree, 5-20 m up in dead branch, often on underside of branch; opening narrow; excavation slow or rapid, at times completed in c. 10 days. Eggs 2-4; incubation 15-21 days, all adults participating, change-overs frequent; hatchlings fed directly or by regurgitation, at up to 15 times per hour; nestling period unknown; fledglings quickly learn to feed themselves, adults may vacate nest and allow young to roost alone in it. Usually 2

young fledge; nest parasitized by Lesser Honeyguide (*Indicator minor*), which often disrupts choruses and activities around nest, despite guarding barbet, and at times delays or disrupts breeding. **Movements.** Resident; usually sedentary, but wandering occurs; vagrant to near sea-level in Kenya. **Status and Conservation.** Not globally threatened. Uncommon in Nigeria; locally fairly common in Kenya and Tanzania. Relatively adaptable, nests in modified habitats so long as they still contain fruiting trees for foraging and dead limbs for nesting. Present in several protected areas, e.g. Murchison Falls National Park (Uganda), Masai Mara Reserve and Nairobi National Park (Kenya), and Tarangire National Park (Tanzania). Angolan race *leucocephalus* is restricted in range, and should be monitored. **Bibliography.** Bannerman (1933, 1953), Britton (1980), Brooke (1970), Brown & Britton (1980), Cave & Macdonald (1955), Chapin (1939), Dean (2000), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Friedmann (1930a), Fry *et al.* (1988), Jackson & Sclater (1938), Lewis & Pomeroy (1989), Lippens & Wille (1976), Louette (1981b), Mackworth-Præd & Grant (1957, 1962, 1970), Nikolaus (1987), Pinto (1973, 1983), Short & Horne (1979, 1982b, 1983a, 1985a, 1988b), Short *et al.* (1990), Snow (1978), van Someren (1956), Stevenson & Fanshawe (2001), Zimmerman *et al.* (1996).

### 33. Chaplin's Barbet

#### *Lybius chaplini*

**French:** Barbican de Chaplin **German:** Feigenbartvogel **Spanish:** Barbudo de Chaplin

**Taxonomy.** *Lybius chaplini* S. R. Clarke, 1920, Kafue River, Zambia. Related to *L. leucocephalus* and to *L. rubrifacies*, and all three fairly close also to *L. vieilloti*. Monotypic.

**Distribution.** SC Zambia, in area between Kafue Park and Moshi in W, E to Lusaka.

**Descriptive notes.** c. 19 cm; 64-75 g. Both sexes white, with blackish wings and tail, and red face; wings edged yellow; bill prominently notched. Differs from *L. leucocephalus* in having red and yellow in plumage. Immature duller, without red, and paler, bill lacking or with just trace of 'tooth'. **Voice.** Conspicuous greeting chorus with buzzy, grating notes, nasal "put-ut-ut-" and audible bill-snapping, sometimes leading into duet by 2, occasionally 3, of the group, the song a noisy cackle that speeds up, resembles that of *L. rubrifacies* but sets of notes less precise; also "snip-et" calls in aggression, squawking "yekka-yek-

awk" calls at honeyguides (*Indicator*), "chough" calls, soft "wup" notes. Bill-tapping at nest entrance during change-overs, bill-wiping and wing-flicking sounds in aggression.

**Habitat.** Woodland edges, pastures and open areas with scattered fruiting trees, wooded streambanks, and gardens with nearby fruit trees; almost completely restricted to areas where fig *Ficus sycamorus* is abundant.

**Food and Feeding.** Little known; eats figs and various fruits and berries, also undetermined insects. Gleans in foliage of (non-fruiting) bushes and trees, hops over bark of limbs, probes into mosses and debris on bark, and flycatches from perch. Groups visit fruiting trees, may cross open areas 400 m or more wide to reach these; forages up to 1 km from nest or roost.

**Breeding.** Aug-Nov; also reported in Feb, such late nestings possibly due to interference from Lesser Honeyguide (*Indicator minor*). Nests in groups. In greeting ceremonies, birds hop from side to side, jump over one another, wave one or both wings, bow, swing body, spread and flick tail feathers, move tail up and down or side to side, erect head feathers, and 1 bird may cock tail; *L. torquatus* pairs or groups often elicit calls and chases. Nest excavated by all group-members, at height of 3-9 m in dead tree or, more usually, branch of live tree, such as *Ficus*, or *Parinari mobola*; entrance oval, once 3-6 cm by 4 cm, cavity c. 34 cm deep, chamber in 1 case 5-4 cm by 7-5 cm; territory c. 40 ha in farmland with scattered trees and woodland patches. Eggs 2-4; details of incubation and nesting periods, and helper activities, unknown. Nest parasitized by Lesser Honeyguide; in 1 observation, while 2 group-members chased honeyguides, another member entered nest, carried the 4 barbet eggs individually to entrance, and crushed each one.

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. Currently considered Near-threatened. Locally common, but range restricted probably to only a few hundred km<sup>2</sup>. Adapts to human activities and accepts man-altered habitats, so long as trees are still present for nesting, roosting and feeding; fortunately, when woodland is cleared for agriculture, fig trees are commonly left intact. However, minimum acceptable density of fig trees remains undetermined; research needed in order to establish ecological requirements, and also precise distribution. Occurs in Kafue National Park (Zambia), though present in only small numbers.

**Bibliography.** Anon. (1998a), Aspinwall & Beel (1998), Benson *et al.* (1971), Colebrook-Robjent & Stjernstedt (1976), Collar & Stuart (1985), Collar *et al.* (1994), Dowsett & Dowsett-Lemaire (1980, 1993), Dowsett & Forbes-Watson (1993), Fry *et al.* (1988), Horne & Short (1988), Leonard *et al.* (2001), Mackworth-Præd & Grant (1962), Short & Horne (1983b, 1985a, 1988a, 1988b), Snow (1978), Stattersfield & Capper (2000).

### 34. Red-faced Barbet

#### *Lybius rubrifacies*

**French:** Barbican à face rouge **German:** Rotgesicht-Bartvogel **Spanish:** Barbudo Carirrojo

**Taxonomy.** *Pogonornynchus rubrifacies* Reichenow, 1892, Biharamulo, north-west Tanzania. Related to *L. leucocephalus* through *L. chaplini*, the combined group also fairly close to *L. vieilloti*; also related to *L. guifsobalito* and *L. torquatus*. Distinct from all, however, in morphology; duet form nearest to that of *L. chaplini*, but songs of male and female of present species differ, as they do in *L. guifsobalito*. Monotypic.

**Distribution.** SW Uganda, E Rwanda and NW Tanzania.

**Descriptive notes.** 17-5-18-5 cm. Both sexes entirely brown-black, except for red face and yellow edges of flight-feathers; bill grey to horn-coloured. Differs from *L. guifsobalito* in having less red in plumage, no white on wing-coverts; from *L. torquatus* in all-dark body. Immature greyer, without red on head, paler bill lacks "tooth". **Voice.** Group greeting ceremonies with grating, "skizzy" notes, "eh" notes and chatter calls, with some bill-snapping and bill-wiping; this may lead to noisy duet of up to c. 6-5 seconds, one giving "kkaa" or "bakk" notes, the other higher-pitched "go" or "ko" notes ("ga-bakk" duet), differing from *L. leucocephalus* and *L. chaplini* in more or less synchronous, sexually different songs. Bill-wiping, bill-snapping and wing-rustling sounds in interactions.

**Habitat.** Inhabits woodland, including *Acacia polyacantha* woods along lakes and streams, and also mixed *Albizia-Acacia-Commiphora* woodland; also occupies *Combretum-Acacia* and *Combretum-Ficus* wooded grassland, at 1140-1550 m.

**Food and Feeding.** Diet composed of figs and other fruits, and undetermined insects. Flycatches for insects at times, and plucks fruits from foliage of fruiting bushes and trees. Forages in groups.

**Breeding.** Gonadal data of specimens indicate breeding in Feb-Mar and Oct. Social, in groups of up to 7. Tail-cocking, gliding-floating flight

displays, hunched posture with rump, back and facial feathers erected, bowing and swinging of body with vocalizations in greeting ceremonies and before duets. 1 cavity excavated by 2 birds at 18 m in branch of dead *Acacia polyacantha*, but possibly a roosting hole; defends variably sized territory, including against *L. torquatus* in riverine woods where co-occurring with latter, and then frequent interactions. No information on clutch size, incubation and nesting periods, and other aspects of breeding.

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. Currently considered Near-threatened. Has smallest range of any African barbet. Perhaps locally common, but total population small. Status uncertain, thought possibly vulnerable, but probably not under immediate threat. Large area of habitat where species was common in 1982 has been subjected to change as settlers poured into a major portion of Akagera National Park (E Rwanda), as a result of the civil war; roughly two-thirds of park has been lost. Habitat in Tanzania thought to be reasonably secure, but species occurs in very low densities here. More information is required about this species' biology, and on its numbers in SW Uganda and NW Tanzania. Present in Lake Mburo National Park (Uganda), Akagera National Park (Rwanda) and Ruvuvu National Park (Burundi).

**Bibliography.** Bennun & Njoroge (1996), Britton (1980), Collar & Stuart (1985), Collar *et al.* (1994), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Fry *et al.* (1988), Horne & Short (1988), Jackson & Sclater (1938), Mackworth-Præd & Grant (1957), Robertson (1997a), Schouteden (1966), Short & Horne (1983b, 1985a, 1988a, 1988b), Short, Horne & Muringo-Gichuki (1990), Short, Horne & Vande weghe (1983), Snow (1978), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), Stevenson & Fanshawe (2001).

### 35. Black-billed Barbet

#### *Lybius guifsobalito*

**French:** Barbican guifsobalito **German:** Purpurmasken-Bartvogel **Spanish:** Barbudo Guifsobalito

**Taxonomy.** *Lybius guifsobalito* Hermann, 1783, Ethiopia.

Closely related to *L. torquatus* (similar size, coloration, displays, sexual duet roles), but not so close as to form a superspecies with it, although each reacts strongly to playback of the other's voice. Also related, less closely, to *L. rubrifacies*. Birds become smaller clinally from N to S, but insufficient for racial differentiation; populations from White Nile southwards formerly separated as race *ugandae*. Monotypic.

**Distribution.** E Sudan, Eritrea and W & C Ethiopia, S to extreme NE Zaire, C Uganda, W Kenya and CN Tanzania; range expanding in W Kenya. Recently reported from N Cameroon, so may occur in Central African Republic.

**Descriptive notes.** 16-18 cm; 35-57 g. Chunky, short-tailed, mostly black barbet. Both sexes with red forehead, face and throat to upper breast, mainly black body; some yellow to white on edges of flight-feathers and (when fresh) rectrices, also in wing-coverts; black bill has 1-2 "teeth". Differs from *L. torquatus* in black lower underparts. Immature duller, red areas more orange and less extensive, bill without "teeth". **Voice.** Complex greeting ceremonies with chattering, grating, "kek" notes, often leading to duet or occasionally 3-bird singing, with distinct sexual songs, one (male?) lower "a-poot",

other higher-pitched "kik-ka", in synchrony over 3-10 seconds or more; duet similar to that of *L. torquatus* but noisier, faster; "wup-wup-" in series by lone bird, possibly location or gathering call; during encounters grating calls, "kek" calls, chatter calls, and frequent loud bill-wiping and wing-fluttering.

**Habitat.** Open woodland, such as *Acacia* and *Combretum-Terminalia*, bushy woods, edges of riverine forest and woods, gardens and cultivated areas with fruiting trees; even uses eucalyptus groves for singing. Occurs at 900-1600 m, up to 2200 in Ethiopia.

**Food and Feeding.** Berries and fruits, including figs, guavas, papayas, peppers and others, as well as ants, termites, beetles, Hemiptera and other insects. Gleans along branches and in foliage, picking fruit and insects; flycatches at intervals, extensively so when termites are flying.

**Breeding.** Oct-Dec, but Mar-May in Ethiopia. Groups of up to 7 perform greeting ceremonies, with bowing, tail-swinging, erection of head feathers, bill-wiping, tail-cocking; also floating flight display to perch, and wing-fluttering; 1 duetters cocks tail, partly spreads wings, as other slightly raises wings, bows and pivots to each side. Roosting cavities recorded at 5 m and 8 m, and nest presumably similar, but no details. No reliable information available on clutch size, incubation and nesting periods, and relative behaviour of pair and helpers.

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. Locally common in SE of range; probably locally common elsewhere. Seems to be reasonably adaptable; occurs in some degraded habitats, and is expanding its range in places. This species' biology, however, is little known and requires study. Present in Awash National Park (Ethiopia) and Murchison Falls National Park (Uganda).

**Bibliography.** van Beirs (1997), Benson (1994), Britton (1980), Britton & Britton (1971), Brown & Britton (1980), Cave & Macdonald (1955), Chapin (1939), Cheesman & Sclater (1935), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Friedmann (1930a, 1930b), Fry *et al.* (1988), Horne & Short (1988), Jackson & Sclater (1938), Lewis & Pomeroy (1989), Lippens & Wille (1976), Mackworth-Præd & Grant (1957, 1970), Nikolaus (1987), Payne (1967a), Robertson (1994), Short & Horne (1983b, 1985a, 1988b), Short *et al.* (1990), Smith (1957), Snow (1978), Speir (1990), Stevenson & Fanshawe (2001), Zimmerman (1967), Zimmerman *et al.* (1996), Zinner (2001).

# 36. Black-collared Barbet

## *Lybius torquatus*

**French:** Barbican à collier    **German:** Halsband-Bartvogel    **Spanish:** Barbudo Acollarado

**Taxonomy.** *Bucco torquatus* Dumont, 1816, Brazil; error = Cookhouse, eastern Cape Province, South Africa.

Closest relative is *L. guifsobalito* (with similar size, coloration, displays, sexual duet roles), but the two are not so close as to form a superspecies, though they react strongly to playback of each other's voice. Also related, less closely, to *L. rubrifacies*. Race *bocagei* intergrades with *congius* and *torquatus*, and both *vivacens* and *irroratus* intergrade with *zombae*; partly white morphs occur in at least two races (*zombae*, *irroratus*), and have been treated as races under names "*albigularis*" and "*nampunju*"; birds from W Zimbabwe described as *lucidiventris* are inseparable from *bocagei*. In past, race *bocagei* was erroneously listed as a race of *Stactolaema leucotis*. Seven subspecies recognized.

### Subspecies and Distribution.

*L. t. pumilio* Grote, 1927 - E Zaire, S Uganda, E Rwanda and W Tanzania S to NE & E Zambia, N & W Malawi and NW Mozambique.

*L. t. irroratus* (Cabanis, 1878) - coastal E Kenya S to CE Tanzania.

*L. t. zombae* (Shelley, 1893) - SE Tanzania to SC Malawi and NE & C Mozambique.

*L. t. congius* (Reichenow, 1898) - N & NC Angola E to SC Zaire and NW Zambia.

*L. t. bocagei* (Sousa, 1886) - S Angola and NE Namibia E to SW Zambia, N Botswana and W Zimbabwe.

*L. t. vivacens* Clancey, 1977 - E Zimbabwe and S Malawi to WC & SC Mozambique.

*L. t. torquatus* (Dumont, 1816) - SE Botswana and Transvaal E to Swaziland and E South Africa.

**Descriptive notes.** 17.5-19 cm; 35-48 g in N, 45-80 g in S. Common, conspicuous, vocal and social brown, black and yellow barbet. Both sexes of nominate race with red (sometimes yellow) over much of head and throat, black hindcrown, nape and mantle, with brown remaining upperparts finely vermiculated with black; black band across breast, yellow belly; large bill black with 1 or 2 "teeth". Differs from *L. rubrifacies* in yellow belly, more red in plumage, brown back; from *L. melanopterus* in yellow belly, no dark thigh patch. Immature duller, little or no red on head, brown bill paler and lacking "teeth". Race *congius* like nominate,

but separated by *bocagei*, which is yellower ventrally, with few lateral vermiculations on flanks; *pumilio* smaller, more orangey on head and breast, paler yellow belly becoming whiter on flanks; *vivacens* similar to *pumilio*, but browner above with finer vermiculations, still paler, whiter, below; *irroratus* resembles *pumilio*, but smaller, paler below, with hair-tipped red throat-breast feathers

that hang over black collar; *zombae* variable, with no red on head, face rather spotted to streaked white, orange or yellow on black, underparts paler and less yellow, white-marked morphs common. Voice. Complex, sexually discrete songs in duet, starting with greeting ceremony involving "tyaw", grating "zzzz", chatter, and "chatter-tyaw" calls that lead into synchronized "pudit" and higher, longer "tay" songs in "pudit-tay, pudit-tay" duet; duets have 2-20 sets of the 2-note forms in 2-10 seconds; also "pup" or "wup" in series, "yaaak" in alarm, and low notes. Wing-fluttering at c. 33 beats per second, and bill-tapping at or inside nest.

**Habitat.** Diverse open woodland to pasture habitats, avoiding deserts and forest; includes farmland, gardens, *Acacia* woodland, riverine woods, wooded grassland, and *Parinari-Pericopsis* woodland. From sea-level to 1820 m.

**Food and Feeding.** Grapes, guavas, figs, and fruits of *Euclea*, *Hippobromus*, *Lycium*, *Rhus*, *Royena*, *Scutia*, *Trichelia* and *Ziziphus*, among others; also ants, rose chafers, beetles, bees and other hymenopterans, and other insects. Gleans in foliage, and picks and probes along bark of twigs and on trunks of bushes and trees; works in lichens, debris and termite tunnels. Pecks out and eats seeds from dried pods of *Cassia abbreviata*. Occasionally flycatches from perch.

**Breeding.** Aug-Apr in most areas, also Apr-May in Rwanda and E Zaire, also Jul in last; mainly Sept-Dec S of Angola and Zimbabwe; up to 4 clutches in a season. Social, nests in group. Displays include bill-wiping, bill-pointing, bowing, bobbing, swinging of body and bill, swinging and flicking of tail, tail-cocking, wing-rustling, slow gliding display flight, with greeting ceremonies, duets and bill-tapping. Nest, excavated mainly or fully by primary pair, 0.5-6 m up in stump or dead limb or branch, often on underside, cavity to 48 cm deep, tunnel from entrance c. 8-5 cm; territory 20-50 ha in N, to 125 ha in S. Eggs 1-5, in S average clutch size 3-3; incubation, by all members of group, with guard barbet outside, period 18-19 days; nestlings fed by all group-members, reach entrance at c. 28 days, fledge in 33-35 days; young stay in group for c. 5 months, some remaining as helpers through following season. Parasitized by Lesser Honeyguide (*Indicator minor*), disruptions by which can also delay breeding.

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. Common in many parts of range; coastal race *irroratus* apparently locally fairly common, but habitat diminishing and its population probably requires monitoring. Species' aggressiveness towards other hole-nesters, and its frequent dominance over smaller barbets through interactions and even enlarging of their nesting and roosting holes, possibly renders it less vulnerable to loss of suitable breeding sites. Present in numerous protected areas, e.g. Ruvuvu National Park (Burundi), Rhodes Matopos National Park (Zimbabwe) and Kruger National Park and Mkuzi Reserve (South Africa).

**Bibliography.** Abell (1992), Belcher (1930), Benson & Benson (1977), Benson *et al.* (1971), Bingham (1999), Bowland (1988), Britton (1980), Brown & Britton (1980), Chapin (1939), Clancey (1956, 1971a, 1977d, 1977e, 1984a), Cooper & Groves (1969), Cyrus (1988), Dean (2000), Donnelly (1973), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Friedmann & Loveridge (1937), Fry *et al.* (1988), Ginn *et al.* (1989), Goodwin (1996), Harrison *et al.* (1997), Horne & Short (1988), Irwin (1981, 1996), Jackson & Selater (1938), Lewis & Pomeroy (1989), Lippens & Wille (1976), Liversidge (1991), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Moyer (1980), Penrith (2000), Penry (1994), Pinto (1983), Rankin (1981), Rutgers & Norris (1977), Short & Horne (1979, 1982a, 1983a, 1985a, 1988b, 1992c), Short *et al.* (1990), Skead (1950), Snow (1978), Steyn (1996), Steyn & Densham (1975), Steyn & Scott (1974), Tarboton (2001), Tarboton *et al.* (1987), Vande weghe (1974), Ward (1986, 1989), Williams (1966), Zimmerman *et al.* (1996).

PLATE 10

inches 3  
cm 8

## 37. Brown-breasted Barbet

*Lybius melanopterus*

French: Barbican à poitrine brune

German: Braunbrust-Bartvogel

Spanish: Barbudo Pechipardo

Other common names: Black-winged Barbet

**Taxonomy.** *Pogonias (Laimodon) melanopterus* W. K. H. Peters, 1854, Mocimboa, Mozambique.

Related to *L. minor*; also to the *L. bidentatus* group, which includes that species and the superspecies formed by *L. dubius* and *L. rolleti*. Paler brown Somalian birds sometimes placed in separate race, *didymus*, but in fresh plumage they are dark, as are those from farther S, so separation not justified. Monotypic.

**Distribution.** Mainly coastal, from S Somalia to SC Mozambique, ranging inland along rivers, more so in S, reaching to EC Kenya, CS Tanzania and N & SE Malawi; inland populations often disjunct.

**Descriptive notes.** c. 19 cm; 45-61 g. Long-tailed barbet with pale bill. Male with head red, giving way to brown on breast and back, lower back mostly white; thighs blackish, conspicuous against white belly; bill light horn, with 1 or 2 "teeth". Female like male, but at least 1 female known with flank spots, suggesting sexual dimorphism. Immature duller, less red. Voice. No song, equivalent perhaps is "nyekk" or "rrakk", singly, or up to 10 at 1 per second; sometimes

more noisy "nyaaaaak"; also nasal grating "skzzzz" at c. 2 per second during encounters and prior to copulation. Loud wing-fluttering and bill-wiping during aggressive interactions.

**Habitat.** Inhabits forest patches and partly cut-over areas, as well as forest edges, cultivated trees, riverine forest or woods, gardens, and trees along roads of villages and city suburbs. Generally found below 600 m, but occurs up to 1700 m in both Tanzania and Malawi.

**Food and Feeding.** Relatively little known. Feeds on insects (including hymenopterans),

and also on figs, cultivated fruits and diverse other fruits and berries. Flycatches, sometimes making 3-4 captures in a single flight; also gleans insects and fruits in foliage and along branches and twigs.

**Breeding.** Nov-Jun, also Aug; has 2 broods in places, in captivity breeds up to 3 times a year. Usually breeds in social groups of up to 7, sometimes including subadults from earlier brood. Much allopreening, tail-flipping and bowing among all group-members. Nest not described in detail, but 1 likely nest at 6 m in stub of broken large dead tree; apparently territorial. Clutch size unknown, but up to 3 young, possibly 4, recorded; no data on incubation, fledging, and other

## Family CAPITONIDAE (BARBETS) SPECIES ACCOUNTS

aspects of breeding. Interactions with parasitic Lesser Honeyguide (*Indicator minor*) occur, sometimes delaying nesting.

**Movements.** Resident; largely sedentary, but may wander some distance along rivers.

**Status and Conservation.** Not globally threatened. No data available on numbers; groups in mixed cultivation and woodland along roads at intervals of c. 300–500 m. Breeds in Liwonde National Park (Malawi). Often very local, and uncommon, and these factors, together with disjunct nature of distribution, suggest that it may be vulnerable; precise limits of range in S still require confirmation. More information also required on species' biology. Although interfered with by *L. torquatus*, it is dominant over that species; probably affected adversely by nest parasitism by Lesser Honeyguide.

**Bibliography.** Archer & Godman (1937–1961), Ash & Miskell (1983, 1998), Belcher (1930), Benson & Benson (1977), Bohmke & Macek (1994), Britton (1980), Brown & Britton (1980), Cordeiro (1989), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Friedmann & Loveridge (1937), Fry *et al.* (1988), Jackson & Selater (1938), Johnston-Stewart & Heigham (1982), Lane (1982), Lewis (1984), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957, 1962), Michler (1999), Nyirenda (1992), Short & Horne (1985a, 1988b, 1992c), Short *et al.* (1990), Snow (1978), Stevenson & Fanshawe (2001), Zimmerman *et al.* (1996).

## 38. Black-backed Barbet

### *Lybius minor*

**French:** Barbican de Levaillant **German:** Rosenbauch-Bartvogel **Spanish:** Barbudo Frentirrojo  
**Other common names:** MacClounie's Barbet (*macclounii*)

**Taxonomy.** *Pogonias minor* Cuvier, 1817, north Angola.

Related both to *L. melanopterus* and to the *L. bidentatus* group, latter including that species and the superspecies formed by *L. dubius* and *L. rolleti*. Race *macclounii* considered a separate species by some, but interbreeds with nominate *minor* over a considerable area (SW Zaire to NC Angola); form sometimes referred to as “*intercedens*” is hybrid between those races. Two subspecies currently recognized.

**Subspecies and Distribution.**

*L. m. minor* (Cuvier, 1817) - S Gabon to W Zaire and S to WC Angola.

*L. m. macclounii* (Shelley, 1899) - NE Angola, SC Zaire, S Burundi and W Tanzania S to N & W Zambia and NW Malawi.

**Descriptive notes.** 19.5–21 cm; 40–57 g. Long-tailed, pale-billed barbet with much white in plumage. Male nominate race with red forehead and forehead, blackish lores, rest of head brown; upperparts blackish-brown; white below, with orange-pink on belly, black thighs; bill light pinkish-grey to pale horn-grey, often tinged greenish above and pink below, with 1 or 2 “teeth”; orbital skin whitish-ochre to violet; legs pale, pinkish-flesh. Female like male, but at least two females known with spotting on flanks suggestive of sexual dimorphism. Immature duller, lacks red, has yellow in place of pink.

Race *macclounii* has sides of head white, hindcrown and upperparts black, with white bands on each side of mantle meeting at mid-back to form white “V”. Voice. Song of trilled buzzy notes at c. 26 per second, 1–3 seconds long, resembles those of *Trachyphonus vaillantii* and *L. bidentatus*; “krek” or “krek-ek” call like major call of *L. bidentatus*; also fast or slow grating in interactions, screeching calls used with grating, also “car” note. Other signals are bill-tapping, hard bill-wiping and wing-rustling.

**Habitat.** Woodland, gardens and open places with scattered trees and plantations, edges of forest, riverine vegetation, and thickets in formerly wooded country; enters pine plantations when foraging. Attracted to termite mounds and carton-ant nests.

**Food and Feeding.** Diet little known: fruits, berries, their seeds, also palm-nut fibres; and various flying insects and larvae, such as inchworms. Feeds from ground to canopy, in branches and foliage; plucks fruits, gleans insects, and flycatches, and hovers to take insects.

**Breeding.** Mainly Aug–Dec; also later, to Apr, in Gabon and Zaire, and as early as Jul in Malawi. Nests in pairs or trios. Tail-flitting, swinging of tail and body, bowing, tail-cocking and allopreening occur. Nest excavated by 2 adults, of which 1 possibly a helper, at 2–8 m in arboreal carton-ant nest, or tree stub or dead branch (e.g. of *Brachystegia* or *Syzygium guineense*), tunnel in carton-ant nest 10 cm deep and leading to 10-cm spherical chamber; readily renews in new chamber, even within 25 cm of old nest; territorial, but nests as close as 300 m, and nest defended against hole-nesters such as starlings (Sturnidae), other barbets (*L. torquatus* kept 50 m or more away), and Lesser Honeyguides (*Indicator minor*). Eggs 3–4; incubation by all adults; incubation and fledging periods unknown; fledglings follow adults, are fed entirely on fruits. Probably parasitized by Lesser Honeyguide.

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. Appears to be scarce to locally more common. Adaptable, occurs in gardens, but requires suitable nesting sites. Almost certainly suffers through nest parasitism by honeyguides. Present in Ruvuvu National Park (Burundi).

**Bibliography.** Anon. (1998a), Aspinwall & Beel (1998), Belcher (1930), Benson & Benson (1977), Benson & White (1957), Benson *et al.* (1971), Bouet (1961), Britton (1980), Brooke (1964), Carter *et al.* (1984), Chapin (1939), Dean (2000), Dowsett (1969), Dowsett & Dowsett-Lemaire (1980, 1993), Dowsett & Forbes-Watson (1993), Fry *et al.* (1988), Goodwin (1964), Grant & Mackworth-Praed (1942), Johnston-Stewart & Heigham (1982), Lippens & Wille (1976), Mackworth-Praed & Grant (1957, 1962, 1970), Pinto (1983), Ripley & Heinrich (1966), Short (1982a), Short & Horne (1985a), Snow (1978, 1979), Stevenson & Fanshawe (2001), Traylor (1960, 1963), Verheyen (1953).

## 39. Double-toothed Barbet

### *Lybius bidentatus*

**French:** Barbican bidenté **German:** Doppelzahn-Bartvogel **Spanish:** Barbudo Bidentado  
**Other common names:** Tooth-billed Barbet

**Taxonomy.** *Bucco bidentatus* Shaw, 1798, Nigeria.

Relationship with *L. dubius* and *L. rolleti* indicated by plumage pattern and by sexual dimorphism in flank pattern; related also, but less closely, to *L. minor* and *L. melanopterus*. Races only slightly differentiated; also, proposed races *friedmanni* from S Cameroon to Cabinda (N Angola) and *aethiops* from Ethiopia now included within *aequatorialis*. Two subspecies recognized.

**Subspecies and Distribution.**

*L. b. bidentatus* (Shaw, 1798) - Guinea-Bissau, Guinea, Sierra Leone and Liberia E to C Cameroon.  
*L. b. aequatorialis* (Shelley, 1889) - E Cameroon E to C Ethiopia, S to NW Angola, N Zaire, Burundi and NW Tanzania.

**Descriptive notes.** c. 23 cm; 65–91 g. Large, white-billed red and black barbet. Male nominate race glossy black above, with small white patch on lower back, narrow red wingbar; face and underparts red, with white patch between red belly and black rear flanks; yellow skin around eye, iris yellow to brownish; bill yellowish-white with 2 notches. Distinguished from *L. dubius* and *L. rolleti* by red, not black, throat and breast, and lack of distinct grooves on “double-toothed” bill. Female differs from male only in having tiny black spots or streaks on red adjacent to white flank patch. Immature duller, orbital skin and iris grey. Race *aequatorialis* with

paler and narrower wingbar. **VOICE.** Song a buzzy trill of doubled notes at 23–35 per second for up to 15 seconds; pair-members sing synchronously, usually one singing much longer than other: single to triple “krex”, noisy location call, variable, like some calls of *L. melanopterus*, *L. minor* and *L. dubius*; also double “aaaaarrk” notes, “awk”, “uh-uh-” sounds, all with fast mechanical clicking elements. Loud bill-snapping and bill-wiping, taps at nest entrance, and flicks wings loudly during encounters.

**Habitat.** Forest understorey, particularly at edges and around clearings, also secondary forest, streamside forest and woods, thickets, dense woods, trees over cultivation and gardens. Lowlands to 1800 m generally, to 2300 m in W Kenya.

**Food and Feeding.** Eats fruits and arthropods: avocados, figs, fruits of *Musangu*, papayas, red peppers, palm nuts; and ants, beetles, Hemiptera, emergent termites, and various larvae. Insects hunted among leaves and along bark; also flycatches occasionally to frequently. Usually forages in dense foliage below 10 m.

**Breeding.** Season long, perhaps all year in many areas; more often Nov–May in W Africa, also Apr–Nov in Cameroon, Gabon, Ethiopia and Angola. In pairs, with or without helpers. Displays mainly by pair, include tail movements, erection of flank feathers (showing sex), bowing, allopreening. Nest excavated mainly by pair, at 2–30 m in rotten tree stub or branch, including isolated tree near cover but in open, cavity entrance 5 cm, depth to 46 cm; nest defended against oxpeckers (*Buphagus*) and Lesser Honeyguide (*Indicator minor*). Eggs 2–4; incubation with many change-overs, period c. 13–14 days; hatchlings fed insects, later more fruit, by pair and any helpers, all of which also keep nest clean; nestling period 37–39 days; fledglings, helpers if any, and parents return nightly to roost in nest.

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. Widespread, and reasonably common almost everywhere in range; locally common in Sierra Leone; uncommon and local in Nigeria; fairly common in Kenya; rare, possibly overlooked, in Liberia, where extremely few confirmed records. Adaptable. Occurs in several protected areas, e.g. Comoé National Park (Ivory Coast), Mount Kupé National Park (Cameroon), Murchison Falls National Park (Uganda), Akagera National Park (Rwanda) and Ruvuvu National Park (Burundi).

**Bibliography.** Bannerman (1933, 1953), Bates (1930), Britton (1980), Brosset & Éard (1986), Brown & Britton (1980), Cave & Macdonald (1955), Chapin (1939), Cheesman & Selater (1935), Cheke & Walsh (1996), Christy & Clarke (1994), Colebrook-Robjent (1984), Colston & Curry-Lindahl (1986), Dean (2000), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), England (1976), Faust (1969), Field (1999), Friedmann (1930a), Fry *et al.* (1988), Gatter (1997), Grimes (1987), Halleux (1994), Jackson & Selater (1938), Lamarche (1980), Lewis & Pomeroy (1989), Lippens & Wille (1976), Louette (1981b), Mackworth-Praed & Grant (1957, 1962, 1970), Nikolaus (1987), Pinto (1983), Rand *et al.* (1959), Short & Horne (1985a), Short *et al.* (1990), Snow (1978), Taylor (1983), Thiollay (1985a), Zimmerman *et al.* (1996).

## 40. Bearded Barbet

### *Lybius dubius*

**French:** Barbican à poitrine rouge **Spanish:** Barbudo Pechirrojo  
**German:** Furchenschnabel-Bartvogel

**Taxonomy.** *Bucco dubius* J. F. Gmelin, 1788, Mopti, Mali.

Forms a superspecies with *L. rolleti*; both are also closely related to *L. bidentatus*. Monotypic.

**Distribution.** W Sahel from N Senegambia and Guinea-Bissau E to SW Chad, S to Guinea, C Ivory Coast, C Ghana, Togo and Benin, C Nigeria, C Cameroon and NW Central African Republic.

**Descriptive notes.** c. 25.5 cm; 80–108 g. Distinctive, large, red, black and white barbet with big yellow bill. Male glossy black above, with white patch on lower back; black hair-like feathers projecting over chin and base of bill; red cheeks and underparts with black breastband, white flank patch, black rear flanks; yellow skin around eye, yellow iris; bill yellow with 2 “teeth”, and grooves. Distinguished from *L. rolleti* by yellow facial skin and eye, red on breast, bill with grooves on underside as well as on sides; from *L. bidentatus* by larger size, black breastband, bigger and more yellow bill with grooves. Female differs from male in having

black spots on white flank patch. Immature like adult but duller, red areas orangey, bill duller and with grooves and “teeth” obscure or lacking. **VOICE.** Song not known; has “krawk” or “caw” notes, noisy but less grating than in *L. bidentatus*; also whirring “hurr-hurr-” reported.

**Habitat.** Occurs around trees in dry areas, including in *Acacia*, baobabs (*Adansonia digitata*), figs, fruiting trees in gardens, and in thickets, open woods, abandoned farms, secondary growth, and

associated undergrowth, from near sea-level to c. 1500 m.

**Food and Feeding.** Almost unknown. Groups move from fruiting tree to fruiting tree, readily clipping fruits with powerful bill; presumably takes insects as well.

**Breeding.** May-Sept in W, also Dec in Niger and Ghana; Feb-Jul or to Sept farther E in Nigeria and Cameroon. Social, in groups of up to 5. Displays undescribed apart from flicking of long tail. Nest excavated at any height in dead stub or dead branch, e.g. of *Acacia* or palm; territory probably large and irregular, but data lacking. Reported to lay 2 eggs; no other information on wild-living birds; in captivity, 2 eggs, incubation at least 16 days, hatching on consecutive days, nestling period c. 40 days.

**Movements.** Resident and apparently sedentary.

**Status and Conservation.** Not globally threatened. Common in Senegambia, common in Nigeria, and thought to be at least locally common elsewhere, although no data on numbers. Clearing of trees, especially dead ones, and desertification presumably disadvantageous to this species; on other hand, planting of fruit trees and clearing of forest in S parts of range likely to favour it, although bringing it into greater sympatry and possible competition with adaptable *L. bidentatus*. Research required on species' ecology and biology. Occurs in numerous protected areas, e.g. W National Park (Niger), Saloum Delta National Park and Niokola Koba National Park (Senegal), Abuko Nature Reserve (Gambia), Comoé National Park (Ivory Coast), Falgore Reserve (Nigeria), Bénoué National Park (Cameroon) and Bamingui-Bangoran National Park (Central African Republic).

**Bibliography.** Bannerman (1933, 1953), Barlow *et al.* (1997), Bates (1930), Callaghan (1999), Chappius (1981), Cheke & Walsh (1996), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Fry *et al.* (1988), Genz (1999), Giraudoux *et al.* (1988), Gore (1990), Grimes (1987), Helsens (1996), Lamarche (1980), Larison *et al.* (2000), Louette (1981b), Mackworth-Præd & Grant (1970), Morel & Morel (1990), Rodwell (1996), Serle (1950), Short & Horne (1985a, 1988b), Snow (1978), Thiollay (1985a), Traylor & Parelius (1967).

41. Black-breasted Barbet

*Lybius rolleti*

French: Barbican à poitrine noire                      Spanish: Barbudo Pechinegro  
German: Schwarzbrust-Bartvogel

**Taxonomy.** *Pogonias Rolleti* de Filippi, 1853, Upper White Nile in extreme south Sudan. Forms a superspecies with *L. dubius*; both are closely related to *L. bidentatus*. Monotypic.

**Distribution.** S Chad, NE Central African Republic and S Sudan to extreme NE Zaire and N Uganda.

**Descriptive notes.** c. 27 cm; 96-105 g. Distinctive, large, big-billed, black, white and red barbet. Male all glossy black, except for white patch on lower back, red belly, white flank patch; black hair-like feathers around base of bill, especially out over nostrils; facial skin blue to grey, eyes brown; ivory bill "toothed" and with grooves on sides. Distinguished from *L. dubius* by all-black throat and breast, and dark eyes and facial skin; from *L. bidentatus* additionally by larger size, much heavier bill with prominent grooves. Female has small black spots on white flank patch. Immature less glossy black, browner, reds duller and more orange-red. VOICE. Almost unknown; low, harsh grating note reported, and loud fluttering wing sounds.

**Habitat.** E Sahelian areas with woods, thickets and scattered trees, such as trees along water-courses, also in gardens and cultivation, even at times in eucalyptus groves; at 200-1200 m or more, to as high as 2134 m in W Sudan.

**Food and Feeding.** Diet of fruits, including guavas, mangoes, figs and others; presumably eats insects as well. Foraging behaviour not described, nor has occurrence in groups.

**Breeding.** Feb-Jul, perhaps occasionally later, to Nov, in N; Sept-Dec in N Uganda. Nest excavated in tree, at up to c. 5 m. Eggs apparently 1-2; incubation and nestling periods unknown; adults carry food in bill to nestlings, remove faecal material from nest. No other information available.

**Movements.** Presumably resident and sedentary.

**Status and Conservation.** Not globally threatened. One of the least well known of all barbets; no information on numbers, probably uncommon or, perhaps, locally more common; ecology and breeding biology very poorly known. Could come under threat through desertification of habitat and removal of dead wood for fires; potentially assisted by forest clearance in S of range, but there it is subject to competition from adaptable *L. bidentatus*.

**Bibliography.** Bretagnolle (1993), Britton (1980), Carroll (1988), Cave & Macdonald (1955), Chapin (1939), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Fry *et al.* (1988), Germain (1992), Goodwin (1964), Lynes (1925), Mackworth-Præd & Grant (1957, 1970), Nikolaus (1987), Pedersen (2000), Short & Horne (1988b, 1991), Short *et al.* (1990), Snow (1978), Stevenson & Fanshawe (2001).

PLATE 11

inches 4  
cm 10

## Subfamily CALORHAMPHINAE

### Genus *CALORHAMPHUS* Lesson, 1839

#### 42. Brown Barbet

##### *Calorhamphus fuliginosus*

French: Barbu fuligineux German: Braunbartvogel Spanish: Barbudo Pardo

**Taxonomy.** *Mycropogon fuliginosus* Temminck, 1830, Pontianak, west Borneo. Relationships unclear, and species remains very poorly known. Race *detersus* possibly inseparable from *hayii*. Four subspecies currently recognized.

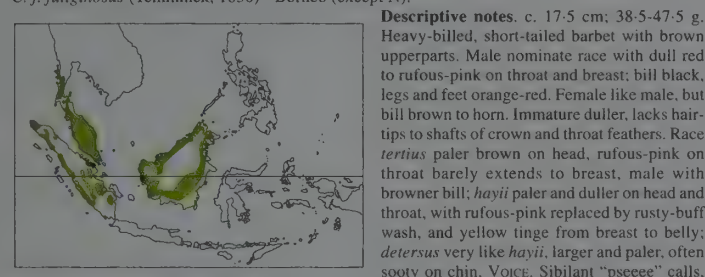

##### **Subspecies and Distribution.**

*C. f. detersus* Deignan, 1960 - S Myanmar (extreme S Tenasserim) and adjacent peninsular Thailand (S to Trang).

*C. f. hayii* (J. E. Gray, 1831) - Malay Peninsula and Sumatra.

*C. f. tertius* Chasen & Kloss, 1929 - N Borneo.

*C. f. fuliginosus* (Temminck, 1830) - Borneo (except N).

usually in series; also "pseeoo" call.

**Habitat.** Inhabits primary lowland forest, rarely up to 1000 m in lower hill forest; also occurs in swampy forest, some secondary forest and cut-over areas with fruit trees; sometimes found in cacao plantations.

**Food and Feeding.** Fruits such as those of *Ficus*, and berries; seeds of fruits to 10 mm found in stomachs; also undetermined insects. Usually feeds in small groups of up to 6 or 8 individuals, in understory to canopy, birds calling squeakily as they forage. At times moves along tree surfaces, in clusters of leaves, clinging in manner of tit (Paridae).

**Breeding.** Jan-Jul; Feb-Sept in Borneo. Social; up to 3 or more pairs nest in single tree or stub. Nest 1-10 m up, occasionally as high as 20 m, in stump, dead tree or branch, or in arboreal carton-ant or termite nest. Clutch 2-3; no information on incubation and fledging periods.

**Movements.** Resident and, so far as known, sedentary.

**Status and Conservation.** Not globally threatened. Fairly common to common in most of range; common in Borneo. Range of habitats used suggests some adaptability. Present in several protected areas, e.g. Khao Nor Chuchi (Thailand), Batu Punggul Forest Reserve and Gunung Mulu National Park (Peninsular Malaysia) and Kerinci-Seblat and Way Kambas National Parks (Sumatra). Research required, notably into possible taxonomic relationships.

**Bibliography.** Baker (1934a), Bromley (1952), Chasen (1939), Deignan (1960), Duckworth & Kelsh (1988), Holmes & Burton (1987), Jeyarajasingam & Pearson (1999), Laman *et al.* (1996), Lambert (1987, 1989a), Lekagul & Round (1991), Lim Kim Seng (1992), MacKinnon & Phillips (1993), van Marle & Voous (1988), McClure (1966), Medway (1972), Medway & Wells (1976), Nee & Guan (1993), Riley (1938), Robinson (1928), Robinson & Chasen (1939), Robson (2000), Round (1988), Short & Horne (1991), Smythies (1986, 1999), Thompson (1966), Vowles & Vowles (1997), Wells (1985, 1999), Wells *et al.* (1978), Wilkinson, Dutton & Sheldon (1991), Wong (1986).

**Food and Feeding.** Figs and other fruits, also insects; in captivity also grapes, apples, pears, bananas, and breeding captives consumed locusts, mealworms, mice and small dead rats, all mandibulated before being fed to young. Forages in pairs or family groups, pecking and probing, also hanging in foliage to reach fruits or insects.

**Breeding.** Jan to mid-Sept. Breeds in pairs. Males countering, holding body nearly horizontal, in encounters may fall to ground clapping and pecking one another. Both adults excavate cavity in dead tree or branch at 4 m or more above ground. Eggs not described.

clutch probably 2; incubation period unknown; both parents feed young at first, each remaining in nest until other returns to feed; in captivity, nestling diet shifted to solely fruit at c. 1 week; nestling period c. 42 days. Fledglings fed by parents for 5-8 days after fledging, then feed independently.

**Movements.** Resident; sedentary. 1 bird recaptured at same site 13 months after first netted.

**Status and Conservation.** Not globally threatened. Restricted-range species; present in Sumatra and Peninsular Malaysia EBA. Uncommon to locally common in Peninsular Malaysia; common in Sumatra. Although appears to be under no immediate threat, clearing of slope forests in its restricted range may soon fragment populations severely. Present in several protected areas, e.g. Kerinci-Seblat National Park (Sumatra).

**Bibliography.** Allen (1953), Baker (1934a), Berlioz (1936), Glenister (1971), Holmes (1996), Jeyarajasingam & Pearson (1999), MacKinnon & Phillips (1993), Madoc (1976), van Marle & Voous (1988), McClure (1964a, 1964b), Medway (1972), Medway & Wells (1976), Robinson (1909, 1911, 1928), Robinson & Chasen (1939), Robson (2000), Rutgers & Norris (1977), Seth-Smith (1929), Stattersfield *et al.* (1998), Sujatnika *et al.* (1995), Wells (1985, 1999), Wilkinson & McLeod (1984).

### Genus *MEGALAIMA* G. R. Gray, 1842

#### 44. Great Barbet

##### *Megalaima virens*

French: Barbu géant German: Heulbartvogel Spanish: Barbudo Grande  
Other common names: Giant Barbet, Giant/Great Hill Barbet, Great Himalayan/Himalayan Great Barbet

**Taxonomy.** *Bucco virens* Boddaert, 1783, China.

Related to *M. lagrandieri*, but not very closely. Races weakly to moderately marked; Indochinese birds, described as race *indochinensis*, now considered indistinguishable from nominate; birds of Mishmi Hills (NE Assam) formerly recognized as race *mayri*, but inseparable from *clamator*. Four subspecies currently recognized.

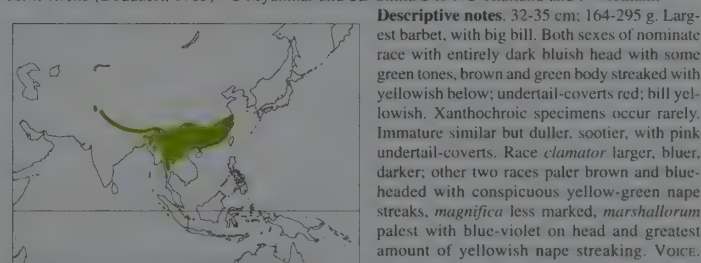

##### **Subspecies and Distribution.**

*M. v. marshallorum* (Swinhoe, 1870) - NE Pakistan and NW India E to W Nepal.

*M. v. magnifica* Stuart Baker, 1926 - E Nepal E to C Assam.

*M. v. clamator* Mayr, 1941 - NE Assam, N Myanmar, SW China (W Yunnan) and NW Thailand.

*M. v. virens* (Boddaert, 1783) - C Myanmar and SE China S to NC Thailand and N Vietnam.

**Descriptive notes.** 32-35 cm; 164-295 g. Largest barbet, with big bill. Both sexes of nominate race with entirely dark bluish head with some green tones, brown and green body streaked with yellowish below; undertail-coverts red; bill yellowish. Xanthochroic specimens occur rarely. Immature similar but duller, sootier, with pink undertail-coverts. Race *clamator* larger, bluer, darker; other two races paler brown and blue-headed with conspicuous yellow-green nape streaks, *magnifica* less marked, *marshallorum* palest with blue-violet on head and greatest amount of yellowish nape streaking. Voice.

Loud, distinctive "kee-aar" to "peeao" notes in long series, with countersinging; female may give shorter, faster notes, male slower, longer notes; also harsh "karr-r", "gyok", soft notes in short series, soft song notes, and a long, repeated querulous note by displaying paired birds. Noisy wing-rustling, especially in display.

**Habitat.** Forest, both deciduous and evergreen, and wooded valleys on mountain slopes; visits orchards and garden trees with fruits. Usually at 800-2400 m, but breeds down to 300 m in Himalayas, also up to 3000 m, and reaches sea-level in SE China.

**Food and Feeding.** Diverse fruits, especially figs, berries, wild plums, ivy berries, barberries, "medlar" and "pepul" fruits; also flower petals of rhododendrons, blossom of pear (*Pyrus sinensis*), nectar and petals of silk cotton tree (*Bombax ceiba*), and buds and catkins of trees such as *Ulmus*. Also eats ants, termites, hornets, beetles, cicadas, mantids and other insects. Hawks for insects at times, may drop on to insect from above. Outside breeding season, gathers in numbers of up to 40 at fruiting tree.

**Breeding.** Feb-Aug or Sept; sometimes 2 or even 3 broods in a season. Much singing and countersinging, simultaneous singing of pair; courtship displays with tail-wagging and head-bowing. Nest excavated by male and female, 3-12 m up in dead tree or branch, often on underside of latter, cavity can be 60 cm or more deep; sometimes old woodpecker hole used. Eggs 2-5, mainly 3-4, laid on wood chips at bottom of cavity; both parents incubate, feed young, enter and leave nest rapidly; incubation period 13-15 days, nestling period more than 38 days; fledged young call like adults, are effectively independent in c. 7-8 days. In captivity known to live for 13 years.

**Movements.** Resident, with altitudinal movements; those at elevations above c. 800 m migrate down to lower hilly areas and valleys for winter.

## Subfamily MEGALAIMATINAE

### Genus *PSILOPOGON* S. Müller, 1835

#### 43. Fire-tufted Barbet

##### *Psilopogon pyrolophus*

French: Barbu à collier German: Rotbüschel-Bartvogel Spanish: Barbudo Picofuego

**Taxonomy.** *Psilopogon pyrolophus* S. Müller, 1835, Sumatra.

Genus rather closely related to *Megalaima*. Monotypic.

**Distribution.** Mountain slopes of Peninsular Malaysia and Sumatra; recently reported extreme S Thailand.

**Descriptive notes.** c. 29 cm; 107-149 g (Malaysia). Largely green barbet of mountains. Male with red-tipped crown feathers, grey face, yellow throat patch bordered by black chestband; red tuft of feathers at base of bill; bill sturdy, yellow with irregular black bar in centre. Female lacks red on crown. Immature duller, greyer, sootier, nasal tuft mainly whitish. Voice. Trilling song 3-8 seconds long, sounding like a cicada, notes shorten and increase in tempo from 1-2 to 12-14 per second, "dddzza-ddzsa-" to "-zz-zz-zz-"; also a whistled note, and a squeak.

**Habitat.** Primary and secondary forest, forest edges and patches, especially in dense foliage with vines and creepers. Mostly at 900-1500 m, locally down to 400 m, and up to 2020 m.

**Status and Conservation.** Not globally threatened. Common in N Indian Subcontinent, although very local in Pakistan; possibly still present in Bangladesh, but no recent records; common in SE Asia. Somewhat adaptable where some forest exists, as on slopes amid valley cultivation. Present in numerous protected areas across extensive range, e.g. Namdapha National Park (India), Tai Po Kau Nature Reserve (Hong Kong) and Nam Nao, Doi Inthanon and Kaeng Krachan National Parks (Thailand).  
**Bibliography.** Ali (1962, 1977, 1996), Ali & Ripley (1983), Ali *et al.* (1996), Baker (1934a), Bünigener (1990), Caldwell & Caldwell (1931), Deignan (1945), Delacour & Jabouille (1931), Dodsworth (1912), Dymond (1998), Eames & Ericson (1996), Etchécopar & Hue (1978), Grimmett *et al.* (1998, 2000), Herkiots (1954), Inskipp & Inskipp (1991), Lekagul & Round (1991), Lewthwaite (1993), MacKinnon & Philipps (2000), Martens & Eck (1995), Morioka & Sakane (1981), Riley (1938), Ripley (1982), Roberts (1991), Robson (2000), Round (1988), Rutgers & Norris (1977), Shrestha (2000), Smythies (1986), Viney & Philipps (1983), Vo Quy & Nguyen Cu (1995), Wells (1999), Whistler (1941), Yahya (2000), Zhao Zhengjie (1995).

## 45. Red-vented Barbet

### *Megalaima lagrandieri*

**French:** Barbu à ventre rouge **German:** Rotsteiß-Bartvogel **Spanish:** Barbudo Ventrirrojo  
**Other common names:** Lagrandieri's Barbet

**Taxonomy.** *Megalaima Lagrandieri* J. Verreaux, 1868, Baria, Cochinchina. Possibly connects genus with *Psilopogon*, and has sometimes even been placed in latter. Allied to *M. virens*, but not particularly closely. Races not particularly well defined. Two subspecies currently recognized.

#### Subspecies and Distribution.

*M. l. rothschildi* (Delacour, 1927) - N Laos and N Vietnam.

*M. l. lagrandieri* J. Verreaux, 1868 - S Laos and S Vietnam.

**Descriptive notes.** c. 29 cm. Large, green to bronzy green barbet. Both sexes of nominate race with head mostly brown, greyish on sides and throat, blue line over eye; red undertail-coverts; reddish feathers in bristly tuft at base of bill; bill large, dull, with yellowish tip and cutting edges. Immature duller, browner, with orangey tuft at bill base. Race *rothschildi* darker brown and green than nominate, shows little or no yellow mixed with red in nasal tuft. **Voice.** Loud song or call of "kyaa", "kyow" or "yowt" notes, singly, or in series at 30-75 notes per minute for up to 10 seconds or more; alarm "grrrik-grrrik".

**Habitat.** Evergreen and semi-evergreen forest; occurs in lowlands and on forested slopes and ridges, to 2100 m.

**Food and Feeding.** Eats fruits such as figs, and insects, but details unknown. May gather at fruiting trees more regularly than does *M. virens*.

**Breeding.** Data from specimens suggest season Jan-Jul. Male and female of pair probably sing together in territorial formation or maintenance; countersinging occurs. Nest, eggs, incubation period and other details of breeding undescribed.

**Movements.** Resident and probably sedentary.

**Status and Conservation.** Not globally threatened. Uncommon to common; often one of commonest barbets in its rather limited range, where it appears to be widespread. This species' ecology and biology, however, are very poorly known, and study is required to elucidate its conservation status. Present in Nam Bai Cat Tien National Park, Bach Ma National Park and Cuc Phuong National Park (Vietnam).

**Bibliography.** Chazee (1994), Delacour & Jabouille (1931), Duckworth *et al.* (1999), Eames (1995), Eames & Ericson (1996), Eames & Robson (1992), Eames *et al.* (1994), Goodwin (1964), Robinson & Kloss (1919b), Robson (1996a, 2000), Robson, Eames, Nguyen Cu & Truong Van La (1993a, 1994b), Robson, Eames, Wolstencroft *et al.* (1989), Stepanyan (1995), Thewlis, Duckworth *et al.* (1996), Thewlis, Timmins *et al.* (1998), Vo Quy & Nguyen Cu (1995).

## 46. Brown-headed Barbet

### *Megalaima zeylanica*

**French:** Barbu à tête brune **German:** Braunkopf-Bartvogel **Spanish:** Barbudo Cabecipardo  
**Other common names:** Green Barbet(l), Oriental/Great/Large Green Barbet

**Taxonomy.** *Bucco Zeylanicus* J. F. Gmelin, 1788, Sri Lanka.

Forms a superspecies with *M. lineata*, and in past often treated as conspecific; they are narrowly sympatric in N India and SW Nepal, but with no apparent hybridization. Possibly related also to *M. viridis* and *M. faiostricta*, but not very closely. W Himalayan birds (Kangra to Garhwal) previously recognized as race *kangrae*, but now considered inseparable from *caniceps*. Three subspecies currently recognized.

#### Subspecies and Distribution.

*M. z. caniceps* (Franklin, 1831) - SW Nepal and N India (Punjab and Uttar Pradesh S to N Maharashtra, Orissa and Bihar).

*M. z. inornata* Walden, 1870 - CW & SW India (Maharashtra, Goa and Karnataka).

*M. z. zeylanica* (J. F. Gmelin, 1788) - S India (Kerala, S Tamil Nadu) and Sri Lanka.

**Descriptive notes.** 25-28 cm; 108-140 g. Large, streaky green and brown barbet. Both sexes of nominate race with prominent pale streaks on brown head, mantle and breast; throat brown; rest of plumage green, wing-coverts with white spots; bill brown-yellow or flesh-coloured, becoming red-orange when breeding; large area of facial skin dull yellow, turning orange or red-orange when breeding; legs yellowish. Distinguished from *M. lineata* by white wing-covert spots, brown throat, narrower white streaks on foreparts, larger area of bare facial skin with dark feathering around it. Immature duller. Race *inornata* larger and

paler, duller brown, but brown encroaches on mid-back and belly, streaks far less prominent, crown almost buffy; *caniceps* also large and pale, but brown restricted anteriorly as in nominate race, and streaking well defined. **Voice.** Song starts with trilling, then double "po-kok" or "too-kkak" notes

in long or short, regular or irregular series, up to 200 notes per minute at start, slowing to 80 or 60, notes harsher than in *M. lineata*; trills also given alone; alarm of "kuk" notes, also laugh-like mobbing call; begging "karr" notes as in *M. lineata*.

**Habitat.** Forest, neither very wet nor very dry, also edges, gardens and tree plantations, deciduous woods and scrubland, and even roadside trees. In New Delhi has adapted to suburban gardens and fruiting trees.

**Food and Feeding.** Feeds on fruits, especially figs, *Syzygium* fruits, and berries, including those of coffee, and also tomatoes and garden fruits; takes flower petals and nectar of *Bombax*, *Erythrina* and *Butea*; also takes animal food including beetles, mantids, ants, termites, and various large and small lizards. In one study in WC India, present species appeared to prefer much larger fig species (*Ficus bengalensis*, *F. mysorensis*) than did *M. haemacephala*. May gather with other barbets and frugivorous birds. Often bathes.

**Breeding.** Feb-Oct. Both sexes sing simultaneously, and countersing with others. Nest, excavated by both adults, at 2-15 m in tree or branch, often on underside, or in fence post, cavity to 46 cm. Eggs 2-4; incubation and nestling periods unknown; female incubates, broods young at night, both sexes incubate during day and feed young; at fledging, adults withhold food to entice young to leave nest.

**Movements.** Resident; makes only local movements to fruiting trees, orchards.

**Status and Conservation.** Not globally threatened. Locally common in much of India; locally fairly common in W Nepal; common in Sri Lanka. Aggressive and somewhat adaptable barbet. Has been reported as being a minor pest in coffee plantations, but recent work indicates the contrary, as species takes stem-boring *Xylotrichus quadripes*. Present in several protected areas, e.g. Corbett National Park (NC India) and Bellanwila-Attidiya Sanctuary (Sri Lanka).

**Bibliography.** Abdulali (1974), Ali (1962, 1969, 1996), Ali & Ripley (1983), Baker (1934a), Bhunya & Sultana (1983), Daniels, R.J.R. (1997), Dhindsa & Sandhu (1982), Grimmett *et al.* (1998, 2000), Harrison (1999), Henry (1998), Inskipp, C. & Inskipp (1991), Inskipp, T. *et al.* (1996), Kaul & Ansari (1981), Lamsfuss (1998), Mahabal & Lamba (1987), Majumdar *et al.* (1992), Martens & Eck (1995), Mukherjee (1952, 1953, 1995), Phillips (1978), Rand & Fleming (1957), Ripley (1982), Rutgers & Norris (1977), Saha & Dasgupta (1992), Short & Horne (1991), Shrestha (2000), Sugathan & Varghese (1996), Whistler (1941), Yahya (1980, 1988, 1991, 2000).

## 47. Lineated Barbet

### *Megalaima lineata*

**French:** Barbu rayé **German:** Streifenbartvogel **Spanish:** Barbudo Listado  
**Other common names:** Green Barbet(l), Grey-headed Barbet

**Taxonomy.** *Capito lineatus* Vieillot, 1816, Australasia; error = Java.

Forms a superspecies with *M. zeylanica*, and often treated as conspecific in past, but no apparent hybridization in the narrow area of sympatry in N India and SW Nepal. Possibly related also to *M. viridis* and *M. faiostricta*, but not very closely. Race *hodgsoni* tends towards nominate race in Peninsular Malaysia; other forms described include *rana* (Kumaon to WC Nepal), *katru* (Orissa) and *intermedia* (Myanmar to Indochina), but all now included within *hodgsoni*. Two subspecies currently recognized.

#### Subspecies and Distribution.

*M. l. hodgsoni* (Bonaparte, 1850) - NW India and Nepal E to SC China (W Yunnan), S to Orissa, Bangladesh, Manipur, S Myanmar, S Vietnam and N Peninsular Malaysia.

*M. l. lineata* (Vieillot, 1816) - Java and Bali.

**Descriptive notes.** 25-30 cm; 115-205 g. Large, green and streaky barbet; individual variation in intensity of coloration. Both sexes of nominate race heavily streaked on head, upper mantle and breast, whitish streaks broader than dark brown ones; throat and chin tend to be whitish; rest of plumage green; bill yellow, pink or horn, becoming creamy pink with yellow base when breeding; yellow or gold skin around eye; legs yellow. Distinguished from *M. zeylanica* by bolder white streaking, pale throat, no wing-covert spots, smaller area of bare orbital skin. Immature duller, buffier. Race *hodgsoni* clinically larger to N and NW. **Voice.**

Song usually with trilled introduction, then series of "poo-tok", often long, at 40-90 notes per minute, notes clearer, less noisy, and first syllable of each pair longer than in *M. zeylanica*, and songs can vary with single or triple notes mixed in; female song faster, trilled sets of notes, alone or with male; has long "hoo-hoo" series, also long trill followed by shorter ones, and several guttural and whistling notes, as well as others.

**Habitat.** Evergreen forest, especially at clearings and edges, also pine forest, teak, sal and deciduous forest and woodland, open secondary forest, plantations, gardens with cover, and fig and other fruiting trees along roads, even into urban areas.

**Food and Feeding.** Diverse fruits, especially figs, those of *Grewia*, strawberries, in captivity also bananas; flower petals and nectar from species of *Erythrina* and *Bombax* and others; larvae of various insects, termites; also frogs, nestling birds and probably bird eggs. Congregates at fruiting trees with other barbets.

**Breeding.** Jan-Jul in most areas; Sept-May in Malay Peninsula; Jan-Jul and Sept-Oct in Java and Bali. Territorial, sings much of year, role of female in territory defence uncertain; in aggression birds droop wings, gape, call. Both adults excavate nest-hole in dead tree or branch, even standing log, or stump, 2-12 m above ground, cavity to 50 cm deep. Eggs 2-4; both parents incubate, both feed young; incubation period c. 14-15 days; other details of nesting largely unknown.

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. Common in Nepal, fairly common locally in India, frequent in Bhutan, locally common in Bangladesh; common in SE Asia. Aggressive and adaptable species. Present in numerous protected areas, e.g. Corbett and Kaziranga National Parks (India), Chitwan National Park (Nepal), Doi Inthanon National Park (Thailand) and Nam Bai Cat Tien National Park (Vietnam).

**Bibliography.** Abdulali (1974), Ali (1977, 1996), Ali & Ripley (1983), Ali *et al.* (1996), Baker (1934a), Berwick (1952a, 1952b), Bromley (1949), Deignan (1945, 1963), Delacour & Jabouille (1931), Eames & Ericson (1996), Glenister (1971), Grimmett *et al.* (1998, 2000), Hellebrekers & Hoogerwerf (1967), Inskipp, C. & Inskipp (1991), Inskipp, T. *et al.* (1996), Jeyarajasingam & Pearson (1999), Lekagul & Round (1991), MacKinnon & Philipps (1993, 2000), Madoc (1976), Martens & Eck (1995), Medway & Wells (1976), Mukherjee (1952, 1953), Riley (1938), Ripley (1982), Robinson & Chasen (1939), Robson (2000), Round (1988), Short & Horne (1991), Shrestha (2000), Smythies (1986), Stepanyan (1995), Vo Quy & Nguyen Cu (1995), Wells (1999), Whistler (1941), Xu Weishu *et al.* (1996), Yahya (1980, 1988, 2000), Zhao Zhengjie (1995).

## 48. White-cheeked Barbet

*Megalaima viridis*

**French:** Barbu vert      **German:** Grünbartvogel      **Spanish:** Barbudo Cariblanco  
**Other common names:** Brown-headed Barbet(!), (Indian) Little/Small Green Barbet

**Taxonomy.** *Bucco viridis* Boddaert, 1783, Mahé, India.

Possibly related, though not very closely, to *M. zeylanica* and *M. lineata*, also to *M. faiostricta*, and other streaky *Megalaima*. Monotypic.

**Distribution.** WC & SW India, from SW Madhya Pradesh (R Narbada) S to Palni, Nilgiri Hills, Bangalore area and W Tamil Nadu.

**Descriptive notes.** c. 23 cm; 71-90 g. Green barbet, both sexes having dark brown head with conspicuous white ear-covert patch and white line above eye; throat white, breast and neck brown with broad white streaks; facial skin dark; legs greyish. Differs from *M. zeylanica* in smaller size, and white cheek patch. Immature duller, browner or greyer, with patterns obscured. **VOICE.** Song starts with loud trill of c. 1 second, followed by series of double "tu-kot" notes that shorten to "t'kot", tempo varying, mainly 1-2 per second; song-like "tot-tot" singly or irregularly in alarm, aggression, also fast song notes and trills during encounters;

"cheen-cheen" pre-copulatory call; begging "karr-karr-" notes, become louder as young are fed.

**Habitat.** Primary and secondary forest and woodland, including wet deciduous and evergreen, also parks, plantations such as coffee, and fruit trees in gardens and parks; is pest in coffee plantations and orchards. At sea-level to 1800 m, rarely 2400 m.

**Food and Feeding.** Banyan, pipal, other figs and fruits and berries, including those under cultivation; sips nectar; animal food, especially insects including butterflies, dragonflies, mantids, cicadas, beetles and winged termites, as well as earthworms and spiders. In one study in S India, present species preferred much larger fig species (*Ficus mysorensis*, *F. insignis*) than did *M. rubricapillus*; c. 30% of its dietary items consisted of animal food. When feeding on figs, commonly swallows the fruit whole. Takes insects and larvae in foliage and along branches and trunks; hawks for moths and winged termites; sometimes lands on ground. Sometimes gathers in parties of up to c. 20 to feed on fruits. Aggressive at fruiting trees, and in mixed feeding flocks, and also about nest.

**Breeding.** Dec-Jul, before heaviest monsoon rains; commonly 2 broods, second started 4-6 days after fledging of first. Nests in pairs, which persist more than 1 year. Nest excavated in c. 20 days, mainly by male, female doing some work, in dead branch, cavity entrance 5-1 cm in diameter, average depth 32-2 cm; territory is nesting tree, nests rarely 19 m apart in different trees; sometimes destroys eggs or young of *M. rubricapillus* nesting nearby. Eggs 2-4, usually 3, laid at 1-day intervals starting 3-5 days after nest completed; incubation by both parents, female incubating at night, eggs covered 75% of daytime, period 14-15 days; eggs hatch within 1 day, chicks fed by both adults, mainly insects to 5 days, switching at 5-10 days to fruits, feeding rates 9-6, 8-5 and 4-6 per hour respectively for broods of 3, 2 and 1; young brooded until day 14; nestling growth averages 2-7 g per day to 21 days, then slight loss as fed less; faecal sacs carried away 2-4 times per hour at first, later 6-7 times per hour for 3 nestlings; nestling period 36-38 days, food withheld during last 2-3 days; all young fledge on same day, are fed only 2-4 days before becoming independent, dispersing out of area in 10 days. Fledging success 75-5%; suffers predation by hawks such as Shikra (*Accipiter badius*), Brown Hawk-owl (*Ninox scutulata*) and palm squirrels (*Funambulus*).

**Movements.** Resident and essentially sedentary, dispersing over short distances.

**Status and Conservation.** Not globally threatened. Reasonably common throughout range, and adaptable. Has been reported as being a minor pest in coffee plantations, but recent work indicates the contrary, as species takes stem-boring *Xylotrechus quadripes*; also important in consuming large numbers of caterpillars of *Hyblaea pueria*, a grave defoliator of teak (*Tectona grandis*). Present in several protected areas, e.g. Rajiv Gandhi (Nagarhole), Mudumalai, Periyar and Indira Gandhi National Parks (India).

**Bibliography.** Ali (1969, 1996), Ali & Ripley (1983), Baker (1934a, 1934b), Balachandran (1999), Berlioz (1936), Chakravarthy & Purna Chandra Tejasvi (1992), Daniels, R. J. R. (1997), Goodwin (1964), Grimmett *et al.* (1998), Jayson & Mathew (2008), Kannan (1998), Kazmierczak (2000), Mahabadi & Lamba (1987), Ripley (1982), Rutgers & Norris (1977), Saha & Dasgupta (1992), Sugathan & Varghese (1996), Yahya (1980, 1987, 1988, 1991, 2000), Zacharias & Gaston (1999).

## 49. Green-eared Barbet

*Megalaima faiostricta*

**French:** Barbu grivelé      **German:** Grünohr-Bartvogel      **Spanish:** Barbudo Orejiverde  
**Other common names:** Lineated Barbet(!)

**Taxonomy.** *Bucco faiostrictus* Temminck, 1831, Cochinchina.

May be related, but not very closely, to *M. zeylanica* and *M. lineata*, also to *M. viridis*, or possibly to *M. franklinii* and *M. oorti*. Species name sometimes spelled erroneously as *faiostricta*. Two subspecies recognized.

**Subspecies and Distribution.**

*M. f. praetermissa* (Kloss, 1918) - N Thailand, Laos, N Vietnam and S & SE China (S of Canton).  
*M. f. faiostricta* (Temminck, 1831) - C & S Thailand, Cambodia and S Vietnam.

**Descriptive notes.** c. 24 cm. Streaky-headed, green, short-tailed barbet. Male has brownish streaks on crown and nape, green ear-coverts; malar region and throat streaked; underparts light green with often inconspicuous red or orange spot on each side of breast, variably streaked depending on plumage wear; bill mostly dark. Differs from *M. lineata* in smaller size, smaller and darker bill, green ear-coverts, all-green mantle. Female differs from male in lacking red breast spots, or sometimes in having them present but reduced to mere traces of red or orange-yellow. Immature duller, more olive. Race *praetermissa* larger, with somewhat darker head. **VOICE.** Song a rapid series of compound "twa-ta-ta-tat" or "too-er-took" notes at c. 2.5 per second; also much slower series of single "tawt" or "took", and a trill call.

**Habitat.** Primary evergreen and to some extent deciduous forest, staying in canopy; most common in evergreen forest, not extending into plantations or second growth; seems not to frequent edges, or to leave forest for purpose of foraging. In lowlands to 900 m, sometimes to 1035 m.

**Food and Feeding.** Feeds on fruits such as figs and those of *Trema* and *Eugenia*, berries; presumably also takes some insects, but little is known.

**Breeding.** Feb-Jul, but timing little known. Nest excavated in dead branch or, particularly, dead standing trunk; 2 eggs reported; no information on incubation and nestling periods or on roles of parents.

**Movements.** Resident; sedentary in S, but in N may move more or less extensively in deciduous forest, seeking fruits.

**Status and Conservation.** Not globally threatened. Apparently common in Thailand and Indochina; reportedly rare in China. Seems generally difficult to locate, probably because it favours canopy of evergreen forest, where not easy to detect. Requires monitoring, and study needed of its habits, ecology and breeding biology. Present in several protected areas, including Kaeng Krachan and Khao Yai National Parks (Thailand), and Nam Bai Cat Tien National Park (Vietnam).

**Bibliography.** Deignan (1945, 1963), Delacour & Jabouille (1931), Duckworth (1996), Duckworth *et al.* (1999), Eames (1995), Eames & Ericson (1996), Eames *et al.* (1994), Étchécopar & Hue (1978), Goodwin (1964), Lekagul & Round (1991), MacKinnon & Phillips (2000), McClure (1974), Riley (1938), Robinson & Kloss (1919b), Robson (2000), Robson *et al.* (1989), Round (1988), Stepanyan (1995), Vo Quy & Nguyen Cu (1995), Xu Weishu *et al.* (1996), Zhao Zhengjie (1995).

## 50. Brown-throated Barbet

*Megalaima corvina*

**French:** Barbu corbin      **German:** Braunkehl-Bartvogel      **Spanish:** Barbudo Corvino  
**Other common names:** Javan Barbet(!), Javan Brown-throated Barbet

**Taxonomy.** *Bucco corvinus* Temminck, 1831, Java.

Belongs to the group that also includes *M. chrysopogon*, *M. rafflesii*, *M. mystacophanos* and *M. javensis*. Thought by some to represent *M. chrysopogon* in Java, and this may prove to be a valid interpretation. Monotypic.

**Distribution.** Mountain forests of W Java.

**Descriptive notes.** c. 27 cm; 1 male 130 g. Distinctive, large green barbet with brown head. Both sexes with unstreaked brown head, neck and upper breast, usually with yellow-gold mark on nape; green of upperparts sometimes with blue tint; bill blackish. Immature duller, bill paler. **VOICE.** Song a series of 3- or 4-noted sounds, "too-ta-ta-toot", for c. 20 seconds, each compound note c. 0.9 seconds long; also short fast trill that may introduce song, a slow, short trill that may do likewise, and a rattly alarm note.

**Habitat.** Fragmented, wet mountain forest at 800-2000 m.

**Food and Feeding.** Diet mainly fruits, especially figs; presumably also insects at times. Feeds usually in canopy, alone or in small groups, possibly families, with other fruit-eating birds.

**Breeding.** Annual moult late May-Dec suggests main breeding season Jan-Jun; also Aug, and Oct reported; may be partly double-brooded. Reportedly lays 2 eggs in tree cavity, but no details, and nest and other aspects of breeding undescribed.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Restricted-range species; present in Java and Bali Forests EBA. Formerly listed as Near-threatened, but apparently quite common, at least locally, within its very small range, though no estimates available of population size or even of area of habitat remaining. Information is needed on this species' breeding biology and ecology, also on its requirements for roosting cavities, and on year-round relations of pair-members, in case action should become necessary to conserve it. Known to occur in Gunung Gede-Pangrango National Park (Java).

**Bibliography.** Andrew (1985, 1992), Berlioz (1936), Collar *et al.* (1994), Goodwin (1964), Hellebrekers & Hoogerwerf (1967), Hoogerwerf (1948), Kuroda (1933), MacKinnon (1988), MacKinnon & Phillips (1993), Marshall & Marshall (1871), Nijman & Sözer (1996), Robson (1994), Sergeant (1997), Statterfield *et al.* (1998), Sujatnika *et al.* (1995), Wells (1985).

## 51. Gold-whiskered Barbet

*Megalaima chrysopogon*

**French:** Barbu à joues jaunes      **German:** Goldwangen-Bartvogel      **Spanish:** Barbudo Carigualdo

**Taxonomy.** *Bucco chrysopogon* Temminck, 1824, Sumatra.

Belongs to the group that also includes *M. corvina*, *M. rafflesii*, *M. mystacophanos* and *M. javensis*. Three subspecies recognized.

**Subspecies and Distribution.**

*M. c. laeta* (Robinson & Kloss, 1918) - SW Thailand and Peninsular Malaysia; probably also extreme S Myanmar.

*M. c. chrysopogon* (Temminck, 1824) - Sumatra.

*M. c. chrysopsis* Goffin, 1863 - Borneo.

**Descriptive notes.** c. 30 cm; 110-215 g. Large, green barbet with heavy black bill. Male of nominate race has red forehead, yellow forecrown and red hindcrown, broad brown eyestripe, yellow malar area; greyish-white throat bordered blue at rear; orbital skin dark bluish, bill black. Female

closely resemble trill notes played slowly.

**Habitat.** Evergreen forest, swamp-forest, also tall secondary forest, and around forest clearings; also cacao plantations. Possibly some competition in lowlands with *M. rafflesii*. Occurs in lowlands, but in Borneo and Peninsular Malaysia mainly found in foothills above 250 m, especially at 750-1000 m; up to c. 1500 m.

**Food and Feeding.** Details little known, as this is a canopy bird. Mainly fruits such as figs and berries; probably also insects, seen pecking into dead wood. Specimens often have dirty bill, suggesting foraging or excavating cavities in arboreal carton-ant or termite nests.

**Breeding.** Feb-Aug, or even to Nov, possibly includes reneesting. When breeding, sings through heat of day. Few records of nesting; nest excavated in dead tree or branch; eggs 2; no other information. Longevity to 9 years in captivity.

**Movements.** Presumably resident and sedentary.

**Status and Conservation.** Not globally threatened. Uncommon to common in Thailand and Peninsular Malaysia; common in Sumatra and Borneo. Knowledge of its ecology and population biology lacking, research required. If species is territorial, as is likely, its territories would probably be large, hence fragmenting of habitat could pose a risk to it. Present in several protected areas, including Khao Nor Chuchi (Thailand) and Kerinci-Seblat, Gunung Leuser and Way Kambas National Parks (Sumatra). **Bibliography.** Berlioz (1936), Chasen (1934, 1939), Deignan (1963), Fogden (1970), Glenister (1971), Goodwin (1964), Holmes & Burton (1987), Jeyarajasingam & Pearson (1999), Lambert (1987, 1989a), Lekagul & Round (1991), MacKinnon & Philipps (1993), Madoc (1976), van Marle & Voous (1988), McClure (1966), McClure & Bin Othman (1965), Medway (1972), Medway & Wells (1976), Molesworth (1955), Riley (1938), Robinson (1928), Robinson & Chasen (1939), Robson (2000), Round (1988), Smythies (1986, 1999), Thiollay (1995), Thompson (1966), Wells (1985, 1999), Wells *et al.* (1978), Wilkinson, Dutton & Sheldon (1991).

## 52. Red-crowned Barbet

### *Megalaima rafflesii*

**French:** Barbu bigarré **German:** Vielfarben-Bartvogel **Spanish:** Barbudo Multicolor  
**Other common names:** Many-coloured Barbet

**Taxonomy.** *Bucco Rafflesii* Lesson, 1839, Bangka Island, Sumatra.

Belongs to the group that also includes *M. corvina*, *M. chrysopogon*, *M. mystacophanos* and *M. javensis*; apparently related rather closely to *M. javensis* and *M. chrysopogon*. Birds from S Myanmar and Malay Peninsula described as race *malayensis*, those from Belitang I and Mendanau Is as *billitonis* and those from Borneo as *borneensis*, but no constant differences in plumage coloration or size sufficient to warrant subspecific recognition. Monotypic.

**Distribution.** S Myanmar (S Tenasserim) and peninsular Thailand S to Singapore, E Sumatra, Bangka and Belitang, and Borneo.

**Descriptive notes.** c. 26 cm; 99-150 g. Large, chunky green barbet. Both sexes have red crown, red spot below eye, red mark on side of neck, black and yellow face, as well as blue throat and broad supercilia. Distinguished from other similar barbets by combination of entirely red crown, blue line over eye and yellow face patch. Immature duller than adult, with bright colours muted, bill pale at base. **Voice.** Song starts with low "took" notes at 1 per second, leading to "tuk" notes at c. 3 per second, for 5-15 seconds; some songs end in fast trill "-dattttttt"; songs repeated monotonously, 2-3 per minute.

**Habitat.** Inhabits primary forest, as well as old second-growth forest, *Shorea pavonina* forest, and poor-quality dipterocarp slope forest; also plantations of rubber and durian (*Durio zibethinus*). Almost strictly a lowland species, occurring only below 600 m on mainland, below 500 m in Sumatra; unusually up to 800 m but mostly below 250 m in Borneo. Possibly competes with usually more upland *M. chrysopogon*.

**Food and Feeding.** Little known, as forages in forest canopy. Diverse fruits, such as figs, some cultivated fruits; also insects, some dug from bark with strong bill.

**Breeding.** Jan-Jul; Nov-May in Sumatra. Very little known, and no data on courtship behaviour. Nest reportedly excavated at 1-5 m in tree, 1 at 4-5 m; eggs at least 2; no other information.

**Movements.** Resident, and sedentary so far as is known.

**Status and Conservation.** Not globally threatened. Currently considered Near-threatened. Known to range from scarce to locally fairly common in mainland part of range, but populations now fragmented throughout range; forest clearance has caused its disappearance from virtually all of its former haunts in Thailand, and a similar process is apparent in Malaysia; appears to be common in Sumatra and Borneo, but all primary lowland forests of the region are under imminent threat of destruction. Does show some adaptability, including occurrence as one of few barbets in urbanized Singapore. Very poorly known, however, and much research needed on its ecology and general biology, in particular to assist in assessing its conservation status. Present in several protected areas, including Khao Nor Chuchi (Thailand), Panti Forest Reserve and Bako National Park (Peninsular Malaysia), Bukit Timah Nature Reserve (Singapore) and Way Kambas National Park (Sumatra).

**Bibliography.** Berlioz (1936), Deignan (1963), Duckworth & Kelsh (1988), Gibson-Hill (1949a), Goodwin (1964), Holmes & Burton (1987), Jeyarajasingam & Pearson (1999), Laman *et al.* (1996), Lekagul & Round (1991), Lim Kim Seng (1992), MacKinnon & Philipps (1993), van Marle & Voous (1988), McClure & Bin Othman (1965), Medway & Wells (1976), Mees (1986), Riley (1938), Robinson (1928), Robinson & Chasen (1939), Robson (2000), Round (1988), Smythies (1986, 1999), Stattersfield & Capper (2000), Thiollay (1995), Voous (1961), Vowles & Vowles (1997), Wells (1985, 1990, 1999), Wells *et al.* (1978), Wilkinson, Dutton & Sheldon (1991).

## 53. Red-throated Barbet

### *Megalaima mystacophanos*

**French:** Barbu arlequin **German:** Harlekinbartvogel **Spanish:** Barbudo Arlequín  
**Other common names:** Gaudy Barbet

**Taxonomy.** *Bucco mystacophanos* Temminck, 1824, Sumatra.

Belongs to the group that also includes *M. corvina*, *M. chrysopogon*, *M. rafflesii* and *M. javensis*. Forms described as *aurantiifrons* from peninsular Thailand and *humii* from Borneo now included within nominate. Two subspecies recognized.

**Subspecies and Distribution.**

*M. m. mystacophanos* (Temminck, 1824) - S Myanmar (SC Tenasserim), SW and peninsular Thailand, Peninsular Malaysia (except S), Sumatra and Borneo.

*M. m. ampala* (Oberholser, 1912) - Batu Is, off W Sumatra.

**Descriptive notes.** c. 23 cm; 60-95 g. Moderately large, green barbet with strongest sexual dimorphism of any Old World capitonid. Male of nominate race has yellow forehead and small yellow malar mark; red crown, loral spot, chin and throat, and mark on side of breast; blue cheek and lower throat; and black eyestripe; bill large, black. Female slightly larger than male, paler, has narrow, pale yellow forehead, pale yellow chin and throat, red loral spot, small red crown patch surrounded by blue, blue over eye and on cheek and malar, often a muted red mark at throat-breast junction, paler lower mandible. Immature pale-

billed, mainly dull green and grey, bright colours muted, reds appear last; sexable c. 2 days after fledging. Race *ampala* differs from nominate in bigger bill, more square and, in female, larger red crown patch, female throat bluer. **Voice.** 2 songs, both vary; one a series of single to 4 "tyuk", "tuk" or "tyowp" notes with variable pauses, some long, between sets of notes, in one case song of 4-note sets had 23 sets, 92 notes, in 36 seconds; second song fast trills in series that slow down and become shorter in each trill, may break up into notes leading to first song; males countering using both songs; male gives low "hoot" to female in display. Sometimes uses bill-tapping signals.

**Habitat.** Foothill and also lowland dipterocarp forest, logged forest, second-growth forest, plantations of rubber, durian (*Durio zibethinus*) and cacao, and also visits fruiting trees in gardens and villages; mainly in canopy, descends to understorey in dense cover. Sea-level to 1060 m; mainly at low elevations, but in C Borneo commonly 750-980 m.

**Food and Feeding.** Mainly fruits, especially figs, also others such as durian; also insect larvae; and snails at times, e.g. in courtship feeding. Captives, when nesting, ate crickets, mealworms, maggots, waxworms and other insects. Insect larvae taken by pecking, making pits in bark; 1 individual worked 20 minutes, pecking over 4 m<sup>2</sup> of surface of dead stub.

**Breeding.** May-Jun on mainland; Nov-May and Sept in Sumatra; in Borneo reported Jun-Jul, but immatures Nov-Jun with most in Apr, so likely breeds all year. Singer flicks tail down, extends throat, keeps bill closed; in courtship feeding, male bows low to female, bill forward, calls. Nest excavated 3-6 m up in tree, or arboreal ant nest or termitarium. Eggs 2-4; in captivity, incubation period 17-18 days, nestling period 24-29 days, incubation and brood-feeding by both sexes, young independent within 1 week, then second brood started; no comparable data for wild birds. Captive female aggressive to male during nesting; in one year female killed male after eggs hatched, later killed 2 of 4 young.

**Movements.** Resident, and probably sedentary.

**Status and Conservation.** Not globally threatened. Currently considered Near-threatened. Seems to be common throughout range; no data on Batu Is race *ampala*. Appears quite adaptable. Information needed on breeding biology of wild populations. Almost all primary lowland forests within its range are under imminent threat of destruction, so its use of some forests at higher altitudes may prove decisive for its survival. Present in several protected areas, including Khao Nor Chuchi (Thailand), Batu Pungul Forest Reserve (Peninsular Malaysia) and Kerinci-Seblat National Park and Sungai Penuh Reserve (Sumatra).

**Bibliography.** Berlioz (1936), Chasen (1939), Deignan (1963), Duckworth & Kelsh (1988), Glenister (1971), Goodwin (1964), Holmes (1996), Holmes & Burton (1987), Jeyarajasingam & Pearson (1999), Lambert (1987, 1989a), Lekagul & Round (1991), MacKinnon & Philipps (1993), van Marle & Voous (1988), McClure (1966), McClure & Bin Othman (1965), Medway & Wells (1976), Meyer de Schauensee (1934), Riley (1938), Ripley (1944), Robinson (1928), Robinson & Chasen (1939), Robson (2000), Roth & Michalski (1994), Round (1988), Short (1973c), Smythies (1986, 1999), Stattersfield & Capper (2000), Thiollay (1995), Thompson (1966), Wells (1985, 1990, 1999), Wells *et al.* (1978), Wilkinson, Dutton & Sheldon (1991).

## 54. Black-banded Barbet

### *Megalaima javensis*

**French:** Barbu de Java **German:** Javabartvogel **Spanish:** Barbudo de Java  
**Other common names:** Javan(!)/Kotoreca Barbet

**Taxonomy.** *Bucco Javensis* Horsfield, 1821, Java.

Belongs to the group that also includes *M. corvina*, *M. chrysopogon*, *M. rafflesii* and *M. mystacophanos*; probably closest to *M. rafflesii*, having similar size and sexual monomorphism, or possibly to *M. mystacophanos*. Monotypic.

**Distribution.** Lowland Java and Bali.

**Descriptive notes.** c. 26 cm; male 115 g. Large green barbet with yellow crown and black bill. Both sexes have black, blue and red head markings; black lores and eyestripe, black extending down through ear-coverts to connect with black breastband; red spot on lores, red throat, red mark on side of breast. Immature duller, bright colours muted, bill paler. **Voice.** Song somewhat variable, usually accelerating series of double "too-took" notes, for 10-45 or occasionally 60 seconds, sometimes with pauses, and sometimes irregular; at times single "too" notes at 3 per second, or "tyaap" and "tap" notes that speed up; not known if both sexes sing.

**Habitat.** Lowland and hill forest, including teak forest, where not densely wooded, also forest patches; up to c. 1500 m.

**Food and Feeding.** Poorly known; fruits such as figs, and insects reported.

**Breeding.** Feb–Sept, and reported also in Dec, thus much of year; perhaps double-brooded. Reportedly lays 2 eggs in tree cavity, but no other details available.

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. Currently considered Near-threatened. Known to be widespread, and often common, though in a much-fragmented habitat. Lowland forests within its range have suffered intensive destruction, so occurrence of species at higher altitudes is of considerable conservation importance. Data on breeding and foraging are needed, as are population estimates and other information from Bali, where species is possibly less numerous. Sometimes trapped for cage-bird trade. Present in several protected areas, including Aas Purwo National Park (E Java).

**Bibliography.** Andrew (1992), van Balen (1999), Berlioz (1936), Collar & Andrew (1988), Collar *et al.* (1994), Goodwin (1964), Grantham (2000), Hellebrekers & Hoogerwerf (1967), Hoogerwerf (1948, 1969), Kuroda (1933), MacKinnon (1988), MacKinnon & Phillips (1993), Nijman & Sözer (1996), Sargeant (1997), Stattersfield & Capper (2000), Wells (1985).

## 55. Yellow-fronted Barbet

### *Megalaima flavifrons*

**French:** Barbu à front d'or **German:** Goldstirn-Bartvogel **Spanish:** Barbudo Frentigualdo  
**Other common names:** Sri Lanka/Ceylon Yellow-fronted Barbet, Yellow-faced Barbet

**Taxonomy.** *Bucco flavifrons* Cuvier, 1816, Sri Lanka. No close relatives. Monotypic.

**Distribution.** Sri Lanka.

**Descriptive notes.** 21–22 cm; male 57–60 g. Medium-sized green barbet. Both sexes with gold forecrown and front of malar, rest of side of head blue, chin and throat blue; pale streaks on nape, pale spots on breast. Immature duller. **Voice.** Song somewhat variable series of double “toowo” or triple “too-ka-o” notes, often starting as fast “towowowow-”, then slowing to c. 1 per second, may last 2 or more minutes; countersinging and likely simultaneous singing of pair; other calls as yet undescribed.

**Habitat.** Most common in SW hill forest, gardens and tree plantations; less common in wet lowland forest, and along streams in drier E; found very locally near streams in drier N. Ranges up to c. 2000 m.

**Food and Feeding.** Various fruits and berries, including figs, also guavas and papayas; takes some insects and small lizards.

**Breeding.** Probably all year, peaks Mar–May and Aug–Sept. Nest excavated in softwood tree such as *Bombax* or *Doona*, mainly at 1–8.3 m, entrance hole 5 cm, cavity excavated to c. 20 cm but if used in several years can be 60 cm or more deep. Eggs 2–3; no information on incubation and fledging periods, or on feeding rates; nestlings said to vary in size, so incubation presumably from first egg, or long intervals in laying.

**Movements.** Resident; probably sedentary, but in drier areas may have to leave territory to seek food. **Status and Conservation.** Not globally threatened. Restricted-range species: present in Sri Lanka EBA. Generally common and adaptable. In some areas considered a pest in orchards, causing crop damage. Present in several protected areas in Sri Lanka, e.g. Bellanwila–Attidiya Sanctuary, Kelani River Forest Reserve, Ingiriya Forest Reserve and Sinharaja Forest Reserve.

**Bibliography.** Abdulali (1974), Ali & Ripley (1983), Baker (1934a), Berlioz (1936), Goodwin (1964), Grimmett *et al.* (1998), Harrison (1999), Henry (1998), Jones *et al.* (1998), Kazmierczak (2000), Kotagama & Fernando (1994), Lamsfuss (1998), Legge (1983), Phillips (1978), Ripley (1982), Rutgers & Norris (1977), Stattersfield *et al.* (1998), Whistler (1944), Wijesinghe (1994).

## 56. Golden-throated Barbet

### *Megalaima franklinii*

**French:** Barbu de Franklin **German:** Goldkehl-Bartvogel **Spanish:** Barbudo de Franklin  
**Other common names:** Gold-throated Barbet

**Taxonomy.** *Bucco Franklinii* Blyth, 1842, Darjeeling.

Related to *M. oorti*, being quite similar in morphology and voice; the two are possibly connected also to *M. faiostriata*. Proposed race *tonkinensis*, from N Vietnam, now considered inseparable from nominate; *transgensis* from peninsular Thailand (known from only five specimens) and *minor* from Peninsular Malaysia, both regarded as indistinguishable from *ramsayi*. Three subspecies currently recognized.

**Subspecies and Distribution.**

*M. f. franklinii* (Blyth, 1842) - WC Nepal and SE Tibet E along Himalayan slopes to N Myanmar, and S China (W & S Yunnan, SW Guangxi), S to Bangladesh (no recent records), N Thailand, N Laos and N Vietnam.

*M. f. ramsayi* (Walden, 1875) - C Myanmar and NW Thailand S through Malay Peninsula.

*M. f. auricularis* (Robinson & Kloss, 1919) - E Laos and S Vietnam.

**Descriptive notes.** c. 22.5 cm; 50–73 g (*ramsayi*), 71–101 g (*franklinii*). Chunky green barbet often showing blue or even violet tones, especially in wings, with red on forehead and nape, golden on crown and throat. Male of nominate race has broad black eyestripe, greyish ear-coverts, deeper golden colour on upper throat, paler lower throat. Female less violet in wings. Immature duller, greener, bright colours and black muted. Race *ramsayi* has slightly narrower red forehead, duller yellow on throat, and ear-coverts and rear eyestripe streaked black and whitish; *auricularis* has red nape patch smaller, ear-coverts washed violet, entire throat

deep yellow, has thin blackish line from rear of supercilia around head to form collar along junction of yellow throat and green breast. **Voice.** Variable song starts with trill, can continue as all-trill song, or trill followed by “tuk” notes at 1 per second or these interspersed with trills sporadically; or followed by double or triple “tu-KEE-ow”, or variably “too-ka-weel”, at 58–65 per minute; in latter

type (Indian, Nepalese and Malaysian versions very similar), first note is soft, thus at a distance only 1 or 2 elements of the compound note heard.

**Habitat.** Montane forest, evergreen or moist deciduous, frequently along steep ravines and broken slopes, with mosses and ferns a frequent element. Generally at 900–2200 m, rarely to 600–800 m, more often above 2200 m, and to 2700 m; usually at higher elevations than *M. oorti* and *M. asiatica*. **Food and Feeding.** Mainly frugivorous, taking especially figs, various berries, such as winberries, and guavas; arthropods occasionally noted as part of diet. Unobtrusive; feeds in middle storey and canopy, occasionally descending to understorey. Sometimes visits fruiting tree in numbers.

**Breeding.** Mar–Aug in most areas, Feb–May in Malaysia. Monotonous singing and countersinging, singer points bill upwards as it calls. Nest excavated by male and female at 2–6 m in rotten dead tree or stump, often leaning over stream; entrance hole less than 5 cm, short entry tunnel, then cavity downwards to c. 25 cm, nest-chamber c. 8 cm in diameter. Eggs 2–5; both parents incubate and both also feed young, but incubation and nestling periods unknown, and roles of each parent unclear; male sometimes sings near nest-hole while female incubates; no other information.

**Movements.** None known; some birds may move downhill from higher elevations in N of range.

**Status and Conservation.** Not globally threatened. Sometimes common in parts of very extensive range, but little known. Locally frequent in NW of range, and common in Bhutan; no recent records from Bangladesh, but thought that it may possibly still survive there in Chittagong Hill Tracts; common in much of SE Asia. Preference for steep, densely wooded ravines may be of benefit to its conservation. Present in several protected areas, including Doi Inthanon and Kaeng Krachan National Parks (Thailand).

**Bibliography.** Ali (1977), Ali & Ripley (1983), Ali *et al.* (1996), Baker (1934a), Berlioz (1936), Deignan (1945, 1963), Delacour & Jabouille (1931), Dickinson (1986), Eames (1995), Eames & Ericson (1996), Échécopar & Hue (1978), Glenister (1971), Grimmett *et al.* (1998, 2000), Inskipp & Inskipp (1991), Jeyarajasingam & Pearson (1999), Lekagul & Round (1991), MacKinnon & Phillips (2000), Martens & Eck (1995), McClure (1964a, 1964b), Medway & Wells (1976), Meyer de Schauensee (1934), Morioka & Sakane (1981), Riley (1934, 1938), Ripley (1982), Robinson & Chasen (1939), Robson (2000), Robson *et al.* (1989), Round (1988), Smythies (1986), Stepanyan (1995), Vo Quy & Nguyen Cu (1995), Wells (1999), Wells *et al.* (1978), Yahya (2000), Zhao Zhengjie (1995).

## 57. Black-browed Barbet

### *Megalaima oorti*

**French:** Barbu malais **German:** Schwarzbrauen-Bartvogel **Spanish:** Barbudo Cejinegro  
**Other common names:** Embroidered/Malayan/Müller’s Barbet; Hainan Barbet (*faber*); Taiwanese/Formosan Barbet (*nuchalis*)

**Taxonomy.** *Bucco Oorti* S. Müller, 1835, Sumatra.

Related to *M. franklinii*, with similar morphology and vocalizations, and both possibly connected also to *M. faiostriata*. Also probably allied to *M. asiatica* and *M. incognita* and to group that includes *M. henrici*, *M. armillaris* and *M. pulcherrima*, and has also been considered by some authors to be close to *M. monticola*. Very well-marked races *sini* and *faber* could prove specifically distinct; *nuchalis* also sometimes thought possibly to be a distinct species, but tends to bridge differences between these two races and nominate *oorti* and *annamensis*; thus, all are considered better treated as races of present species. Five subspecies currently recognized.

**Subspecies and Distribution.**

*M. o. nuchalis* (Gould, 1863) - Taiwan.

*M. o. sini* (Stresemann, 1929) - S China (Guangxi).

*M. o. faber* (Swinhoe, 1870) - Hainan I.

*M. o. annamensis* (Robinson & Kloss, 1919) - S & E Laos and S Vietnam.

*M. o. oorti* (S. Müller, 1835) - Peninsular Malaysia and Sumatra.

**Descriptive notes.** c. 21.5 cm; 62–123 g. Montane green barbet with red on forehead or lores and nape, yellow-gold throat with blue lower border, red on breast, black stripe over and behind eye and in upper malar region, blue ear-coverts. Both sexes of nominate race with only little red on nape, broadly yellow-tipped crown feathers, red on breast restricted to small lateral spot. Immature duller, with colours subdued. Races *sini* and *faber* with black crown, more red on breast, former with more red on nape sometimes extending to mantle, and some *faber* also with suggestion of red on mantle; *nuchalis* and *annamensis* intermediate between

those and nominate, yellow-crowned with more red on nape than nominate, *nuchalis* with red on mantle, *annamensis* sometimes with hint of that and with broader black eyestripe and more blue on lower throat. **Voice.** Song a series of triple-noted phrases, “too-tuk-trrrrrk”, at 65–75 phrases per minute, accent on third note, phrases sometimes with soft extra initial note or extra terminal “-ta” (vocal) data reported only from Malaysia, Sumatra and Vietnam; singer turns head, giving soft-loud variation.

**Habitat.** Generally lower montane forest and upper dipterocarp forest in Malaysia, also pine forest and orchards and towns with fruiting trees in Sumatran highlands; subtropical and some tropical evergreen forest in China. Above 300 m in Taiwan, 600 m in Sumatra, 900 m elsewhere, to 2000 m or occasionally 2400 m; usually occurs at elevations below *M. franklinii* and above *M. henrici*.

**Food and Feeding.** Little known. Fruits comprise its diet, and probably takes insects when breeding, but no information available. Active in canopy and subcanopy.

**Breeding.** Feb–Nov in Sumatra, Mar–Jun in Malaysia, probably Feb–May in Hainan and Jun–Aug in Taiwan. Countersinging occurs in breeding period. Nest excavated at 2–10.5 m above ground in tree; 3 eggs reported in Taiwan; no further details available. A captive lived 5 years and 9 months.

**Movements.** Resident; upslope post-breeding movement reported in Taiwan.

**Status and Conservation.** Not globally threatened. Fairly common to common in most of range; common in Sumatra. Range fragmented, and clearing of forest at altitudinal levels where this species lives may place it in jeopardy; race *sini* of Yao Shan range in China may be at risk, as may be rare *faber* in Hainan, both of which occur in a limited range, and both of which could also be distinct species. Too little information available on population and breeding biology for its conservation needs to be assessed; further research required. Present in several protected areas, including Bach Ma National Park (Vietnam) and Kerinci-Seblat National Park and Sungai Penuh Reserve (Sumatra).

**Bibliography.** Allin & Edgar (1948), Berlioz (1936), Delacour & Jabouille (1931), Eames (1995), Eames & Ericson (1996), Eben (1985), Échécopar & Hue (1978), Glenister (1971), Goodwin (1964), Hill (2001), Inskipp *et al.* (1996), Jeyarajasingam & Pearson (1999), MacKinnon & Phillips (1993, 2000), Madoc (1976), van Marle & Voors (1988), Medway & Wells (1976), Robinson (1928), Robson (2000), Robson *et al.* (1993a), Schifter (1967), Severinghaus & Blackshaw (1976), Stepanyan (1995), Thiollay (1995), Vo Quy & Nguyen Cu (1995), Wells (1999), Xu Weishu *et al.* (1996), Zhao Zhengjie (1995).

## 58. Blue-throated Barbet

### *Megalaima asiatica*

**French:** Barbu à gorge bleue **German:** Blauwangen-Bartvogel **Spanish:** Barbudo Gorgiazul  
**Other common names:** Blue-breasted/Blue-cheeked Barbet

**Taxonomy.** *Trogon asiaticus* Latham, 1790, Calcutta.

Closely related to *M. incognita*, and a mixed pair reported in the wild, while race *chersonesus* somewhat intermediate between the two species; also related to *M. franklinii* and *M. oorti*. Has in past been thought to form a superspecies with *M. monticola*, and was sometimes even considered conspecific, but morphological differences seem sufficient to warrant separate species status. Form described as race "*rubescens*" from S Assam and NW Myanmar is a morph of nominate *asiatica*; *laurentii*, described from Yunnan, is a synonym of *davisoni*. Three subspecies currently recognized.

#### **Subspecies and Distribution.**

*M. a. asiatica* (Latham, 1790) - NE Pakistan E along Himalayas to N Myanmar and S China (W Yunnan), S to Bangladesh and C Myanmar.

*M. a. davisoni* Hume, 1877 - SE Myanmar E to S Yunnan and N & C Vietnam.

*M. a. chersonesus* (Kloss & Chasen, 1927) - E peninsular Thailand.

**Descriptive notes.** 22-23 cm; 61-103 g. Medium-sized, short-tailed green barbet with blue throat and face. Both sexes of nominate race with black-edged red cap and forehead broken by yellowish and black or blue bands across mid-crown; eye conspicuous amid surrounding blue; sometimes has tiny black and red submoustachial spot at base of mandible; red mark on each side of upper breast. Erythristic morph ("*rubescens*") more or less red over back and even on underparts. Differs from *M. incognita* in crown pattern, and in all-blue face and throat without black bar. Immature duller, head pattern subdued. Race *davisoni* paler blue

on head, blue mid-crown, female lacks red lateral breast spot; *chersonesus* has still paler blue on head, at least on throat, chin even showing yellowish, crown mostly blue with small red nape patch. **VOICE.** Song of 3-note phrases, "tu-ku-tuk", in variably long series, often ending in short trill; also version with 4-note phrase, "ta-tu-ku-tuk", at 90-105 phrases per minute; song much softer, less noisy, than those of *M. zeylanica* and *M. lineata*, and with 1-2 more notes per phrase; other calls not fully described.

**Habitat.** Primary and secondary evergreen and deciduous mountain forest, also clearings, edges, orchards, plantations, and gardens, and entering towns and cities where fruiting trees present. Near sea-level in NE India and Bangladesh; more usually 200-2000 m, rarely up to 2450 m. Normally at higher elevations than *M. incognita* where the two co-occur.

**Food and Feeding.** Eats figs and other fruits, and berries, also flowers of pistachio (*Pistacia integerrima*) and probably others; also many insect larvae, mantises, crickets and centipedes. Captives eat fruits, even entire dates, and vigorously pursue and eat various insects. Bashes larger animal prey against limbs before consuming them. Forages in canopy, but comes to understorey for fruits. Seems less shy than most congeners.

**Breeding.** Mar-Jul; also later in S and at low altitudes, where double-brooded. Countersinging and simultaneous singing of paired birds; bobbing and head-turning and tail-twitching in display, much courtship feeding. Nest excavated by both adults, at 1.5-8 m, sometimes higher, in dead tree or branch, often on underside, sometimes in tree over water; entrance large, even to 7 cm, with short tunnel inwards, then downwards to 10-30 cm or more, nest-chamber c. 10-15 cm across; may use same nest for 2 years, or enlarge old woodpecker hole. Eggs 2-5, mainly 3-4; both adults incubate, eggs attended by 1 parent at all times, period c. 14 days; both parents feed young, carry away faecal sacs; nestling period not known; fledglings reported to reach independence rapidly. A captive lived for 10 years and 10 months.

**Movements.** Resident, and largely or entirely sedentary; possible downslope movements from highest altitudes in range.

**Status and Conservation.** Not globally threatened. Common almost everywhere in range; common but local in Pakistan, where possibly expanding range; common in Nepal, where densities of 2-5 singing males/km reported; common in India and Bhutan, and locally common in Bangladesh; generally common in SE Asia. Isolated race *chersonesus* sometimes considered under threat, but apparently not uncommon within very small range. An adaptable species. Present in numerous national parks, e.g. Corbett and Kaziranga (India), Chitwan (Nepal) and Nam Nao and Kaeng Krachan (Thailand).

**Bibliography.** Abdulali (1974), Ali (1977, 1996), Ali & Ripley (1983), Ali *et al.* (1996), Baker (1934a), Berlioz (1936), Biswas (1947), Cheng Tsohsin (1964), Deignan (1945, 1963), Delacour & Jabouille (1931), Eames & Ericson (1996), Échécopar & Hùe (1978), Fox (1933), Goodwin (1964), Grimmett *et al.* (1998, 2000), Inskipp, C. & Inskipp (1991), Inskipp, T. *et al.* (1996), Lekagul & Round (1991), MacKinnon & Phillips (2000), Mierow & Shrestha (1978), Norris (1950), Rand & Fleming (1957), Riley (1938), Ripley (1982), Roberts (1991), Robinson (1928), Robson (2000), Round (1988), Rutgers & Norris (1977), Schifter (1967), Shrestha (2000), Smythies (1986), Stepanyan (1995), Vo Quy & Nguyen Cu (1995), Wells (1999), Whistler (1941), Xu Weishu *et al.* (1996), Yahya (1980, 2000), Zhao Zhengjie (1995).

## 59. Moustached Barbet

### *Megalaima incognita*

**French:** Barbu de Hume **German:** Grünscheitel-Bartvogel **Spanish:** Barbudo Bigotudo  
**Other common names:** Hume's Blue-throated Barbet

**Taxonomy.** *Megalaima incognita* Hume, 1874, Tenasserim.

Closely related to *M. asiatica*, with mixed pairing reported in the wild; race *chersonesus* of latter somewhat intermediate between the two species. Three subspecies recognized.

#### **Subspecies and Distribution.**

*M. i. incognita* Hume, 1874 - S Myanmar (Tenasserim) and W Thailand.

*M. i. elbeli* Deignan, 1956 - NE & E Thailand, N Laos and N Vietnam.

*M. i. euroa* (Deignan, 1939) - SE Thailand, Cambodia, S Laos and S Vietnam.

**Descriptive notes.** 22-23 cm. Medium-sized green barbet with blue cheeks and blue throat divided by black bar. Both sexes of nominate race with green crown, very narrow red forehead patch and red nape patch, black eyestripe; chin paler, yellowish or greenish; red spot at each side of upper breast. Differs from *M. asiatica* in paler blue face and throat broken by black submoustachial line. Immature duller, especially brighter colours muted, breast-side spots small or absent. Race *euroa* with larger red patch on hindcrown and nape, paler green-blue throat than nominate; *elbeli* with red nape patch as nominate, throat pale and more greenish-blue than in *euroa*.

**VOICE.** Several songs or variants, main one starts with single "tuk" that shifts into double "tuk-uk" or triple "tuk-a-tuk" notes, another with triple-noted sets each ending in trill, "tuk-tuk-rrrrr"; generally short, c. 1 phrase per second for 10-12 seconds, but countersinging results in longer, more rapidly uttered songs; song notes sometimes used as single-phrase call; also long, variable trills, up to 25 seconds or more, may mark interactions.

**Habitat.** Evergreen monsoon forest and edges, generally at 400-1400 m, less commonly to c. 2000 m; where occurring with *M. asiatica*, is usually found at lower altitudes. Seems not to leave forest cover.

**Food and Feeding.** Fruits of various figs and of other trees, such as *Macaranga* and *Trema*; when breeding also insects, including cerambycid beetles and stick-insects. Insects hammered to break them into pieces, before being fed to young.

**Breeding.** Few data. Season Dec-Jun. Sings for 9 months of year. Cavity excavated in dead tree or branch, at 10-15 m; once in "piccolo" tree that also contained nest of *M. falcistricta*. Eggs and incubation and nestling periods undescribed; young reportedly fed mostly fruits, some insects.

**Movements.** Resident, and sedentary so far as is known.

**Status and Conservation.** Not globally threatened. Apparently fairly common to common in much of range. Little known. Strictly a forest species, living at altitudes where much clearance occurs; data therefore needed in order to monitor this barbet, and to assess its conservation status and requirements. Present in several national parks, e.g. Kaeng Krachan, Khao Yai and Nam Nao (Thailand).

**Bibliography.** Baker (1934a, 1934b), Berlioz (1936), Chazee (1994), Deignan (1956, 1963), Delacour & Jabouille (1931), Duckworth (1996), Duckworth *et al.* (1999), Eames & Ericson (1996), Goodwin (1964), Lekagul & Round (1991), McClure (1974), Meyer de Schauensee (1934), Riley (1938), Robson (2000), Round (1988), Smythies (1986), Stepanyan (1995), Vo Quy & Nguyen Cu (1995).

## 60. Mountain Barbet

### *Megalaima monticola*

**French:** Barbu montagnard **German:** Borneobartvogel **Spanish:** Barbudo Montano

**Taxonomy.** *Cyanops monticola* Sharpe, 1889, Mount Kinabalu, Borneo.

Relationships unclear. Has been considered to form a superspecies with *M. asiatica*, and sometimes even thought conspecific, but differences in morphology indicate separate species status. Has also been allied by some authors to *M. oorti*. Monotypic.

**Distribution.** Mountains of N Borneo, from Mt Kinabalu S to Kapuas and Kayan Mts

**Descriptive notes.** 20-22 cm; male 65-110 g, female 83-112 g. Rather small, chunky, green barbet with yellowish throat. Male has forecrown bluish-yellow, hindcrown and nape red with partial blue border, head pattern somewhat obscured by fine streaking; throat with yellowish-buff wash, more or less spotted grey and often with some blue visible at rear, red mark on each side of upper breast. Female like male, but larger. Immature duller, with orange-red hindcrown-nape patch. **VOICE.** Song repeated phrases of fast notes, "tu-tu-tu-tu-tu" to faster "tu-t-t-t-tu", variable number of notes in phrase, up to 6 phrases per second, with irregular, brief pauses; song can last for several minutes.

**Habitat.** Lower montane and slope dipterocarp forest, also edges, and garden and orchard fruit trees near and even in villages. Usually at 600-1200 m, uncommonly 300-1670 m; occurs at roughly same elevations as *M. eximia*; replaced by *M. henrici* at c. 600 m and lower, and by *M. pulcherrima* at c. 1320 m, with little or no overlap with them.

**Food and Feeding.** Diverse fruits, including "lunuk" berries and figs; probably some insects. Forages at all levels, climbing and searching on bark of trunks and stems of bushes. Joins mixed-species foraging flocks of babbler (*Stachyris*, *Yuhina*).

**Breeding.** Very poorly known. Data from specimens indicate season Nov-Jun. No information available on nest, eggs, incubation, nestling life, and parental roles.

**Movements.** Resident and probably sedentary.

**Status and Conservation.** Not globally threatened. Restricted-range species; present in Bornean Mountains EBA. Appears to be quite common and somewhat adaptable, but no details on numbers. Little-known species, and nothing known of its breeding biology; much research required. Known to occur in Mount Kinabalu and Gunung Mulu National Parks (Borneo).

**Bibliography.** Andrew (1992), Berlioz (1936), Davison (1992, 1997), Goodwin (1964), Greenway (1978), Holmes (1997), Inskipp *et al.* (1996), Jenkins & de Silva (1978), MacKinnon & Phillips (1993), Prieme & Heegaard (1988), Robson (1998), Smythies (1999), Stattersfield *et al.* (1998), Sujatnika *et al.* (1995), Wells (1985), Wells *et al.* (1978), Wilkinson, Dutson & Sheldon (1991), Wilkinson, Dutson, Sheldon, Noor & Noor (1991).

## 61. Yellow-crowned Barbet

### *Megalaima henrici*

**French:** Barbu à sourcils jaunes **Spanish:** Barbudo Coronigualdo  
**German:** Gelbscheitel-Bartvogel

**Taxonomy.** *Bucco henricii* Temminck, 1831, Sumatra.

Closely related to *M. armillaris* and *M. pulcherrima*, with which has sometimes been considered conspecific or to form a superspecies; all three likely also to be related to group including *M. oorti*, *M. asiatica* and *M. incognita*. Races rather poorly differentiated. Two subspecies recognized.

**Subspecies and Distribution.**

*M. h. henricii* (Temminck, 1831) - S peninsular Thailand S to Sumatra.

*M. h. brachyrhyncha* (Neumann, 1908) - Borneo.

**Descriptive notes.** 21.5-22.5 cm; 65-83 g. Green, sturdy-billed barbet with blue throat and much yellow on crown. Both sexes of nominate race with central hindcrown blue, golden-yellow from forehead extending broadly around crown over eyes; black lores and line through eye, pale green cheeks and line over eye; narrow red band on upper neck side, red mark on each side of breast at border of throat. Immature duller, bright colours paler, only forehead yellow, and base of bill pale, greyish. Race *brachyrhyncha* smaller-billed, less bright, with blue areas more violet-blue, green of ear-coverts yellower, yellow top of head less golden.

**VOICE.** Song usually a long series of phrases, each with 2-7 "tuk" notes preceded by, or sometimes followed by, brief trill, "ttrrrt"; phrases of 2-3 seconds, may sometimes lack trill note.

**Habitat.** Mainly lowland dipterocarp forest, also mixed and dipterocarp hill forest; secondary as well as primary forest; low swampy forest, cacao plantations, partly logged forest. Younger males may utilize suboptimal habitats. Below 750 m, rarely to 950 m; mainly over 200 m in Sumatra; in Borneo replaced by *M. monticola* above c. 600 m, with little or no overlap; usually found below *M. oorti*.

**Food and Feeding.** Eats fruits, mainly figs (*Ficus*); other foods not known. An individual monitored for 4 days ranged over 7.5 ha and spent 75% of time near or at fruiting *Ficus binnendykii* tree; movements primarily from that tree to canopy of a 40-m tree in which it roosted. No other information on feeding habits.

**Breeding.** Data from specimens indicate season Feb-Aug. Seen at roosting or nesting holes in canopy of trees; reported to excavate nest 9 m above ground in tree. No other information.

**Movements.** Resident, thought to be sedentary.

**Status and Conservation.** Not globally threatened. Currently considered Near-threatened. Uncommon in Thailand, fairly common in Peninsular Malaysia; seemingly more common in Sumatra and Borneo, but even so not numerous there. Widespread destruction of lowland forests is prevalent throughout its range, so occurrence at higher altitudes may prove important for survival of this species; concomitant loss of fig trees is almost certainly reducing numbers. Present in several protected areas, e.g. Khao Nor Chuchi (Thailand) and Gunung Mulu National Park (Peninsular Malaysia). Information on its biology is urgently needed.

**Bibliography.** Berlioz (1936), Bromley (1952), Chasen (1939), Deignan (1963), Glenister (1971), Goodwin (1964), Greenway (1978), Holmes & Burton (1987), Jeyarajasingam & Pearson (1999), Lambert (1989a, 1989b), Lekagul & Round (1991), MacKinnon & Phillips (1993), van Marle & Voous (1988), McClure (1966), Medway (1972), Medway & Wells (1976), Riley (1938), Robinson (1928), Robinson & Chasen (1939), Robson (2000), Round (1988), Smythies (1999), Stattersfield & Capper (2000), Thiollay (1995), Thompson (1966), Wells (1985, 1999), Wells *et al.* (1978), Wilkinson, Dutton & Sheldon (1991).

## 62. Flame-fronted Barbet

### *Megalaima armillaris*

**French:** Barbu souci-col **German:** Temminckbartvogel **Spanish:** Barbudo Coroniazul  
**Other common names:** Orange-fronted(!)/Blue-crowned Barbet

**Taxonomy.** *Bucco armillaris* Temminck, 1821, Java.

Closely related to *M. henricii* and *M. pulcherrima*, with all three sometimes thought to be conspecific or to form a superspecies; all are apparently related also to group including *M. oorti*, *M. asiatica* and *M. incognita*. Races not well differentiated; E Javan birds intermediate in size between those of W Java and those of Bali. Two subspecies recognized.

**Subspecies and Distribution.**

*M. a. armillaris* (Temminck, 1821) - Java.

*M. a. baliensis* (Rensch, 1928) - Bali.

**Descriptive notes.** 20-21.5 cm; 63-74 g. Smallish, heavily set green barbet with stout bill, and extensive yellow to orange forehead. Both sexes of nominate race have yellowish-orange from forehead and forecrown, blue mid-crown to nape, black line through eye, black at front of malar; gold to orange mark on each side of lower neck, and golden-orange across upper breast. Immature duller, areas of yellow-orange and blue paler, smaller. Race *baliensis* slightly larger, with forehead slightly more red-orange or brown-orange, and a similar tendency on sides of neck and breast. **VOICE.** Song a series of short trills, "t-t-t-rrr", repeated end-

lessly; also single buzzy "ttrrr" note.

**Habitat.** Primary lowland and hill forest, edges, fruiting trees in nearby gardens and plantations; found at all levels up to c. 2500 m, commonest above 600 m.

**Food and Feeding.** Fruits, including coffee fruits, also some insects; spiders also recorded. In captivity, nestlings eat mealworms, crickets and young mice.

**Breeding.** Feb-Jul, also Sept-Jan; possibly double-brooded. Courtship feeding occurs. Nest excavated high in tree; in captivity, both adults excavate cavity to 35 cm deep, completed in 1 month. Eggs 2; in captivity, incubation by both parents, period 13-15 days, female aggressive to male after hatching, young fed by both parents, 1 tapping on outside results in other leaving; hand-reared young open eyes at c. 14 days, feathers emerge at 17 days, first flight at c. 37 days. Captive pair produced 3 clutches each of 2 eggs, hand-rearing resulting in 3 healthy immatures.

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. Restricted-range species: present in Java and Bali Forests EBA. Generally not uncommon, and is the commonest barbet in Java and Bali. Appears somewhat adaptable. Information required on species' ecology and biology in the wild. Present in Gunung Gede-Pangrango National Park and, apparently rare, in Aas Purwo National Park (Java).

**Bibliography.** Andrew (1985, 1992), Berlioz (1936), Goodwin (1964), Grantham (2000), Hellebrekers & Hoogerwerf (1967), Hoogerwerf (1969), Kuroda (1933), MacKinnon (1988), MacKinnon & Phillips (1993), Marshall & Marshall (1871), Mason & Jarvis (1989), Mees (1996), Nijman & Sözer (1996), Parr (1996), Sargeant (1997), Stattersfield *et al.* (1998), Sujatnika *et al.* (1995), Wells (1985).

## 63. Golden-naped Barbet

### *Megalaima pulcherrima*

**French:** Barbu élégant **German:** Prachtbartvogel **Spanish:** Barbudo Elegante  
**Other common names:** Golden-rumped/Kinabalu Barbet

**Taxonomy.** *Megalaima pulcherrima* Sharpe, 1888, Mount Kinabalu, Borneo.

Closely related to *M. henricii* and *M. armillaris*, and all three have been considered conspecific or to form a superspecies; all appear also to be related to group that includes *M. oorti*, *M. asiatica* and *M. incognita*. Monotypic.

**Distribution.** N Borneo mountains, from Kinabalu and Trus Madi S to Mulu and Murud.

**Descriptive notes.** 20-21.5 cm; 55-76 g. Distinctive, strong-billed, smallish green barbet of mountains. Male with blue from forehead to hindneck, blue throat, gold patch on upper mantle at edge of hindneck; black lores to just behind eye, edged blue; face green, but green-gold over eye. Female perhaps paler gold and blue. Immature duller generally, lacking any gold. **VOICE.** Song of 3-note phrases, "chut-chut-chittt", variably long, at 18-25 phrases per minute, ending in 2-note phrases, "chutt-chut" or "chew-chew"; another a series of short trills, "ttrrrt", or trill-note phrases, "ttrrr-ttrrr-ttrrrt", each with 1-3 short trill notes followed by

longer one; also a "twaak" call in short series.

**Habitat.** Montane primary and secondary forest, moss-clad forest, edges and adjacent partly cut-over areas. At 1000-3100 m; usually above 1500 m, and thus at higher levels than *M. eximia* and *M. monticola*, on Mt Mulu above latter at 1320-1650 m.

**Food and Feeding.** Little known. Meagre data from stomach contents indicate fruits and berries, and a "green shoot". Forages in mid-storey and canopy.

**Breeding.** Data from specimens indicate season Dec-Mar. No other data available.

**Movements.** None known; presumably resident.

**Status and Conservation.** Not globally threatened. Restricted-range species: present in Bornean Mountains EBA. No information on relative abundance, but appears to be rather local. Its upland forest habitat is less threatened than forest at lower elevations. Known to occur in Mount Kinabalu and Gunung Mulu National Parks (Borneo). Although species is in no immediate danger, it is very poorly known; in view of its restricted highland range, data on its ecology and biology are needed in case future action is required for its conservation.

**Bibliography.** Anderson *et al.* (1982), Anon. (2000), van Balen (1997), Berlioz (1936), Davison (1992), Goodwin (1964), Holmes (1997), Jenkins & de Silva (1978), MacKinnon & Phillips (1993), Robson (1996b), Smythies (1999), Stattersfield *et al.* (1998), Strange (2000), Wells (1985), Wells *et al.* (1978).

## 64. Blue-eared Barbet

### *Megalaima australis*

**French:** Barbu à calotte bleue **German:** Blauohr-Bartvogel **Spanish:** Barbudo Variable  
**Other common names:** Crimson-browed/Little Barbet; Large-billed Barbet ("robustirostris")

**Taxonomy.** *Bucco australis* Horsfield, 1821, Java.

Closely related to *M. eximia*, these together comprising the so-called "*Mesobucco* group". Races and "population groups" connected by intermediates; some authors suggest race *orientalis* possibly better lumped within *cyanotis*. Birds from S Myanmar and SW and peninsular Thailand often treated as race *stuarti*, but apparently no more than intermediate form between *cyanotis* and *duvaucelii*. Other described forms include *heberteri* from Bali, considered synonymous with nominate; *borneonensis* from Borneo and *robinsoni* from S Peninsular Malaysia, synonymized with *duvaucelii*; and *invisa* from NW Thailand, synonymized with *cyanotis*. Form described from Assam as "*robustirostris*" long considered a separate species, but apparently matched by specimen from Laos, and these probably represent immature birds of present species. Six subspecies currently recognized.

**Subspecies and Distribution.**

*M. a. cyanotis* (Blyth, 1847) - SE Nepal E to E Bangladesh and NE India, S China (Yunnan), Myanmar (except N & E) and NW Thailand S to N Malay Peninsula.

*M. a. orientalis* (Robinson, 1915) - E Thailand, Cambodia, Laos and Vietnam.

*M. a. duvaucelii* (Lesson, 1830) - Peninsular Malaysia, Sumatra, Bangka and Borneo.

*M. a. gigantorhina* (Oberholser, 1912) - Nias I, off W Sumatra.

*M. a. tanamassae* (Meyer de Schauensee, 1929) - Batu Is, off W Sumatra.

*M. a. australis* (Horsfield, 1821) - Java and Bali.

**Descriptive notes.** 16-17 cm; 26-39 g. Small, green, stout-billed barbet with blue crown and throat, black band between throat and breast. Both sexes of nominate race with blue forehead and crown, yellow ear-coverts and cheeks framed by black eyestripe and moustachial line, black lores; blue throat with black band below, and yellow-gold across breast. Immature duller, head mainly green, lacking pattern and bright colours, bill and orbital skin paler. Races differ mainly in detail and colours of head and breast patterns, variation complex, all lacking yellow on ear-coverts: *cyanotis* with black forehead, blue mid-crown and green

hindcrown, orange-red cheek patch, blue ear-coverts with red above and below, blue throat with narrow black border, no yellow-gold on breast; *orientalis* similar, but slightly larger and paler overall, commonly with narrow red patch across upper breast; *duvaucelii* with black forehead, black ear-coverts with larger red patches above and below, red cheek patch, pale loreal spot, much broader black band on upper breast, some with some red below the black. **VOICE.** Several, variable

"songs", e.g. a series of double "ta-trrrrt" to "tu-tuuk" notes at 96-132 per minute, at times for minutes on end, sometimes ending in pigeon-like "ooooooo", or with single notes interspersed, or as full, single-noted song at 180 notes per minute; also so-called "police-whistle" song, a trilling but burred "tiirrt,tiirrt,-"; grating notes in encounters, irregular series of "teeow" notes, chittering or chattery notes resembling begging calls, and fast trills and series of piping notes.

**Habitat.** Primary forest and edges in lowlands and foothills; mainly evergreen forest, but may move into regrowing and patchy forest, and visit plantations, gardens, bamboo and deciduous forest. Generally below 1200 m, and below 1000 m in Borneo, Bali and Peninsular Malaysia, but to 1500-1600 m in parts of SE Asia and Sumatra, and to 2000 m in Java.

**Food and Feeding.** Fruits, including figs and others, also reportedly insects. Feeding behaviour not reported. Gathers in numbers of up to c. 100 at fruiting trees in Thailand.

**Breeding.** Feb-Jun in much of range; from Jan in Vietnam, Mar-Sept in Thailand, Jan-Jul in Peninsular Malaysia, and Feb-Oct in Sumatra and its islands, Java and Borneo. Sings incessantly, pair-members simultaneously; head-bobbing, side-to-side tail movement in aggressive or courtship displays; courtship-feeds fruits repeatedly before copulation. Nest excavated in dead trunk or branch, often on underside of branch, at up to 25 m, mostly at 3-12 m; may excavate in old woodpecker hole; once beneath arboreal carton-ant nest; 1 nest had entrance hole 3 cm wide, vertical tunnel 20-5 cm deep. Eggs 2-4; incubation and nestling periods, and roles of parents, undocumented.

**Movements.** Resident; generally territorial and sedentary, but some post-breeding movements occur to fruiting sources, including into habitats not used for breeding.

**Status and Conservation.** Not globally threatened. Often one of the commonest of barbets; common in SE Asia, and common in Greater Sundas; scarce and very local in Nepal, and uncommon in India; fairly common locally in Bhutan, and local in Bangladesh. Appears to be adaptable. Present in numerous protected areas, e.g. Kaziranga National Park (India), Kaeng Krachan and Khao Yai National Parks (Thailand), Nam Bai Cat Tien National Park (Vietnam) and Way Kambas National Park (Sumatra).

**Bibliography.** Ali (1977), Ali & Ripley (1983), Ali *et al.* (1996), Baker (1934a), Deignan (1941, 1945, 1963), Delacour & Jabouille (1931), Eames & Ericson (1996), Eames *et al.* (1994), Fleming & Traylor (1968), Glenister (1971), Grimmett *et al.* (1998), Hellebrekers & Hoogerwerf (1967), Inskipp, C. & Inskipp (1991), Inskipp, T. *et al.* (1996), Jeyarajasingam & Pearson (1999), Laman *et al.* (1996), Lambert (1989a), Lekagul & Round (1991), MacKinnon & Phillips (1993, 2000), Madoc (1976), van Marle & Voous (1988), McClure (1966, 1974), McClure & Bin Othman (1965), Medway & Wells (1976), Mees (1996), Riley (1938), Ripley (1944, 1953, 1982), Robinson (1927, 1928), Robinson & Chasen (1939), Robson (2000), Robson *et al.* (1989), Round (1988), Smythies (1986, 1999), Stepanyan (1995), Thiollay (1995), Thompson (1966), Vo Quy & Nguyen Cu (1995), Wells (1999), Wells *et al.* (1978), Wilkinson, Dutton & Sheldon (1991), Zhao Zhengjie (1995).

## 65. Bornean Barbet

### *Megalaima eximia*

**French:** Barbu à gorge noire **German:** Schwarzkehl-Bartvogel **Spanish:** Barbudo Eximio  
**Other common names:** Black-chinned/Black-throated(!)/Crimson-crowned Barbet

**Taxonomy.** *Mesobucco eximius* Sharpe, 1892, Mount Dulit, Borneo.

Closely related to *M. australis*, the two comprising the so-called "*Mesobucco* group". Racial separation of Mt Kinabalu population uncertain, based principally on blue throat colour, but this may be indicative of subadult, and more or less matched by probable subadult specimens from elsewhere in species' range, where also some with mostly blue or mixed throat colour; also, individuals have been seen on Mt Kinabalu with black throat, as adults in rest of range; further research required. Two subspecies tentatively recognized.

**Subspecies and Distribution.**

*M. e. cyanea* (Harrison & Hartley, 1934) - Mt Kinabalu.

*M. e. eximia* (Sharpe, 1892) - mountains of N, NW & C Borneo, from Trus Madi and Brassey Range SW to Poi, Penrissen and Niut, and S to Barito Ulu.

also a fast trill call.

**Habitat.** Wet mountain forest, keeping mostly to canopy. Most specimens from altitudes of 900-1387 m, but occurs down to 370 m in places; generally below *M. pulcherrima*, approximately at elevations of much larger *M. monticola*.

**Food and Feeding.** Data very meagre; figs and other fruits known to be included in diet. Generally feeds in canopy.

**Breeding.** Possibly May-Oct or later. Singer puffs out throat and turns head side to side. Nest and eggs undescribed, and no information on other aspects of breeding.

**Movements.** Resident, presumably sedentary.

**Status and Conservation.** Not globally threatened. Restricted-range species; present in Bornean Mountains EBA. Uncommon, and very poorly known, but occurs in more montane parts of Borneo than does either of that island's 2 other endemic montane capitonids, *M. monticola* and *M. pulcherrima*, e.g. Mount Kinabalu and Gunung Mulu National Parks. Requires further research and, in view of the little that is known about it, should probably be monitored.

**Bibliography.** Anderson *et al.* (1982), Andrew (1992), Berlioz (1936), Davison (1992), Gore (1968), Harrison & Hartley (1934), Holmes (1997), Jenkins & de Silva (1978), MacKinnon & Phillips (1993), Prieme & Heegaard (1988), Smythies (1999), Stattersfield *et al.* (1998), Sujatnika *et al.* (1995), Wells (1985), Wilkinson, Dutton & Sheldon (1991), Wilkinson, Dutton, Sheldon, Noor & Noor (1991).

## 66. Crimson-throated Barbet

### *Megalaima rubricapillus*

**French:** Barbu à couronne rouge **German:** Malabarschmied **Spanish:** Barbudo Capirojo

**Other common names:** Small Barbet; Ceylon Small/Sri Lanka Small/Crimson-fronted Barbet (*rubricapillus*)

**Taxonomy.** *Bucco rubricapillus* J. F. Gmelin, 1788, Sri Lanka.

Closely related to *M. haemacephala*, with which forms the so-called "*Xantholaema* group". Race *malabarica* well marked, sometimes treated as a distinct species; vocalizations, however, very similar to those of nominate. Species name formed from Latin adjectival stem and Latin noun, and must be treated as a noun in apposition, so is therefore indeclinable; modification to "*rubricapilla*" is thus unjustified. Two subspecies currently recognized.

**Subspecies and Distribution.**

*M. r. malabarica* (Blyth, 1847) - SW India (Goa S to S Kerala and W Tamil Nadu).

*M. r. rubricapillus* (J. F. Gmelin, 1788) - Sri Lanka.

**Descriptive notes.** 16-17 cm; 32-42 g. Small, chunky, green barbet with reddish legs and feet. Male nominate race with red forehead, gold over and under eye, black line through eye, all bordered by posterior black band, and behind that some blue that extends around to meet blue of malar; golden-orange throat, orange-red breast marks. Female less bright orange-red on breast. Immature duller, lacking bright markings, paler on throat. Race *malabarica* larger, without gold, has red of forehead extending over forecrown and over entire face, malar and throat to breast, sometimes shows faint streaking below. Voice. Song

a series of groups of 4-12 "tok" or "ta" notes at 2-4 per second, with pause of c. 1 second between groups; nominate race usually faster, more trill-like groups, notes at c. 8 per second; variable, 3-12 notes in a group, 10-30 groups per series, the song or series lasting 30 seconds or longer, sometimes for 5 minutes or more; "cheen-cheen" during copulation, also used in interactions; soft "kwank" notes when feeding together; begging young give "kuk" notes in series, and tap inside nest-cavity.

**Habitat.** Inhabits evergreen forest, forest edges, plantations of fruiting trees, and remnant forest patches, extending into agricultural areas with trees, and gardens; in Sri Lanka also occurs locally along streams, in drier areas; present at up to c. 1300 m. Where range overlaps with that of *M. haemacephala*, the two tend to be separated by habitat, present species being more closely linked to forest.

**Food and Feeding.** Figs, such as those of banyan and bo trees, also other fruits, berries; small insects, including caterpillars, borer larvae, ants and winged termites; unidentified insects fed to young. Congregates at fruiting trees in groups of up to at least 30 individuals. In one study in S India, present species preferred much smaller fig species (*Ficus tsiela*, *F. retusa*, *F. gibbosa*) than did *M. viridis*; animal food constituted c. 20% of dietary items of present species. When feeding on figs, pecks repeatedly at the fruit rather than swallowing it whole.

**Breeding.** Dec-May in India, where c. 50% of pairs double-brooded; Dec-Sept in Sri Lanka. Much courtship feeding. Nest excavated by both adults, for c. 18 days, 8-20 m above ground in underside of thin branch, often below previous year's nest; average measurements 3.85 cm entrance, 17 cm depth, 7.25 cm chamber diameter, but cavity to 1.5 m in trees such as *Erythrina*, *Artocarpus*, *Poinciana*, *Shorea* and coconut; nests well apart, unusually as close as 70 m. Eggs 2-3, usually 2, laid within 3-5 days; female incubates at night, both sexes by day, change-overs with "cheen" calls, period 14-15 days; both adults feed young, regurgitate insects and fruits for c. 4 days, then shift to fruits, rate 2-4 feeds per hour, increasing to c. 13 per hour before fledging; young brooded at first, especially during rain, faecal sacs removed first hourly, later c. 5 times an hour, weight gain of chicks 1.4 g per day to 21 days, then decreases, then remains steady to fledging, at 35-37 days; adults withhold food to encourage fledging; fledglings return to nest with adults for only 2-4 days, then independent and disperse out of area; adults reneat 4-6 days after fledging of first brood. Fledging success over 50 %; greatest cause of failure is attacks by *M. viridis*, which enlarges nest entrance, removes eggs or young; nest often destroyed by *M. viridis* or *M. zeylanica* if in large branch or near their nests.

**Movements.** Resident; mainly sedentary, some feeding outside territory, young disperse away from territory.

**Status and Conservation.** Not globally threatened. Common but local in Indian part of range; common in Sri Lanka in wet lowlands, more local in dry zone. Appears reasonably adaptable, at least in India; in Kerala has adapted to man-altered habitats, and is able to thrive well in plantations and in farmed areas; in Sri Lanka, habitat degradation and destruction are considered possible threats, especially where enforcement of conservation laws and protection of national parks are placed low among priorities. Present in several protected areas, e.g. Indira Gandhi and Periyar National Parks (India), and Sinharaja Forest Reserve and Uda Walawe National Park (Sri Lanka).

**Bibliography.** Abdullali (1974), Ali (1969, 1996), Ali & Ripley (1983), Baker (1934a), Berlioz (1936), Chakravarthy & Purna Chandra Tejasvi (1992), Daniels, R.J.R. (1997), Gokula & Vijayan (1997), Grimmett *et al.* (1998), Grubb & Ali (1970), Harrison (1999), Henry (1998), Inskipp *et al.* (1996), Kannan (1998), Kazmierczak (2000), Lamsfuss (1998), Legge (1983), Phillips (1978), Ripley (1982), Saha & Dasgupta (1992), Sugathan & Varghese (1996), Whistler (1944), Yahya (1980, 1987, 1988, 2000), Zacharias & Gaston (1999).

## 67. Coppersmith Barbet

### *Megalaima haemacephala*

**French:** Barbu à plastron rouge **German:** Kupferschmied **Spanish:** Barbudo Calderero  
**Other common names:** Crimson-breasted/Crimson-headed Barbet

**Taxonomy.** *Bucco haemacephalus* P. L. S. Müller, 1776, Philippine Islands.

Closely related to *M. rubricapillus*, with which forms the so-called "*Xantholaema* group". Forms described from peninsular India, *confusa* from NW and *lutea* from SE, synonymous with *indica*. Nine subspecies currently recognized.

**Subspecies and Distribution.**

*M. h. indica* (Latham, 1790) - NE Pakistan E to S China, S to Sri Lanka, Singapore and Vietnam.

*M. h. delica* (Parrot, 1907) - Sumatra.

*M. h. rosea* (Dumont, 1816) - Java and Bali.

*M. h. haemacephala* (P. L. S. Müller, 1776) - N Philippines: Luzon, Mindoro.

*M. h. homochroa* Dziadosz & Parkes, 1984 - Tablas, probably Romblon, possibly Masbate.

*M. h. celestini* Gilliard, 1949 - Catanduanes, Biliran, Samar, Leyte.

*M. h. intermedia* (Shelley, 1891) - C Philippines: Panay, Guimaras, Negros.

*M. h. cebuensis* Dziadosz & Parkes, 1984 - Cebu.

*M. h. mindanensis* Rand, 1948 - Mindanao.

**Descriptive notes.** 15-17 cm; 30-53 g. Small, chunky, green barbet with streaked underparts, and reddish legs and orbital skin. Male nominate race with red forehead and fore-crown, yellow above and below eye, black eyestripe and moustache, all bordered at rear by black band, with some greyish-blue behind that; chin and throat yellow, red patch on lower throat and upper breast. Female less bright red, has yellow in red breast mark. Immature lacks all red at first, is streaky onto throat, has much paler bill. Races form two basic groups: *indica*, *delica*, *celestinoi* and *mindanensis* with yellow above and below

eye, and yellow chin and throat, like nominate, but these areas wholly or mainly red in *rosea*, *homochroa*, *intermedia* and *cebuensis*; within the two groups, racial differences involve shades of colour, width of breastband and black crownband and their degree of intrusion with respectively yellow and bluish, and small size differences. **VOICE.** Song given persistently through day, on moonlit nights, long series of "tok" or "took" or "tonk" notes, tempo varies greatly, 80-200 per minute, but usually slower and lacking pauses compared with that of *M. rubricapillus*; Nepalese and Philippine songs closely similar; song-like notes also as alarm, and in aggression; also "kuank" notes in short series when feeding together, aggressive grating notes, and young beg with "tuk-tuk-" calls.

**Habitat.** Edges of moist forest, drier deciduous forest, scrub and secondary forest, plantations of diverse trees, mangroves, casuarinas, gardens and fruit trees in villages and even cities, extending into wet forest clearings and areas around logging camps; often breeds along roadsides, in village gardens, or orchards. Generally below 1500 m, to 1830 m in Nepal; rarely reaches 2200-2250 m in Sumatra and Luzon. Overlaps with *M. rubricapillus*, though usually separated ecologically, present species generally occurring in more open, drier habitats.

**Food and Feeding.** Diverse fruits, including figs, pipal fruits, guavas, mangoes, custard-apples, berries; also crickets, beetles, mantids and various insect larvae. In one study in WC India, present species appeared to prefer much smaller fig species (*Ficus gibbosa*, *F. infectoria*, *F. religiosa*) than did *M. zeylanica*. Captives thrive on figs, grapes, lantana berries, mulberries, bananas, milk and

roaches. Feeds at all levels; hawks for flying termites and moths, and works over bark of trees for insects. Gathers at some fruiting trees in numbers of up to 70.

**Breeding.** Jan-Oct in Pakistan, India and Nepal, often double-brooded; generally Feb-Jul in Himalayan region; Nov-May in Sri Lanka; Feb-Jul in SE Asia and Philippines; Apr-Oct in Sumatra and Java. Much singing, puffing throat, turning and bobbing head, flicking tail; courtship feeding frequent. Nest excavated at 1-5-13 m or higher in decayed or dead tree, branch, or fence post, trees including *Erythrina*, mango, *Melia*, *Moringa*, *Pongamia*, rubber, *Bombax* and *Cochlospermum*; new cavity excavated yearly, or female may commence new cavity or enlarge old one following breeding, this then completed in breeding season; cavity entrance 3-8-5 cm, depth 15-80 cm. Eggs 2-4, usually 3; incubation by both parents, for 12-14 days; nestlings fed by both parents, brooded, faecal sacs removed from nest area, nestling period c. 35 days; at least in India fledglings independent at fledging; adults may then begin second brood; fledglings often disperse together, are attracted to other pairs still nesting and are chased away. Breeding success often affected by *M. viridis*, which may evict adults or enlarge and ruin holes.

**Movements.** Generally resident; possibly some migration in NW of range, in Pakistan.

**Status and Conservation.** Not globally threatened. Widespread and common almost throughout range, may be world's commonest barbet; uncommon in Bhutan. Adaptable non-forest species, showing preference for man-altered habitats; able to survive in variety of habitats, including in urban areas. Assisted by forest clearance and logging; since 1930's has invaded C & S Peninsular Malaysia, even colonizing heavily urbanized Singapore. Present in numerous protected areas, e.g. Keoladeo Ghana National Park (India), Nam Bai Cat Tien National Park (Vietnam), Kuala Selangor National Park (Peninsular Malaysia), Way Kambas National Park (Sumatra), Baluran National Park (Java) and Bali Barat National Park (Bali).

**Bibliography.** Ali (1969, 1977, 1996), Ali & Ripley (1983), Ali *et al.* (1996), Baker (1934a), Bharos (1997), Danielsen *et al.* (1994), Deignan (1945, 1963), Delacour & Jabouille (1931), Dhindsa *et al.* (1986), Dickinson *et al.* (1991), Dilger (1953), Dziadosz & Parkes (1984), Eames & Ericson (1996), Échécopar & Hue (1978), Gilliard (1949b), Glenister (1971), Grimmett *et al.* (1998), Harrison (1999), Hellebrekers & Hoogerwerf (1967), Holmes (1996), Inskipp & Inskipp (1991), Jeyarajasingam & Pearson (1999), Lekagul & Round (1991), MacDonald (1960), MacKinnon & Phillips (1993, 2000), Madoc (1976), van Marle & Voous (1988), McClure (1998), Medway & Wells (1976), Mukherjee (1995), Muthukrishnan & Sundarababu (1982), Neville (1973), Phillips (1978), Rabor (1977), Rand (1948), Riley (1938), Ripley (1982), Roberts (1991), Robson (2000), Round (1988), Rutgers & Norris (1977), Smythies (1986), Stepanyan (1995), Thiollay (1995), Tooth (1901), Vo Quy & Nguyen Cu (1995), Wells (1999), Whistler (1941), Whistler & Kinnear (1935), Wingate (1953), Yahya (1980, 1988, 2000), Zhao Zhengjie (1995).

PLATE 14

inches 3  
cm 8

## Subfamily CAPITONINAE

### Genus *CAPITO* Vieillot, 1816

#### 68. Scarlet-crowned Barbet

##### *Capito aurovirens*

**French:** Cabézon oranvert **German:** Olivrücken-Bartvogel **Spanish:** Cabezón Oliva  
**Other common names:** Plaintive Barbet

**Taxonomy.** *Bucco aurovirens* Cuvier, 1829, Peru.

No apparent close relatives. Monotypic.

**Distribution.** SE Colombia E to NW Brazil (E to R Negro), and S through E Ecuador to CE Peru and W Brazil (E & S to Tefe and Acre).

**Descriptive notes.** c. 19 cm; 46-75 g. Green-olive barbet with orange-yellow throat to breast, whitish chin. Male with red crown to nape, some black in olive lores, olive-green ear-coverts, lower underparts olive, grey and yellow. Female with white crown, becoming olive on hindcrown. Immature duller, greyer olive, throat yellow; crown olive, male with traces of red, female with white. **VOICE.** Song a series of low "ttrou" or "ttdoot" notes, effect that of frog or toad calling, some notes more hoarse, croaking, at c. 1-75 per second for up to 9 seconds; sexes sing together, one slower, croaking notes, other faster, clearer; also faster, short, more trilling "twot-twot-" at 3-4 notes per second; several calls, grating-like. Loud wing-rustling during encounters.

**Habitat.** Near water in seasonally flooded várzea forest, floodplain low forest, forest swamps, forest transitional to dryland forest, and secondary forest, using all levels from ground to canopy. Extends upwards only to 500-600 m along Andean foothills.

**Food and Feeding.** Berries, fruits, some insects, details unknown; captives eat beetles, earwigs, mealworms. Gleans in foliage, on branches and twigs, probes into dead leaf clusters. Uncommonly with mixed-species foraging flocks.

**Breeding.** Jan-May in Colombia and Ecuador; Jul-Aug, also Apr and Dec, in Peru; probably Dec onwards in Brazil. Countersinging occurs, singer twitches wings with notes, points bill downwards, turns head side to side. Nest, eggs and all other data on breeding undescribed. Longevity over 5 years in captivity.

**Movements.** Presumably resident.

**Status and Conservation.** Not globally threatened. Overall reasonably common; common in Colombia; fairly common to common in Ecuador, and especially numerous at Limoncocha; fairly common in Peru. Adapted to shifting habitats; probably occupies many riverine islands where undisturbed. Present in several protected areas, e.g. Cuyabeno Reserve (Ecuador).

**Bibliography.** Berlioz (1937), Best *et al.* (1997), Bloch *et al.* (1991), Butler (1979), Chapman (1926), Clements & Shany (2001), Gyldestolpe (1945a), Haffer (1978), Hilty & Brown (1986), Meyer de Schauensee (1949, 1964, 1966, 1982), Norris (1950), Olog (1968), Parker *et al.* (1982), Remsen & Parker (1983, 1984a), Remsen *et al.* (1993), Ridgely & Greenfield (2001), Rodner *et al.* (2000), Rutgers & Norris (1977), Shifter (1962, 1967), Sick (1985, 1993), Stotz *et al.* (1996), Webb (1950).

#### 69. Scarlet-belted Barbet

##### *Capito wallacei*

**French:** Cabézon du Loreto **German:** Loreto bartvogel **Spanish:** Cabezón de Loreto  
**Other common names:** Wallace's Scarlet-belted Barbet

**Taxonomy.** *Capito wallacei* O'Neill *et al.*, 2000, c. 77 km WNW of Contamana, Loreto, Peru. No very close relatives apparent; possibly closest to *C. quinticolor*, *C. hypoleucus* or *C. niger*, but further research required. Monotypic.

**Distribution.** NC Peru E of Andes: known only from isolated low plateau NW of Contamana, between R Huallaga and R Ucayali.

**Descriptive notes.** c. 19.5 cm; 65-78 g. Distinctive black, white, yellow and red barbet. Male has red cap, with red extending to middle of back, white and yellow mid-back to uppertail-coverts; white line over eye, narrow black bar on forehead, black band on lores through eye to black side of neck; malar region and throat to upper breast white, broad red breastband, lower breast to belly golden to yellow, with olive, orange or even red admixed at sides. Female differs from male only in having some white spots in black below eye, and buff to yellow or white marks forming a line on outer scapulars; 1 female with

several black spots at lower edge of red breastband. Immature unknown. **VOICE.** Song a fast, low-pitched trill of c. 2 seconds, "tddddd-", resembles distant woodpecker drumming at fast rate; trill suggests songs of *Eubucco* and *C. brunneipectus*; guttural call notes, "grrrakk", suggest those of *C. hypoleucus*.

**Habitat.** Montane and submontane forest, wet and moss-festooned, some of it stunted, 1350-1500 m. Occurs above elevation at which *C. niger* is found.

**Food and Feeding.** Fruits and their seeds; most likely insects, as well. Occurs in mixed-species foraging flocks, at up to 10 m in trees.

**Breeding.** Moults and gonadal condition of Jul specimens indicate season probably Mar-May. Nest and eggs undescribed, and no other information.

**Movements.** Resident and sedentary.

**Status and Conservation.** Not globally threatened. Species' conservation status uncertain, as its discovery so recent; should probably be considered Vulnerable. Discovered only in Jul 1996, and currently known only from 1 very small and isolated area in NC Peru; has not been located in other areas of Peru, and is probably a relict of formerly larger population. Population size uncertain, but evidently small, although species is fairly common at type locality. Any human modification of habitat and any development and forest clearance in its limited range would be likely to endanger it.

**Bibliography.** Anon (2001), Clements & Shany (2001), Lane (2000), O'Neill *et al.* (2000), Parr (2000).

#### 70. Spot-crowned Barbet

##### *Capito maculicoronatus*

**French:** Cabézon à calotte tachetée **German:** Tropfenbartvogel **Spanish:** Cabezón Pechiblanco

**Taxonomy.** *Capito maculicoronatus* Lawrence, 1861, Atlantic side of Isthmus of Panama.

Has been thought to form a superspecies with *C. squamatus*, but, although sharing some plumage patterns, probably not very closely related; the two are separated geographically by divergent *C. quinticolor*. Forms described as race *pirrensis* from S Panama and NW Colombia and *melas* from Caribbean E Panama now considered indistinguishable from *rubrilateralis*. Two subspecies currently recognized.

**Subspecies and Distribution.**

*C. m. maculicoronatus* Lawrence, 1861 - W Panama (Veraguas) E to Canal Zone.

*C. m. rubrilateralis* Chapman, 1912 - E Panama to NW Colombia (E to Antioquia and S to Valle).

**Descriptive notes.** 16-18 cm; 44-66 g. Black, white and yellow barbet, mainly plain black above. Male nominate race with crown spotted brown-white; white throat, white giving way to yellow, gold or golden-orange on upper breast; mid-breast to undertail white with black spots, with yellow to golden-orange area on flanks. Female entirely black on face and throat to breast. Immature duller. Race *rubrilateralis* with narrower culmen with more grooved nostrils than nominate, more white in crown, flank mark more orange, even red. **VOICE.** Song a series of harsh "kkaaak" notes, gradually shifting to "kkaaakkk" sounds, quality similar to voice of *Semnorhis*; sometimes notes double or triple, sound like throat-clearing; sometimes two birds, possibly pair, sing together, one giving typical slow song, other using softer "kk-ggkkkk" sounds. Some sounds mechanical, possibly bill-snapping.

**Habitat.** Inhabits wet primary lowland and hill forest, and occasionally secondary forest. Occurs from sea-level generally up to 600-900 m, sporadically up to 1000 m; rarely to 1200 m in Tacarcuna area of E Panama.

**Food and Feeding.** Various drupes, other fruits, berries; also insects, such as Orthoptera. Forages in mid-storey to canopy. At times follows army ants, taking fleeing insects. Occasionally groups of up to 6, perhaps families, or up to 10 at fruiting trees.

**Breeding.** Birds in breeding condition Dec-Apr, excavating nest in Mar. in Colombia; fledged young in early Jun in Panama. Male and two females seen at a nest. No other information.

**Movements.** Mostly resident, presumed to be sedentary, though possibly a short-distance migrant in places.

**Status and Conservation.** Not globally threatened. Uncommon to locally fairly common in Panama, where perhaps most numerous in Darién zone; fairly common in Colombia. Species' dependence on forest makes it important that information be secured on its biology, to ensure that its requirements are known, should any future conservation action become necessary.

**Bibliography.** Anon. #### 71. Orange-fronted Barbet

##### *Capito squamatus*

**French:** Cabézon à nuque blanche **German:** Weißnacken-Bartvogel **Spanish:** Cabezón Escamoso  
**Other common names:** Rufous-fronted Barbet

**Taxonomy.** *Capito squamatus* Salvin, 1876, Santa Rita, Ecuador.

Has been thought to form a superspecies with *C. maculicoronatus*; shares some plumage patterns with that species, but probably not very closely related, and is separated geographically from it by divergent *C. quinticolor*. Possibly distantly related to *C. hypoleucus*. Monotypic.

**Distribution.** Extreme SW Colombia (SW Nariño) and W Ecuador (S to El Oro).

**Descriptive notes.** 16-18 cm; 56-64 g. Sturdy-billed, chunky, white-capped, largely black and white barbet. Male with orange to red frontal patch, white crown, variably brown nape; upperparts black, with broad, wavy white edging on tertials; yellowish-white chin to breast, rarely orangish on breast to belly, flanks usually lightly spotted black, with black about lower belly and vent. Female has yellow-orange patch on forehead, fine white bars or vermiculations on black of back and wing-coverts, black chin to mid-breast. Immature duller. **VOICE.** Song low-pitched, very fast, soft, purring trill to c. 4 seconds; call a noisy, single or double "tyik" or "trik"; series of these in alarm, as against snake.

**Habitat.** Inhabits wet lowland and hill forest, commonly ranging into secondary forest, forest edge, nearby cultivated areas, farms, orchards, plantations, and pastures with fruiting trees; will cross large open areas to reach isolated fruiting trees. Mainly occurs in areas below 800 m, but locally

found up to 1500 m. In area of overlap with *C. quinticolor*, the two are apparently separated by habitat, present species more readily moving into forest edge, younger second growth and plantations.

**Food and Feeding.** Diverse fruits and berries, including *Cecropia* species and *Castilla elastica*; also beetles and probably other insects. Stomach contents contained fruit alone in 77%, rest having some arthropods. Forages at all levels in bushes and trees, mainly in pairs, egesting seeds as it feeds; probes into clusters of dead leaves for insects and spiders. Joins mixed-species foraging flocks.

**Breeding.** Jul-Sept, probably earlier as well. Occasionally several males sing alternately from close to a female. Nest, eggs and other aspects of breeding activities virtually unknown; reported to excavate nest high in tree; one probable cavity nest found 4 m up in dead tree, in plantation. Up to 4 young raised by captive pair.

**Movements.** Resident and probably sedentary.

**Status and Conservation.** Not globally threatened. Currently considered Near-threatened. Restricted-range species; present in Chocó EBA. One of the least well-known barbets. No information available on numbers, but species is apparently not common in general, although considered locally quite common in Ecuador. Forest destruction and human colonization are rife within its small range. Nevertheless, although it occupies a small range and is poorly known, it does seem somewhat adaptable, readily occurring in some non-forest habitats. Present in Río Palenque Science Centre (Ecuador).

**Bibliography.** Allen (1998), Berlioz (1937), Best *et al.* (1997), Butler (1979), Chapman (1917, 1926), Hilty & Brown (1986), Jahn *et al.* (2000), Meyer de Schauensee (1949, 1964, 1966, 1982), Olrog (1968), Ortiz & Carrión (1991), Parker & Carr (1992), Remsen *et al.* (1993), Ridgely & Greenfield (2001), Ruigens & Norris (1977), Stadler (1992), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), Stotz *et al.* (1996), Strew (2000b), Terborgh & Winter (1982), Williams & Tobias (1994).

## 72. White-mantled Barbet

### *Capito hypoleucus*

**French:** Cabézon à manteau blanc

**Spanish:** Cabezón Dorsiblanco

**German:** Weißmantel-Bartvogel

**Taxonomy.** *Capito hypoleucus* Salvin, 1897, Valdivia, Antioquia, Colombia.

Appears to be rather isolated within genus; probably related distantly to *C. squamatus*, possibly more closely to newly discovered *C. wallacei* and also to *C. dayi* and *C. brunneipectus*. Racial differences rather slight. Three subspecies currently recognized.

#### Subspecies and Distribution.

*C. h. hypoleucus* Salvin, 1897 - C Andes of NW Colombia (Bolívar to Antioquia).

*C. h. carrikeri* Graves, 1986 - Botero area of R Porce, in Antioquia.

*C. h. extinctus* Graves, 1986 - Magdalena Valley in Caldas, Cundinamarca and Tolima.

**Descriptive notes.** 18-19 cm. Strong-billed, rather chunky, black, white, brown, red and yellow barbet with yellow-horn bill. Male nominate race with red forehead and crown, black side of head; black upperparts with white nape and inverted white "V" on back; white throat and malar region, pale brown breastband, rest of underparts clear yellow-white; bill pale yellow-horn. Differs from all other *Capito* in bill colour. Female has black spot on front of white malar. Immature lacks brown breastband. Racial differences slight: *carrikeri* with more yellow in white of back and underparts than nominate; *extinctus* has

somewhat browner breastband than others. Voice. Song of 15-30 "hoop" notes that rise slightly in tempo, 3-5 seconds long; call a grating "drrrrrt", resembling that of *C. squamatus*; chattering "kek-ek" and "tteeaw" notes when several feeding in same tree. Probably also bill-wiping as display.

**Habitat.** Occupies fragmented lower montane moist forest, forest patches, secondary forest, cacao and coffee plantations with fruiting trees, and forest edges; occurs at 700-1600 m, unusually lower, down to 200 m.

**Food and Feeding.** Berries, fruits, and insects; fruits identified are of *Cupania* and *Cecropia*, and mangoes; stomachs contained "seeds" of fruits, and unidentified insects and fruits. Forages in pairs or families, but several may gather at fruiting trees up to 1 km from cover; usually in canopy. Tears apart dead-leaf clusters for insects, forages among mistletoe clumps. At times joins mixed-species foraging flocks.

**Breeding.** Probably Apr-Sept; seen attending nest in late Apr. and late breeding-period moult starts May. Singer "hoops" in horizontal position, bill downwards, flicks tail up and down with notes; pair-members sing as close together as 6 cm, sing simultaneously, 2 pairs sometimes countering even in isolated fruiting tree unlikely to be within territory. Nests, eggs and other breeding details undescribed.

**Movements.** Resident; leaves territory to feed on fruits, but probably moves only locally.

**Status and Conservation.** ENDANGERED. Restricted-range species; present in Nechí Lowlands EBA. Apparently rare, but locally common; little known. Nominative race possibly extinct; *carrikeri* apparently not observed in wild since 1950. Paradoxically, *extinctus*, thought to be extinct when first described in 1986, is only race known certainly to survive: was relocated in May 1990, and several observations made since then, at a number of sites, suggest that this race is common, if local; indeed, the Serranía de las Quinchas seems to hold a healthy population, which merits further study. Within species' very small range, clearance of forest continuing, with further fragmenting of habitat and many remaining patches on steep slopes; range evidently contracting. It does, however, seem somewhat adaptable, and is by no means restricted to forest. Conservation efforts crippled by lack of knowledge of this species' breeding behaviour, roosting habits, and other ecological aspects. Recommended that protection be sought of patches of habitat as large as possible, perhaps 100 ha, with habitat corridor system connecting these, and also safeguarding of smaller patches.

**Bibliography.** Anon. (1996a), Chapman (1917), Collar & Andrew (1988), Collar, Crosby & Stattersfield (1994), Collar, Gonzaga *et al.* (1992), Graves (1986), Hilty (1985), Hilty & Brown (1986), Meyer de Schauensee (1949,

1964, 1966, 1982), Olrog (1968), Rodner *et al.* (2000), Schifter (1967), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), Stiles *et al.* (1999), Stotz *et al.* (1996), Terborgh & Winter (1982), Wege & Long (1995).

## 73. Black-girdled Barbet

### *Capito dayi*

**French:** Cabézon du Brésil

**German:** Kehlbinden-Bartvogel

**Spanish:** Cabezón Brasileño

**Other common names:** Day's Barbet

**Taxonomy.** *Capito dayi* Cherrie, 1916, Porto Velho, River Madeira, Brazil.

Possibly related to *C. hypoleucus*. Monotypic.

**Distribution.** Amazonian Brazil between upper R Madeira and upper R Tocantins, S to E Bolivia (NE Santa Cruz) and WC Mato Grosso.

**Descriptive notes.** 16-17 cm; 56-74 g. Sturdy-billed black and white barbet with black "girdle" across white underparts. Male with crimson cap, white lateral marks on back, white or yellow-white tertial patch; cinnamon throat, variably barred to unmarked; hair-tipped white breast feathers, yellowish rear flanks to lower belly, red undertail-coverts; whitish bill. Female differs in having all-black crown. Immature not described. Voice. Song a series of "hoo" or "troh" notes at 3-6 per second for up to 10 seconds, recalls that of *C. hypoleucus* and also of Striated Antthrush (*Chamaeza nabilis*); noisy "kuk" notes at c. 2

per second, also a grating rattle.

**Habitat.** Lowland and lower hill slopes in moist to wet forest canopy, ranging into secondary forest with fruiting trees; also unoccupied, old cacao plantations. Reaches upper R Paraguay system at 50-550 m.

**Food and Feeding.** Feeds mainly on fruits, including figs, *Cecropia* fruits and others, but also takes some arthropods. Typically encountered as solitary individuals or in pairs to small groups, usually high in trees; feeds at 2-30 m, mainly at 15-25 m; forages in dead-leaf clusters. Joins mixed-species foraging flocks.

**Breeding.** Poorly known. Data, mainly from Amazonia and Rondonia, suggest breeding Aug-Nov, also Feb and Jun. Sings erect with tail down, bill slightly below horizontal, throat and breast feathers erected so that hair-like-tips stand out. Nest and eggs unreported.

**Movements.** Resident, presumably sedentary.

**Status and Conservation.** Not globally threatened. No precise information available on numbers. Because of its rather restricted range, and as forest habitat becomes increasingly fragmented, the status of this species should be monitored. Information required on its breeding habits and general requirements. Known to occur in Noel Kempff Mercado National Park (Bolivia).

**Bibliography.** Anon. (1995a), Bates *et al.* (1989), Berlioz (1937), Greenway (1978), Haffer (1978, 1987, 1993a, 1997a, 1997c), Kratter *et al.* (1992), Meyer de Schauensee (1966, 1982), Naumburg (1930), Novaes (1976), Novaes & Lima (1992a), Olrog (1968), Pearman (1994a), Remsen & Traylor (1989), Remsen *et al.* (1993), Schubart *et al.* (1965), Sick (1958a, 1985, 1993), Stotz, Fitzpatrick *et al.* (1996), Stotz, Lanyon *et al.* (1997), Zimmer *et al.* (1997).

## 74. Cinnamon-breasted Barbet

### *Capito brunneipectus*

**French:** Cabézon à poitrine brune

**German:** Zimtbrust-Bartvogel

**Spanish:** Cabezón Pechipardo

**Other common names:** Brown-chested Barbet

**Taxonomy.** *Capito brunneipectus* Chapman, 1921, Villa Braga, River Tapajós, Brazil.

Was long merged in *C. niger*, but differs markedly in morphology from all races of that species, and has distinctive song; may not be related directly to *C. niger*. Monotypic.

**Distribution.** Brazil S of Amazon, between lower R Madeira and lower R Tapajós; S limit of range unknown.

**Descriptive notes.** c. 18 cm; male 58 g. Chunky-billed black, cinnamon, whitish and olive to yellow barbet. Male with dull gold top of head, black patch through eye; black back with converging yellow lines; buffy yellowish-white throat, underparts streaky olive or yellow with cinnamon breastband; bill pale grey and black. Female duller than male, has more buff-yellow markings on wings, more cinnamon throat finely spotted black. Immature undescribed. Voice. Song a rapid "hoo" trill of short notes accelerating from c. 20 to c. 40 per second, ending "brrrrrrrr"; resembles songs of *Eubucco* and *C. wallacei*.

**Habitat.** Lowland wet forest, usually in canopy.

**Food and Feeding.** Known foods are insects and other arthropods, but few stomachs examined; presumed to eat fruits as well. Climbs vines, hops on branches and twigs. Joins mixed-species foraging flocks.

**Breeding.** A male with enlarged testes was found moulting in Aug, and some birds collected were completing moult Jul-Aug; thus species possibly breeds prior to Jul, perhaps as early as Mar-Apr. No other information available.

**Movements.** Probably resident.

**Status and Conservation.** Not globally threatened. Known from only few localities, namely Boim, Igarapé, Villa Braga and Borba, and S limit of range currently unknown. Not rare near Boim. Species' small range, coupled with the fact that so little is known about its habitat requirements and breeding habits, suggests that it should be monitored; its conservation status possibly requires reassessment. It may be relevant that a genus of spiny tree rat (*Lonchothrix*) and a CITES-listed marmoset (*Callithrix humeralifer*) are among mammals with an almost identical distribution to this barbet's.

**Bibliography.** Berlioz (1937), Chapman (1921a, 1928b), Emmons (1990), Griscom & Greenway (1941), Haffer (1997c), Olrog (1968), Oren & Parker (1997), Sick (1985, 1993).

## 75. Black-spotted Barbet

### *Capito niger*

**French:** Cabézon tacheté **German:** Tupfenbartvogel **Spanish:** Cabezón Turero  
**Other common names:** Gilded Barbet (*auratus*)

**Taxonomy.** *Bucco niger* P. L. S. Müller, 1776, no locality = Cayenne. No very close allies; possibly fairly close to *C. quinticolor*. Was long considered to include *C. brunneipectus* as race, but that species differs markedly in morphology from all races of present species, and has distinctive song; the two are perhaps not related directly. Nominat race may be specifically distinct from all others, latter then constituting a separate polytypic species, *C. auratus*, but nominate *niger* may meet other races in N Brazil (Roraima); given similarity of all forms herein included in present species, combined with individual distinctiveness of all American barbet species currently recognized, it seems best to avoid such a split until studies have been carried out in areas of possible overlap in Roraima. Many races intergrade. Other races described from NW Brazil are *transiens* (upper R Negro), considered synonymous with *nitidior*, and *novaolindeae* (Nova Olinda) and *arimae* (R Purús), both treated as synonymous with *amazonicus*, possibly fitting into a cline from orange-throated *insperatus* in S towards red-throated *amazonicus* in N; birds described as race *intermedius* (WC Venezuela) inseparable from *aurantiicinctus*; forms *macintyreii* from SW Colombia and Ecuador and *conjunctus* from Peru fall within range of variation of *punctatus*. Form "*bolivianus*" known only from type specimen of unknown locality, possibly from R Beni (N Bolivia); now thought most likely to be an aberrant specimen of *insperatus*. Nine subspecies currently recognized.

#### Subspecies and Distribution.

*C. n. aurantiicinctus* Dalmás, 1900 - Venezuela in upper Orinoco region, W Bolívar and Amazonas.  
*C. n. niger* (P. L. S. Müller, 1776) - E Venezuela, the Guianas, and NE Brazil N of Amazon.  
*C. n. punctatus* (Lesson, 1830) - SC Colombia (from Meta) along lower E Andes to C Peru (Junín area).  
*C. n. nitidior* Chapman, 1928 - extreme E Colombia and S Venezuela S to near Peru-Brazil border (N of Amazon) and to lower R Japura.  
*C. n. hypochondriacus* Chapman, 1928 - N Brazil from Roraima (Maraca) S along R Branco to angle between lower R Negro and R Solimões.  
*C. n. auratus* (Dumont, 1816) - NE Peru from mouth of R Napo S along R Amazon and R Ucayali.  
*C. n. amazonicus* Deville & Des Murs, 1849 - W Brazil S of R Solimões from upper R Juruá and Tefe E to R Purús.  
*C. n. orosae* Chapman, 1928 - E Peru from R Orosa E to R Javari, S to extreme W Brazil (Cruzeiro del Sol region of Acre).  
*C. n. insperatus* Cherrie, 1916 - SE Peru, N Bolivia and W Brazil (Calama).

**Descriptive notes.** 16-19 cm; 41-72 g. Brightly patterned barbet, with spots or streaks below; much individual variation in richness of coloration. Male nominate race with red forehead, yellowish crown and nape, latter streaked dusky, whitish to straw-yellow supercilia; broad black band from lores back to neck side; upperparts black with yellowish line on each side of mantle, pale yellowish wingbar and tips of tertials; throat red, breast and belly yellow, flanks tinged olive with some black streaks. Female more heavily marked, pale flecking and edging above, more heavily spotted or streaked below. Immature duller. Races differ mainly in head colours and amount of markings below, falling into three groups: red-throated (*niger*, *nitidior*, *auratus*, *amazonicus*); orange-throated (*aurantiicinctus*, *hypochondriacus*, *insperatus*); and orange-throated with female spot-throated (*punctatus*); with *orosae* intermediate between *auratus* and *insperatus*. Voice. Song of double, sometimes single, low "hoot" notes in series for 5-60 but usually 6-20 seconds, ventriloquial, 1-2 double notes per second, increasing somewhat in tempo and dropping in volume, confusable with Blue-crowned Motmot (*Momotus momota*) song and possibly with higher-pitched, more trilling, double-noted song of *Eubucco richardsoni*; call soft "trra-trra" notes.

**Habitat.** Lowland and low hill floodplain-forest, *terra firme* forest, riverine forest in later successional stages, second growth, edges, clearings, and gardens and plantations; reaches humid lower montane forest, and mossy elfin forest in Peru; also in palms and forest patches in some savanna areas. Replaced by *C. aurovirens* in várzea and undergrowth. Up to 1000 m in Brazil, to 1600 m in Venezuela, to 1700 m in Ecuador, and locally over 1500 m in Peru.

**Food and Feeding.** Diverse fruits, such as figs, those of *Cecropia*, *Ocotea*, *Pagala plicata*, *Guarea guara*, mangoes, form up to 80% of diet; nectar at times; also various insects, e.g. grasshoppers, locusts, and spiders eaten, can represent up c. 18% of diet. Captives accepted bananas, raisins, locusts, mealworms, and young mice. Hangs, reaches, probes, peers, seeks insects in dead-leaf clusters from a nearby perch, goes over limbs and trunks where lichens growing, may tap at bark. Usually solitary, sometimes in pairs; up to 10-15 can gather at large fruiting tree. Occasionally joins mixed-species foraging flocks, working canopy to middle or lower levels. Sometimes follows Red-throated Caracaras (*Dapirius americanus*) as they hunt for wasp nests.

**Breeding.** Sept-May or later, to Jul, in N & NE of range; Mar-Nov in Colombia and Ecuador; Jun or Jul to as late as Feb in Peru to Bolivia. Display involves cocking and twisting of tail, male bouncing around female, also flutter-flight displays, chases; male sings with head arched and bill down, tail flicking upwards with each note. Pair excavates cavity at 5-12 m in tree, cavity c. 20-30 cm deep. Eggs 3-4; both parents incubate, period unknown; fledging at c. 34 days.

**Movements.** Resident, and sedentary, no movements known.

**Status and Conservation.** Not globally threatened. Commonest Neotropical barbet. In Peru, 10-5 pairs/100 ha in mature forest, 15 pairs/100 ha in transition forest, and up to 20 pairs/100 ha in late successional riverside habitat. Fairly common in Colombia; fairly common to common in Ecuador; uncommon in Peru. Voices of several races unknown. An important species, providing cavities used later by other species; if this barbet comes under threat, others will also suffer.

**Bibliography.** Berlioz (1937), Blake (1950), Bloch *et al.* (1991), Bond & Meyer de Schauensee (1943), Brodkorb (1939b), Chapman (1917, 1921b, 1926, 1928b), Cherrie (1916), Chubb (1916), Clements & Shany (2001), Foster *et al.* (1994), Friedmann (1948), Greenway (1978), Gyldestolpe (1945a, 1951), Haffer (1997c), Haverschmidt & Mees (1994), Hellmayr (1907a, 1907b, 1910, 1929), Hilty & Brown (1986), Karr *et al.* (1990), Krabbe (1991), María & Olivares (1967), Meyer de Schauensee & Phelps (1978), Moskovits *et al.* (1985), Norton (1965), Parker & Bailey (1991), Phelps & Phelps (1958), Remsen *et al.* (1993), Ridgely & Greenfield (2001), Robbins *et al.* (1987), Robinson (1997), Robinson & Terborgh (1997), Rosenberg (1997), Rutgers & Norris (1977), Schroeder (1999), Selater & Salvin (1873), Sick (1985, 1993), Snyder (1966), Stotz *et al.* (1996), Thiollay (1992), Thiollay & Jullien (1998), Tostain *et al.* (1992), Ward (1971), Willard *et al.* (1991), Zimmer (1930).

## 76. Five-coloured Barbet

### *Capito quinticolor*

**French:** Cabézon à cinq couleurs **Spanish:** Cabezón Cincocolores  
**German:** Fünffarben-Bartvogel

**Taxonomy.** *Capito quinticolor* Elliot, 1865, Colombia.

Relationships unclear, but possibly close to *C. maculicoronatus* and *C. squamatus*, and also to *C. niger*. Monotypic.

**Distribution.** W Colombia from C Chocó (Quibdó area) S to NW Ecuador (Esmeraldas).

**Descriptive notes.** 17-18 cm; 54-69 g. Rather heavy-billed barbet. Male black above, with red cap, yellow "V" on mantle, yellow wingbar and edges of tertials; white throat to breast, gold or orange on belly, with black spots on flanks. Female black above, streaked with golden-yellow, including on crown, ear-coverts and wing-coverts, markings sometimes orange; below, spotted black on white throat and breast, more streaky gold flanks, clear yellow-gold belly. Immature not described. Voice. Both sexes sing low-pitched, hollow, hoop trill of 3-8 seconds at c. 1.5 notes per second; also guttural "churr" call.

**Habitat.** Lowland wet forest, forest edges, adjacent second growth and disturbed forest, generally below c. 350 m, but locally up to c. 600 m. In area of contact with *C. squamatus*, apparently separated by habitat, present species being more closely tied to primary and mature secondary forest.

**Food and Feeding.** Mainly fruits; some insects. Forages in canopy to mid-level, at edges to understorey. Joins mixed-species foraging flocks at times, working through branches and foliage.

**Breeding.** Essentially unknown. Specimens suggest season Apr-Jul. Seen in pairs, possibly with third bird at times. Male bows, bill down, inflates throat, pumps head downwards and forwards with each note as it sings, cocks tail at times. Pair reported apparently incubating 5 m up in old woodpecker hole in tree near stream. No other information available.

**Movements.** Assumed to be sedentary.

**Status and Conservation.** Not globally threatened. Currently considered Near-threatened. Restricted-range species; present in Chocó EBA. Formerly classed as Vulnerable, but recent work shows that more forest remains in the region than had been feared. Nonetheless, species remains little known. In one study, found at linear density of 3-5 pairs/km of disturbed forest in N Ecuador. In Ecuador, first encountered only in 1990; its limited range there contains only two protected areas holding potentially suitable habitat, Cotacachi-Cayapas National Park (marginal) and Awá Ethnographic Reserve; species not yet located at either, and their effective protection seems uncertain; surveys required. Situation in Colombia apparently more encouraging, with recent records at several sites and large areas of forest remaining intact, with no immediate threats apparent. In general, and in long term, forest destruction and associated human settlement are main threats. Despite local occurrence in restricted range, species also occurs in second-growth forest and therefore not totally dependent on undisturbed habitats. Information urgently needed on its biology if it is to be monitored appropriately and effective action taken to conserve it.

**Bibliography.** Anon. (1996a), Berlioz (1937), Best *et al.* (1997), Chapman (1917), Collar *et al.* (1994), Hellmayr (1911), Hilty & Brown (1986), Jahn *et al.* (2000), María & Olivares (1967), Meyer de Schauensee (1949, 1964, 1966, 1982), Olrog (1968), Pearman (1993a), Remsen *et al.* (1993), Ridgely & Greenfield (2001), Rodner *et al.* (2000), Salaman (1994), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), Stotz *et al.* (1996), Terborgh & Winter (1982).

PLATE 15

inches 3  
cm 7

# Genus *EUBUCCO* Bonaparte, 1850

## 77. Lemon-throated Barbet

### *Eubucco richardsoni*

**French:** Cabézon à poitrine d'or **German:** Goldbrust-Bartvogel **Spanish:** Cabezón Pechiamarillo

**Taxonomy.** *Capito richardsoni* G. R. Gray, 1846, no locality = Ecuador.

No close relatives, and the only lowland member of genus. A specimen from upper R Napo (Ecuador) represents a hybrid between nominate race of present species and race *orientalis* of *E. bourcierii*. N races with blue nape sometimes combined as "richardsoni group", with yellow-naped S races referred to as "aurantiicollis group". Form from S Colombia and N Peru described as *granadensis* considered synonymous with nominate, but possibly a valid race; birds from C Peru named as race *coccineus* now considered inseparable from *aurantiicollis*. Four subspecies currently recognized.

#### Subspecies and Distribution.

*E. r. richardsoni* (G. R. Gray, 1846) - SE Colombia (S from Meta), E Ecuador and N Peru (W of Iquitos).

*E. r. nigriceps* Chapman, 1928 - NE Peru from lower R Putumayo and lower R Napo, E to extreme NW Brazil (W Amazonas N of Amazon).

*E. r. aurantiicollis* P. L. Sclater, 1858 - E Peru from R Maraón, E to W Brazil S of Amazon (E almost to R Jurúá) and S to NW Bolivia.

*E. r. purusianus* Gyldestolpe, 1941 - W Brazil S of Amazon, from R Jurúá E to upper R Madeira.

**Descriptive notes.** c. 15-5 cm; 24-40 g. Multicoloured, sharp-billed, active barbet with marked sexual dimorphism. Male nominate race with red crown, blue nape, green upperparts; chin red with variable black admixed, throat yellow, breast orange-red, belly and flanks greener and streaked dark; bill greenish-horn to yellow. Female with black line above bill, grey-blue forehead becoming green on crown, black ear patch with golden superciliary continuing around rear of patch; throat bluish, breast orange-gold, lower underparts streaked on pale blue-yellow ground colour. Immature duller, shows sexual features early.

Race *nigriceps* has back slightly more blue-green, male with black to maroon-black crown; *aurantiicollis* has yellow nape, more yellow or even orange in dorsal green, male with more gold or orange on throat; *purusianus* close to *aurantiicollis*, but male pinkish-red on breast, yellowish nuchal patch narrower. **VOICE.** Song of soft double or usually triple "hoo" notes in fast, trill-like series, c. 4 compound notes per second for 1.5-5 seconds; sometimes slower, and overall slower than in other *Eubucco*.

**Habitat.** Generally lowland forest, also dense second growth, forest edges and clearings, and forest edge of flooded várzea; reaches upper tropical hill forest, rarely to 1375 m, usually below 1100 m. Numbers greater in late forest stages near rivers and lakes than in mature forest.

**Food and Feeding.** Fruits such as those of *Cecropia* and their seeds, also grasshoppers, locusts, spiders, less often roaches; c. 37% of food arthropods. Forages, usually alone or in pairs, in canopy to mid-levels, at 12-24 m, occasionally down to 5 m. Clings to take fruits. Over one-third of feeding spent seeking insects in dead-leaf clusters, tearing these apart; often hangs upside-down. Frequently joins mixed-species foraging flocks.

**Breeding.** Season probably Feb or Apr to Nov, or somewhat earlier in S. Males countering from canopy, c. 7 songs per minute, singer bows head with notes, erects crown and nape feathers, flits tail in time with notes. Nest and eggs undescribed; territory c. 10 ha. No other information.

**Movements.** Probably sedentary.

**Status and Conservation.** Not globally threatened. Considered common in many areas; uncommon in Ecuador and Peru. Reported densities of 4-5 pairs/100 ha. Information on breeding needed in order to assess species' requirements. Probably competes with larger *Capito niger*, which often commences singing just as present species starts, causing latter to cease or to move away. Present in several protected areas, e.g. Cuyabeno Reserve (Ecuador) and Tambopata Reserve (Peru).

**Bibliography.** Berlioz (1937), Bloch *et al.* (1991), Borges *et al.* (2001), Butler (1979), Chapman (1917, 1926, 1928a), Clements & Shany (2001), Foster *et al.* (1994), Gyldestolpe (1951), Haffer (1978), Hilty & Brown (1986), Krabbe (1991), María & Olivares (1967), Meyer de Schauensee (1949, 1964, 1966), Olivares (1962), Parker & Bailey (1991), Parker *et al.* (1982), Perry *et al.* (1997), Remsen & Parker (1984a), Remsen & Traylor (1989), Remsen *et al.* (1993), Ridgely & Greenfield (2001), Robinson & Terborgh (1997), Rosenberg (1997), Schulenberg & Remsen (1982), Sick (1985, 1993), Stotz *et al.* (1996), Terborgh *et al.* (1990), Traylor (1951b).

## 78. Red-headed Barbet

### *Eubucco bourcierii*

**French:** Cabézon à tête rouge **German:** Andenbartvogel **Spanish:** Cabezón Cabecirrojo  
**Other common names:** Flame-headed/Bourcier's Barbet

**Taxonomy.** *Micropogon Bourcierii* Lafresnaye, 1845, Colombia.

Original naming of species confused, with male described first and on very next page female named as "*Micropogon Hartlaubii*". Has been thought to form a superspecies with *E. tucinkae*, and even regarded as conspecific, but the two appear to be only distantly related. Probably not closely related to other members of genus, although race *orientalis* has hybridized with nominate race of *E. richardsoni* in E Ecuador. Six subspecies recognized.

#### Subspecies and Distribution.

*E. b. salvini* (Shelley, 1891) - Costa Rica and W Panama.

*E. b. anomalus* Griscom, 1929 - E Panama (around Cerro Pirre, Cerro Tacarcuna); probably also adjacent NW Colombia.

*E. b. bourcierii* (Lafresnaye, 1845) - Andes of W Venezuela disjunctly S to C Colombia (E side of C Andes, slopes of E Andes).

*E. b. occidentalis* Chapman, 1914 - slopes of W Andes in Colombia.

*E. b. aequatorialis* (Salvadori & Festa, 1900) - W Ecuador on W Andean slope and in coastal mountains.

*E. b. orientalis* Chapman, 1914 - E Andean slope of Ecuador, and N Peru (Cajamarca, Amazonas).

**Descriptive notes.** c. 16 cm; 30-45 g. Small, pale-billed, multicoloured green barbet. Male nominate race with black around base of bill, red head and neck, narrow whitish nape band, green upperparts; red on throat and upper breast fading to yellowish on belly, flanks with greenish streaks; bill yellow. Female much duller, no red, with blue ear patch bordered with black and gold at rear, greenish-yellow throat, breast golden. Immature as respective adult but duller, can be sexed at fledging, but male retains some green on head for months. Races vary mainly in extent of red on male underparts, whether to breast or to belly, with variable orange and gold

at rear of red, in *aequatorialis* red ending sharply in yellow on breast; females vary in having forehead black or mixed black and blue, in extent and colour of yellow or orange behind ear-coverts, and in other minor ways. **VOICE.** Short, fast trill song "pooooddddddrrrrrr", notes c. 27 per second, for c. 2 seconds, ventriloquial, inconspicuous, similar to songs of *E. versicolor* and *Capito brunneipictus*; chatter call notes; young beg squeakily. Also aggressive wing-fluttering.

**Habitat.** Primary forest in undergrowth, about trails and clearings, ranging into thickets and secondary forest of wet montane tropical and subtropical areas; frequently on ridges; in cloudforest. Mainly at 1000-1800 m, but also lower, to c. 400 m in Middle America and W South America, rarely down to 200 m; to c. 2400 m in Colombia, 1900 m in Ecuador, and 2100 m in Costa Rica.

**Food and Feeding.** Fruits, berries of *Miconia*, *Myrica*, *Ocotea* and others; at feeders and in captivity, melons, tomatoes, apples, carrots, guavas, cherries, bananas; also takes flies, earwigs, beetles, caterpillars, roaches, spiders, even scorpions. Feeds at 2-15 m. Acrobatic; gleans, hovers, and hangs; seeks out dead-leaf clusters, pecking and tearing them for arthropods. Often solitary, or in pairs, aggressive; occasionally in groups of up to 8 at fruiting trees. Joins mixed-species foraging flocks.

**Breeding.** Mar-Jul from Middle America S to Colombia, Ecuador and Peru; Dec-Apr in Venezuela. Singing male fluffed head and neck feathers, dropped tail below "humped" rump, in response to playback of *E. richardsoni* song. Both members of pair excavate nest, or enlarge old woodpecker hole, at c. 0.5-2.5 m in tree or stub, or occasionally in rotten fence post; nest entrance c. 3 cm, depth to c. 18 cm. Eggs 2-5; incubation period c. 15 days; hatchling fed insects at start, nestling period 31-42 days.

**Movements.** Some downslope post-breeding movement noted in Costa Rica and Panama, probably occurs also in Ecuador.

**Status and Conservation.** Not globally threatened. Often local; fairly common in Colombia; uncommon to fairly common in Ecuador; rare and local in Peru. Since this species is inconspicuous, often silent, it could be more common than is apparent. Seems to disappear when all primary forest has been removed, hence needs to be monitored. Present in several protected areas, e.g. Tapantí National Park and Guayabo National Monument (Costa Rica), and Río Nambí Natural Reserve (Colombia).

**Bibliography.** Bartmann (1975), Berlioz (1937), Bloch *et al.* (1991), Chapman (1914b, 1917, 1926), Clements & Shany (2001), Ebert (1985, 1986), Faust (1969), Griscom (1929, 1935), Haffer (1987), Hellmayr (1911), Hilty (1997), Hilty & Brown (1986), Karr *et al.* (1990), Krabbe (1991), María & Olivares (1967), Meyer de Schauensee (1949, 1964, 1966), Meyer de Schauensee & Phelps (1978), Miller (1963), Parker & Carr (1992), Parker *et al.* (1982), Remsen & Parker (1984a), Remsen *et al.* (1993), Ridgely & Greenfield (2001), Ridgely & Gwynne (1989), Ridgway (1914), Robbins, Parker & Allen (1985), Robbins, Ridgely *et al.* (1987), Rutgers & Norris (1977), Salaman (1994), Schifter (1967), Slud (1964), Stiles (1983), Stiles & Skutch (1989), Stotz *et al.* (1996), Wetmore (1968a), Wheelwright *et al.* (1984), Worth (1938).

## 79. Scarlet-hooded Barbet

### *Eubucco tucinkae*

**French:** Cabézon de Carabaya **Spanish:** Cabezón de Carabaya  
**German:** Scharlachkopf-Bartvogel

**Taxonomy.** *Capito tucinkae* Seilern, 1913, Carabaya, Peru.

Has been thought to form a superspecies with *E. bourcierii*, and long considered conspecific, but appears to be very distinct species, only distantly allied to *E. bourcierii*. No close relatives within genus. Monotypic.

**Distribution.** E Peru from lower R Ucayali, E to W Amazonian Brazil (E to R Tejo in upper R Jurúá area of Acre) and S to W Bolivia (La Paz).

**Descriptive notes.** c. 17 cm; 40-44 g. Red-headed barbet with black chin, golden-yellow nuchal band, green upperparts with some red on mantle, yellow bill. Male with red throat with some yellow showing, red breaking into orange and yellow on lower breast, grey patch on sides impinging on red of breast, and olive-streaked flanks. Female has pale yellow throat, golden-orange band on breast, less orangey below. Immature undescribed. **VOICE.** Song a fast "oop-ooop-ooop" series at c. 6.5-7 notes per second for 2-4 seconds, much recalling Afrotropical *Tricholaema lacrymosa*, faster than song of *E. richardsoni*, can be given at 5

songs per minute; longer songs repeated sustainably by male in response to playback.

**Habitat.** Found within c. 150 m of rivers and oxbow lakes, in "zabolo", bamboos and *Heliconia* in thick understorey beneath such trees as *Cecropia*, *Cedrela odorata*, *Nectandra*, *Acacia*, *Erythrina*, *Sapium* and *Terminalia*; also occurs in overgrown, abandoned farm gardens near rivers and on river islands. From c. 150 m to, occasionally, as high as 850 m or higher along rivers emerging from Andes.

**Food and Feeding.** Diverse fruits of various figs, *Coussapoa*, *Cecropia*, *Psychotria*, *Tabernaemontana*, and others, especially of Lauraceae; also flowers or nectar of *Inga*, *Quararibea* and *Combretum*; also diverse insects, such as termites, and other arthropods. Studies indicate diet c. 60% fruits, 40% arthro-

Pods. Feeds at 2–11 m, gleaning and plucking fruits; systematically seeks dead-leaf clusters in bushes, vines and trees, probing and tearing at them for insects and other animals. Joins mixed-species foraging flocks of wrens (Troglodytidae), tanagers (Thraupidae) and others.

**Breeding.** Season possibly Jul and later in Peru. Male sings with head bowed, bill nearly touching breast. Pair excavated cavity in fig tree 1.5 m over water in Sept, nest abandoned later. No other information available.

**Movements.** Resident, and sedentary so far as is known.

**Status and Conservation.** Not globally threatened. Restricted-range species: present in Southeast Peruvian Lowlands EBA. Few data on numbers; judged to be rare in Peru. In study in Peru, maximum c. 3 pairs/100 ha in late successional *Ficus/Cedrela* forest along R Manu; fewer pairs in earlier and later successional stages. Possibly more common and adaptable than perceived, for its habitat is irregularly worked by ornithologists, and it is fundamentally a species of ever-changing, shifting river-edge habitat. Comparison could be made with *Capito aurovirens*, which occupies similar habitat to N & E of this species. Further data required on its breeding habits and requirements.

**Bibliography.** Anon. (1995a), Clements & Shany (2001), Collar, Crosby & Stattersfield (1994), Collar, Gonzaga *et al.* (1992), Foster *et al.* (1994), Haffer (1978), Meyer de Schauensee (1982), O'Neill (1969), Olrog (1968), Parker & Bailey (1991), Parker, Castillo *et al.* (1991), Parker, Parker & Plenge (1982), Remsen & Parker (1983, 1984a), Remsen *et al.* (1993), Robinson (1997), Robinson & Terborgh (1997), Stattersfield *et al.* (1998), Stotz *et al.* (1996), Terborgh, Fitzpatrick & Emmons (1984), Terborgh, Robinson *et al.* (1990), Traylor (1951b), Whittaker & Oren (1999), Williams (1995).

## 80. Versicoloured Barbet

### *Eubucco versicolor*

**French:** Cabézou élégant

**German:** Buntbartvogel

**Spanish:** Cabezón Versicolor

**Taxonomy.** *Bucco versicolor* P. L. S. Müller, 1776, Maynas, Peru.

No close relatives. Races well marked, but general patterns similar; also, they interbreed, and intermediates occur. Three subspecies recognized.

**Subspecies and Distribution.**

*E. v. steerii* (P. L. Slater, 1878) - N Peru from WC Amazonas S to N Huánuco.

*E. v. glaucogularis* (Tschudi, 1844) - E Huánuco S to N Cuzco.

*E. v. versicolor* (P. L. S. Müller, 1776) - S Peru (Cuzco, Puno) to NC Bolivia (Cochabamba).

**Descriptive notes.** c. 16 cm; 26–41 g. Small, sturdy-billed, multicoloured barbet. Male of nominate race red-capped, with narrow black around base of bill, green to blue-green upperparts; red throat, lower throat and malar blue, blue on nape; yellow on breast, red centre of lower breast, green flank streaks; eyes red, bill yellowish. Female has blue around eye, on ear-coverts and to throat, orange-gold over eye and around rear of ear-coverts; narrow red band on breast, green-blue to blue-green on lower breast. Immature shows dull or partial colouring of adult of respective sex, eyes brown. Races differ mainly in throat and

malar colours of male, and in amount and intensity of orange around ear-coverts and tone of breast colour of female: male *glaucogularis* with red upper throat, blue mid-throat, orange lower throat, yellow malar; male *steerii* with middle and lower throat yellow, yellow malar, no breastband; female more yellow-crowned. **Voice.** Song a fast, low-pitched trill c. 2 seconds long at c. 30 notes per second, given 3–5 times per minute, resembles that of allopatric *E. bourcierii*, also somewhat that of *Capito brunneipectus*.

**Habitat.** Submontane humid forest with prominent epiphytes and mosses, also old secondary forest, less often in Bolivian dry forest; occurs at 675–2225 m, more usually at 1000–2000 m.

**Food and Feeding.** Diverse fruits and their seeds c. 80% of diet; also takes beetles and other arthropods, mainly by poking and tearing at clusters of dead leaves. Usually solitary or in pairs, sometimes in company of mixed feeding flocks.

**Breeding.** All facets essentially unknown. Data from specimens suggest season Jul–Dec. Apparently territorial in pairs; male sings regularly.

**Movements.** Probably sedentary.

**Status and Conservation.** Not globally threatened. Very little known, and virtually nothing known of its breeding habits and requirements. Considered uncommon in Peru. Conservation status may need to be reassessed in view of paucity of data; possible that distinct populations could come under threat. Race *steerii*, the most distinctive of the three subspecies, is a candidate for special monitoring.

**Bibliography.** Anon. (1995a), Berlepsch & Stolzmann (1906), Bond (1954), Bond & Meyer de Schauensee (1943), Chapman (1921b), Clements & Shany (2001), Davies *et al.* (1994), Hornbuckle (1999), Meyer de Schauensee (1966, 1982), Olrog (1968), Parker & Bailey (1991), Parker *et al.* (1982), Perry *et al.* (1997), Remsen & Parker (1984a), Remsen & Traylor (1989), Remsen *et al.* (1993), Stotz *et al.* (1996), Traylor (1951b), Zimmer (1930).

## Subfamily SEMNORNITHINAE

## Genus SEMNORNIS Richmond, 1900

## 81. Prong-billed Barbet

### *Semnornis frantzii*

**French:** Cabézou de Frantzius

**German:** Aztekenbartvogel

**Spanish:** Cabezón Cocora

**Taxonomy.** *Tetragonops frantzii* P. L. Slater, 1864, surrounds of San José, Costa Rica.

Relationship with *S. ramphastinus* suggested by bill morphology, but probably not very closely related. Monotypic.

**Distribution.** NC Costa Rica (Tilaran Range) S in mountains to W Panama (W Veraguas).

**Voice.** Song commonly heard, series of hollow "kaw" to "aw" notes at c. 5–6 per second for 10–50 seconds; sexes sometimes sing simultaneously, even duetting, male for longer and at lower pitch; calls include rattles, cackling alarm notes, "skurr" and "kwaahh" aggressive notes, grating, and "tchuk" calls; nestlings squeak sharply.

**Habitat.** Wet montane forest, edges, trees in clearings, and well-developed second growth. Extreme altitude limits 500–2740 m, mostly 1200–2200 m; in Costa Rica most common at 1500–1800 m. Roosts in group, sometimes several groups in 1 cavity, up to 19 birds in 1 hole.

**Food and Feeding.** Fruits from over 20 families of trees, shrubs and epiphytes, such as *Ficus*, and species of *Clusia*, *Guetarda*, *Malaviscus*, *Miconia*, *Ocotea*, *Ossaia*, *Rubus* and *Symplocarpon*, also nectar and some flowers; some insects taken, mostly when feeding young nestlings. Eats whole fruits, breaks fruits or squeezes berries, swallowing juices, discarding rest. Forages in groups of up to 5, or singly.

**Breeding.** Groups break up Feb–Mar, egg-laying Mar–Jun. Nests in territorial pairs, with much singing, countersinging, duetting. Cavity excavated at 3–18 m in tree. Eggs 4–5; parents roost in nest, share incubation, cover eggs over 80% of daytime, incubation period 14–15 days; both adults feed and brood chicks, remove faecal material with wood chips, excavating more to provide needed chips; nestling period unknown; fledglings roost in nest with parents, forage together in group.

**Movements.** None reported, presumably sedentary.

**Status and Conservation.** Not globally threatened. Restricted-range species: present in Costa Rica and Panama Highlands EBA. Often common in limited range, occurs in various parks and reserves in some numbers, e.g. Tapantí National Park and Monteverde Biological Reserve (Costa Rica); tame, generally confiding. No known threats.

**Bibliography.** Anon. (1998b), Berlioz (1937), Blake, E.R. (1958), Blake, J.G. & Loiselle (2000), Delgado (1985), Fogden (1993), Murray (1988), Nadkarni & Matelson (1989), Remsen *et al.* (1993), Ridgely & Gwynne (1989), Ridgway (1914), Skutch (1944b, 1980, 1983, 1987, 1989), Slud (1964), Stattersfield *et al.* (1998), Stiles (1983, 1985), Stiles & Skutch (1989), Stotz *et al.* (1996), Wetmore (1968a), Wheelwright *et al.* (1984), Young *et al.* (1998).

## 82. Toucan-barbet

### *Semnornis ramphastinus*

**French:** Cabézou toucan

**German:** Tukanbartvogel

**Spanish:** Cabezón Tucán

**Other common names:** Toucan-billed Barbet

**Taxonomy.** *Tetragonops ramphastinus* Jardine, 1855, between Quito and Mount Cayambe, in east Ecuadorian Andes.

Related to *S. frantzii*, with which it shares distinctive bill morphology, but relationship not very close. Races poorly defined. Two subspecies currently recognized.

**Subspecies and Distribution.**

*S. r. cauae* Gyllenstein, 1941 - W Colombia on both slopes of W Andes, from Valle to Nariño. *S. r. ramphastinus* (Jardine, 1855) - Andes of NW & WC Ecuador.

**Descriptive notes.** 19–21 cm; 84–111 g. Distinctively patterned, chunky, colourful barbet with short bill "swollen" at base. Male has black around bill base to lores and crown, erectile black tuft on nape, broad white line behind eye, blue-grey ear-coverts and side of neck to throat, golden-olive and brown on back, gold rump, grey-blue in wings and tail; red and gold below; plumage lax, dense; bill very short, broad, deep-based, pale with black mark near tip, prongs not conspicuous in field. Female like male, but black nape lacks tuft. Immature duller, bill prongs not fully developed until c. 4 months. Race *cauae* has less

extensive red on lower underparts. **Voice.** Song a series of foghorn-like "hawnk" to "aw" notes at 1.5–2.5 per second for up to 3 minutes, often by pair-members simultaneously, male at lower pitch and often starting and ending "duets"; clicks bill, often in notes starting song; in addition to snapping-clicking bill sounds, gives clicking calls with bill snaps in them, "bbrrrip", at 1–2 per second; also "gkaa", "caw", rattle and chatter notes, "kawk" notes, purring, and "kyak" contact notes. Wings flop and rustle noisily during interactions.

**Habitat.** Inhabits understorey of wet montane forest, especially at edges and in dense second growth, including low bushy secondary forest with scattered tall trees; also found in overgrown pastures, and feeds in isolated pasture trees. Mainly occurs at 1000–2000 m, but reaches 2400 m in some areas.

**Food and Feeding.** Fruits of at least 62 species of some 20 plant families, mostly of species found in disturbed areas, and including especially *Cecropia* and *Clusia*, but others of the Melastomataceae, Moraceae and Gutiferae also taken; termites and other insects eaten, more so than fruits in Apr. Nestling diet c. 54% fruits, 40% insects, 6% parts of flowers, fungi and vertebrates. Forages at 1–30 m in groups of up to 6. Hops and climbs about, gleaning. Forages for c. 12 hrs of day, at up to c. 270 m from roosting site. Joins mixed-species foraging flocks of flycatchers (Tyrannidae), tanagers (Thraupidae) and warblers (Parulidae).

**Breeding.** Feb–Oct; sometimes 2 or even 3 broods in a season. Group often breaks up at start of breeding; c. 42% nest in pairs, remainder in trios or quartets, but breeding apparently by primary pair only. Much duetting, where species common also much countersinging; probable male cocks tail, fluffs breast, spreads white supercilia. Nest excavated low in dead tree, often *Nectandra* or *Ocotea*, average height above ground 1.5 m in tree with breast-height diameter c. 0.38 m; new cavity excavated yearly, often in same tree as in previous year; territory c. 4–11 ha in SW Colombia. Eggs probably 2–3, mean clutch size c. 1.4; any helpers share incubation, and brooding and

feeding of young; incubation period c. 15 days; fledging 43-46 days; males disperse at c. 308 days of age, females at c. 273 days, juveniles sometimes remain as helpers in following season, older helpers driven away by pair at start of breeding. Success variable: 1 or 2 young fledge in wild, mean 1.3, in captivity sometimes 3; success of first broods higher for pairs with helpers than for those without, but that of subsequent broods equal with or without; some nests lost to falling of stub, also sometimes taken over by Plate-billed Mountain-toucan (*Andigena laminirostris*). Earliest first age of breeding 1-56 years (570 days).  
**Movements.** Resident; sedentary, dispersal averages only 0-5 km.  
**Status and Conservation.** Not globally threatened. CITES III. Currently considered Near-threatened. Restricted-range species: present in Chocó EBA. Generally uncommon to locally common within the c. 20,000 km² area of its range; nests have been found only 270 m apart. Surveys of La Planada Nature Reserve (SW Colombia) in late 1980's, extrapolated to rest of range, suggested total numbers for entire range of c. 73,000 birds. Main problem is taking of birds for cagebird trade,

as well as by local people for pets, this being a major threat in some areas; habitat loss is also a potential problem, with forest destruction rampant in most of range, but species appears to be adaptable, and where not molested occupies secondary thickets and dense growth with scattered trees around gardens. Controlling the illegal taking of birds is considered essential if this species is to be adequately protected. Present in several protected areas, e.g. La Planada Nature Reserve and Río Nambí Natural Reserve (Colombia).  
**Bibliography.** Allen (1998), Álvarez-López (1989), Berioz (1937), Best *et al.* (1997), Bloch *et al.* (1991), Butler (1979), Chapman (1917, 1926), Collar & Andrew (1988), Donegan & Dávalos (1999), Fjeldsá & Krabbe (1990), Gyldestolpe (1941a), Hellmayr (1911), Hilty (1985), Hilty & Brown (1986), King (1978/79), Maria & Olivares (1967), Meyer de Schauensee (1949, 1964, 1966), Remsen *et al.* (1993), Renjifo *et al.* (1997), Restrepo (1990), Restrepo & Beltrán (1989), Restrepo & Mondragón (1988, 1998), Ridgely & Greenfield (2001), Rutgers & Norris (1977), Salaman (1994), Sherbourne (1996), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), Stutz *et al.* (1996), Strewe (2000b), Ward (1972b), Welford (2000).

Class AVES  
Order PICIFORMES  
**Family RAMPHASTIDAE (TOUCANS)**

- Medium-sized to large, colourful arboreal birds with huge bill and long tail.
- 30-61 cm.

- Neotropical, with greatest diversity in Amazonia.
- Tropical forest, mostly in lowlands, but reaching temperate zone in mountains; one species ranges into woodland.
- 6 genera, 34 species, 78 taxa.
- 1 species threatened; none extinct since 1600.

### Systematics

The toucans that comprise the family Ramphastidae have long intrigued biologists and travellers. Because of the uniquely serrated bill tomtia, a characteristic of all toucans, and probably owing to the length of the bill, too, eighteenth-century European scientists initially thought that the toucans' diet was of fish that the birds themselves caught. Toucans are "flagship" species, well known and recognizable representatives of the Neotropical forest.

According to E. Höfling's investigations, the toucans are remarkably uniform morphologically, while S. J. H. Hackett and C. A. Lehn found that, at the genus level, the araçarís (*Pteroglossus*), for example, constitute a group of species that are genetically much alike. With more species on their single continent than the somewhat similar but unrelated hornbills (*Bucerotidae*) have in either the Afrotropics or tropical Asia, toucans have evolved into an ample range of medium-sized to large frugivores. Their overall uniformity, along with many unique features in which they have diverged from their original barbet-like ancestor, argues for their systematic treatment as a family apart from the closely related barbets (*Capitonidae*): nobody could mistake a toucan for a barbet. There is universal agreement that the toucans share an ancestor in common with the American barbets. As C. G. Sibley and J. E. Ahlquist have noted, after the toucans branched from the line that gave rise to Neotropical barbets, the latter retained a barbet morphology; in other words, it was the toucans that diverged, acquired new, "toucan" features, and then diversified, giving rise to the present array of ramphastid species. Hence, it is considered inappropriate to follow the essentially cladistic classifications that either merge all the barbets within one family along with the toucans, as did R. O. Prum, or treat the Neotropical barbets and toucans together as one family separate from the Old World barbets, as did Sibley and Ahlquist, and Sibley and B. L. Monroe. These other modes of classifying the toucans should be viewed as provisional, and limited in considering points of branching, while ignoring the divergence of the toucans from the barbets.

P. J. K. Burton, who investigated features of the feeding apparatus and skull, treated the toucans as a family, which he placed immediately after the barbets and preceding the honeyguides (*Indicatoridae*) and the woodpeckers (*Picidae*). Prum tabulated some morphological, behavioural and other natural-history features and, on the basis of their supposed or real derived states, placed all barbets and toucans in the family

Ramphastidae, preceding the Indicatoridae and the Picidae. Within the Ramphastidae, he arranged the barbets in six subfamilies, followed by a single subfamily of toucans. Sibley and Ahlquist, followed by Sibley and Monroe, studied DNA-DNA hybridization in the Piciformes, and, using these results and some morphological and other traits, came up with a piciform provisional classification in which the honeyguides and the woodpeckers are families, in that sequence, in the infraorder Picides, followed by an infraorder Ramphastides. The latter contains, first, two superfamilies, each with one family of Old World barbets, and then a third superfamily, Ramphastoidea, comprising a single family in which the Neotropical barbets

The toucans are quite uniform morphologically, with rather few taxonomic subdivisions, and the species within these tending to be quite closely related. In the current classification, the Ramphastidae are grouped into six genera, although the Curl-crested Araçari has sometimes been placed in a seventh, *Beauharnaisius*, on the basis of its unique characteristics, primarily its "permed and lacquered" head feathers, and its atypical voice. This species inhabits humid forests in Amazonian Brazil and the eastern lowlands of Peru and Bolivia.

[*Pteroglossus beauharnaisii*.  
Photo: Frank W. Lane/  
FLPA]

The number of species recognized within the Ramphastidae varies widely depending on which taxonomic viewpoint is assumed.

The 34 species recognized here include many distinct subspecies that are sometimes separated at the species level. The Channel-billed Toucan, for example, includes the forms *vitellinus*, *culminatus*, *ariel* and *citreolaemus*, four taxa that differ conspicuously in the colour of their bills and plumage, but which intergrade freely along their contact zones, producing hybrids that have themselves been described as separate taxa in the past.

are placed in one subfamily and the toucans, as the final taxon, in the subfamily Ramphastinae.

Nevertheless, it may be considered better, at least for the time being, to follow the classical arrangement of the toucans amid the barbets, honeyguides and woodpeckers, treating these in four separate families. Thus, the barbets together form the family Capitonidae, followed by the toucans as the Ramphastidae, then the honeyguides in the Indicatoridae, and ending with the woodpeckers in the family Picidae. The traits of the toucans, including their specialized features, are discussed below (see Morphological Aspects).

Fossil toucans are few, and do not go back beyond the Pleistocene. They are therefore, so far, not of much help to systematists.

The morphological uniformity within the Ramphastidae is such that the subdivision of the family into genera is considered sufficient, and recognition of a higher category such as subfamily or tribe is unwarranted. The six genera are closely interrelated, but can be characterized as follows. The green toucanets comprise the genus *Aulacorhynchus*, in which there are six species that tend to occur in montane forest, from Mexico to Bolivia. E. V. Swierczewski and R. J. Raikow used several muscle and tendon conditions to set them apart from at least the genera *Pteroglossus* and *Ramphastos*. The species of *Aulacorhynchus* are relatively small, as their vernacular name toucanet suggests, and they have a long, graduated tail and a more or less typical, long bill that is rather broader at its base than is the case with other toucans. They often have grooves in the bill surface and chestnut tips of the tail. Cytochrome studies by F. K. Barker and S. M. Lanyon suggest that *Aulacorhynchus* comprises a clade with the genera *Andigena* and *Selenidera*. *Aulacorhynchus* is morphologically and behaviourally a toucan, with no particular barbet-type features. The green toucanets are closely similar to one another, and, as P. Schwartz noted, their vocalizations are generally similar. Most are allopatric in their distribution, some replacing each other altitudinally, and all are alike sexually, except that males have a longer, usually distinctly longer, bill than that of the females. Five of the six species were illustrated by J. Gould, in 1854, in his gorgeous portrayal of the family. These

toucanets seem to fall into two groups. The Emerald Toucanet (*Aulacorhynchus prasinus*) along with the superspecies formed by the Groove-billed (*Aulacorhynchus sulcatus*) and the Chestnut-tipped Toucanets (*Aulacorhynchus derbianus*) represents one group, the other being the red-rumped group of a single superspecies comprised of the Crimson-rumped (*Aulacorhynchus haematopygus*), Yellow-browed (*Aulacorhynchus huallagae*) and Blue-banded Toucanets (*Aulacorhynchus coeruleicinctis*). Some sympatry occurs between species of the two groups, but, within either group, there is only a limited degree of range overlap between species, this being exhibited by the Emerald and Groove-billed Toucanets.

The genus *Selenidera*, also with six species, inhabits lowland forest of Amazonia and the Atlantic forest of south-east Brazil and adjacent areas, except that the Yellow-eared Toucanet (*Selenidera spectabilis*) occupies mountain forest from Honduras to north-western South America. These are, with *Aulacorhynchus*, the smallest of the toucans. They have distinctive muscle features, and exhibit sexually dimorphic plumages of a type that is all but unique within the Piciformes, being shared with a couple of aracarids. They are strictly forest toucans, and prefer forest with a well-developed middle storey. Five species have chestnut tips of the tail, and all have fluffy red undertail-coverts used in displays that closely resemble those of species of *Andigena*. Yellow, orange or tawny ear-covert tufts, and a flank patch, as well as a yellow collar, are characteristics of most of these species. The males are black about the head and foreparts, where females are rufous or chestnut to grey. Three paler-eyed species show horizontally slit-like eyes resulting from dark marks on the iris, before and behind the pupil. All of the species replace each other geographically, and J. Haffer considered all six of them to form a superspecies. The Guianan Toucanet (*Selenidera culik*) of north-eastern South America and the montane Yellow-eared Toucanet, however, exhibit certain differences from the other four that would appear to set them apart. The Tawny-tufted (*Selenidera nattereri*), Gold-collared (*Selenidera reinwardtii*), Gould's (*Selenidera gouldii*) and Spot-billed Toucanets (*Selenidera maculirostris*) have nearly identical songs and accompanying displays; they replace

The seven members of the genus *Ramphastos*, with piebald plumage and a huge, brightly coloured bill, epitomize the toucan that is widely popularized through art and advertising. Of these, it is the Toco Toucan that is the most familiar. This is the largest member of the family, with a loud call and an enormous bill; moreover, it is seen more frequently than other *Ramphastidae* across much of its range because it is not tied to forest, often living in quite open habitat near gallery or cerrado woodlands.

[*Ramphastos toco albobularis*, Iguazú National Park, Argentina.  
Photo: Günter Ziesler]

each other around north-western to south-eastern Amazonia and in the Atlantic forest region, and are treated as a superspecies. All but one of the *Selenidera* species were shown in Gould's monograph.

*Andigena*, the mountain-toucan group of four large, montane forest toucans, occurs along the Andes from Colombia and Venezuela to Bolivia. Its members have a dense, lax plumage and a broader-based, less deep long bill than do other large toucans. They are rather like *Selenidera* in their red undertail-coverts, displays and chestnut tipping of the graduated tail, which is, however, longer than in *Selenidera*. Instead of having a bill pattern of long horizontal marks and lateral spots as in the above genera, these flashy, dark toucans have patchy marks and bright splotches on the bill. The sexes are alike in plumage. Their loud, long songs include the longest notes of any piciform so far recorded. The Grey-breasted (*Andigena hypoglaucha*), the Hooded (*Andigena cucullata*) and the Plate-billed Mountain-toucans (*Andigena laminirostris*) replace one another geographically and are thought to form a superspecies. The Black-billed Mountain-toucan (*Andigena nigriroristris*) of the northern Andes has a duller bill and overlaps somewhat with the Grey-breasted Mountain-toucan. Gould's monograph has accounts and illustrations of all four of these spectacular toucans.

Because of its rather soft, fluffy plumage, the Saffron Toucanet (*Bailloni bailloni*) was placed by Gould in the genus *Andigena*, but this is a mainly lowland toucan of the Atlantic forest region, and its nearest relationships appear to be with *Pteroglossus*. Its yellow and green plumage, unmarked except for a red rump, is not particularly *Pteroglossus*-like, nor are its red, yellow and green to brown bill and its red facial skin. In view of its evident differences from other toucans, the Saffron Toucanet is accorded its own monotypic genus. It has many vocalizations, among which the song calls to mind that of the Ivory-billed Araçari (*Pteroglossus azara*). Its graduated tail is, in relation to the bird's total size, the longest in its family. The female is more dully coloured overall than is the male, as well as having a shorter bill.

Ten species of araçari make up the genus *Pteroglossus*, characterized by "clown-like" patterns and colours. These have a long, brightly marked bill, hooked at the tip, and a long, gradu-

ated tail. Sexual dimorphism in two species resembles that exhibited by the *Selenidera* toucanets, and several more show slight aspects of this pattern in their nape and neck colours. The slit-like eye of several *Selenidera* species is suggested, or occurs fully, in three species of *Pteroglossus*. All but two of the ten species are banded yellow, red and/or black below, although the black/red breastband is reduced to a spot in two. Hard, shiny black, curly, modified head feathers distinguish the Curl-crested Araçari (*Pteroglossus beauharnaesii*). The Green (*Pteroglossus viridis*), the Lettered (*Pteroglossus inscriptus*), the Red-necked (*Pteroglossus bitorquatus*) and the Ivory-billed Araçaris seem to form a natural group of less banded, smaller species, and there appear to be no definite grounds for recognizing any superspecies among them, although the first two could possibly be close enough to be treated as such. Another species group is represented by five colourful araçaris, namely, the Collared Araçari (*Pteroglossus torquatus*), the Fiery-billed Araçari (*Pteroglossus frantzii*), the Black-necked Araçari (*Pteroglossus aracari*), the Chestnut-eared Araçari (*Pteroglossus castanotis*) and the Many-banded Araçari (*Pteroglossus pluricinctus*). Within this group, the Collared and Fiery-billed Araçaris form a superspecies, as do the Black-necked and the Chestnut-eared. All five have a nearly identical, piercing "pseet" call given in irregular, sometimes staccato bursts. The Curl-crested Araçari stands apart from these. Generally, the araçaris are lowland-forest species, some favouring riverine situations, but they can extend into hill forest and submontane situations. They occur from Mexico to Paraguay. Gould discussed and illustrated nine of these *Pteroglossus* species, and a number of subspecies of several of them.

For most people, the seven species of the genus *Ramphastos* represent the typical, classic image of a toucan. All are black above, with a white, yellow or red throat to breast, more or less square, short tail, red undertail-coverts, and white or yellow to red uppertail-coverts. These large toucans have a deep, long, variably coloured bill. Anatomical characters are associated with the external nostrils, which, in adults, are hidden beneath the base of the bill. The facial skin and areas around the eye are brightly coloured. All have emarginated, club-shaped tips of the outer two primaries. There is no sexual dimorphism in plumage, but males

When the first specimens of toucans reached Europe in the eighteenth century it was hypothesized that their diet consisted of fish which the bird caught with its long, serrated bill. Looking at the impressive mandibles of this Green Araçari, it is easy to understand why this mistake was made, although the serrations seem to run the wrong way for capturing slippery fish! The long and curiously serrated bill and the strange feathered tongue are adaptations to frugivory, tools that allow the toucan to pluck, manipulate and consume arboreal fruit. Although it looks very heavy, the bill is in fact extremely light, being essentially hollow with thin bony struts for structural support. *Pteroglossus araçaris* have bills that are more distinctly hooked at the tip than in other members of the family. Their plumage is usually vividly patterned in red, yellow and black, and their tails are long and graduated.

[*Pteroglossus viridis*.  
Photo: Chuck Dresner/  
DRK Photo]

usually have a longer bill. Five of the seven species, often termed the "croakers", repeat a single "eerk"-like note in short to long series. These are the Red-breasted (*Ramphastos dicolorus*), the Rainbow-billed (*Ramphastos sulfuratus*), the Choco (*Ramphastos brevis*), the Channel-billed (*Ramphastos vitellinus*) and the Toco Toucans (*Ramphastos toco*), and, according to Haffer and others, they appear to form a natural group. The White-throated Toucan (*Ramphastos tucanus*) and the Yellow-throated Toucan (*Ramphastos ambiguus*) "sing" by using yelping, phrased notes, and these two seem to represent a separate group. There exists what could be seen almost as mimicry in bill and plumage colour patterns between the groups, as demonstrated by the Choco and Yellow-throated Toucans, and the Channel-billed (in part) and White-throated Toucans. In addition, the upperparts of the Rainbow-billed and Choco Toucans, in the first group, and the Yellow-throated Toucan, in the second, are tinted maroon on black. In terms of geographical distribution, the two groups show a large degree of sympatry, whereas the species within either one of the groups do not in general overlap in range with others of the same group. The single exception is the huge Toco Toucan, the only woodland-riverine member of the genus, which overlaps with two species of its own group, the Red-breasted and Channel-billed Toucans, as well as with the White-throated Toucan. The *Ramphastos* species generally are lowland toucans of forest habitats, ranging from Mexico to Argentina, and rarely ascending to 1600-1800 m in Andean valleys. Gould treated and illustrated all seven species and major subspecies of these toucans in his 1854 monograph.

The approach to systematics of species adopted here is that of an evolutionary biologist employing the biological species concept, as discussed by D. Amadon and L. L. Short in 1992, and by Haffer in 1995 and 1997. As pointed out by D. W. Snow, this has served science well, and, indeed, it has been argued by N. J. Collar that it seems the best system when it comes to treating matters of conservation. Tactics include the utilization of data provided at points where taxa in question meet "on the ground", as well as inferences drawn from known, closely related biologi-

cal species that reveal their specific status by co-existing sympatrically without interbreeding. Hybridization with back-crossing can be regarded as a potentially positive evolutionary factor, and not as wholly negative.

Among possible incipient species that some might consider as full species are no fewer than six races of the Emerald Toucanet. The Mexican subspecies *wagleri* differs in several minor features of the bill and in the colour of the crown and forehead, but is otherwise like the nominate race, including in its voice and in the colours of its facial and orbital areas and its eye. The others are *caeruleogularis*, possibly including the form *cognatus*, of Costa Rica to northern Colombia, which has a blue-violet throat; white-throated *albivitta* of north-western South America; grey-throated *phaeolaemus*, which appears to intergrade with the races *albivitta*, *griseigularis* and *cyanolaemus*; blue-throated *cyanolaemus* of north-eastern Peru and eastern Ecuador, which seems to intergrade to the south with *atrogularis*; and the black-throated *atrogularis* and, possibly, *dimidiatus* of eastern Andean slopes in Peru to Bolivia, and nearby lowlands. All of these forms of the Emerald Toucanet share a yellow, black and chestnut bill and certain plumage features, as well as vocalizations, with other conspecific races. None is as distinct as is the subspecies *calorhynchus* of the Groove-billed Toucanet, which is sympatric with at least two races of the Emerald Toucanet, from which it differs in voice, in lacking rusty tail-tips and undertail, and in the structure, if not the colour, of its bill.

The subspecies *calorhynchus* is the only form of any species of *Aulacorhynchus*, other than races of Emerald Toucanet, to have a black and yellow bill. It is sometimes considered a full species, but Schwartz showed it to be like other races of the Groove-billed Toucanet in voice, and it intergrades with the nominate race of that species where the ranges of the two approach one another. In plumage features and in bill structure and pattern, *calorhynchus* closely resembles the other subspecies of the Groove-billed Toucanet.

The two subspecies of the Gold-collared Toucanet of western Amazonia are considered separate species by some cladists.

The epicentre of toucan diversity is Amazonia. They are characteristic birds of tall humid forests throughout much of South and Central America. Members of the genus *Ramphastos*, like these Channel-billed Toucans, are largely confined to the canopy of lowland rainforest, most of them venturing no further than the foothills. Indeed, many are so closely adapted to continuous forest habitat that they gradually lose height when flying over long distances. This means that wide rivers pose an effective barrier to their dispersal, and the ranges of many species and subspecies in the family are divided by the Amazon or its tributaries. For the same reason, very few islands are inhabited by toucans.

[*Ramphastos vitellinus culminatus*, east of River Branco, Amazonian Brazil. Photo: Nick Gordon/ BBC Natural History Unit]

As their name suggests, the four species of mountain-toucan are adapted to montane forest, and in this respect they are almost unique within the family.

This Grey-breasted Mountain-toucan is pictured here in its native habitat: smaller stature epiphyte-laden cloudforest. The species often occurs in clamorous groups and has been seen up to 3650 m above sea-level. It is regularly found right at the tree-line, on the edge of open páramo.

VIREO]

The nominate race and the southern *langsдорffii* differ essentially in bill colours, but intergrade in the upper Ucayali and Huallaga Valleys of north-central Peru. They are otherwise almost indistinguishable, and have the same songs and accompanying displays, which are, moreover, so like those of Gould's and the Spot-billed Toucanets, as well as those of the Tawny-tufted Toucanet, that these might perhaps be treated as conspecific. The four species replace one another around Amazonia, and share in detail the colour markings used in their displays.

Among the araçaris, the two races of the Lettered Araçari, east Amazonian nominate *inscriptus* and west Amazonian *humboldtii*, are sometimes treated as specifically distinct. Western *humboldtii* is larger, has a somewhat different but still "inscribed" bill pattern, and has a red mouth-lining, the latter being black in the nominate race. The two seem to be vocally indistinguishable. Although separated by the Madeira River, they cross it occasionally, or "island capture" may move numbers from one side to the other; in any case, hybrids occur sporadically, and their differences seem not so great as those that exist among related, sympatric species in this group. Indeed, the form *olallae*, described from the Rio Juruá itself, and regarded initially as a full species, was found to be a presumably rare hybrid between the race *humboldtii* of the Lettered Araçari and the broadly sympatric race *mariae* of the Ivory-billed Araçari. Large southern Amazonian rivers likewise separate perhaps incipient species of the Red-necked Araçari, the Tocantins River separating *bitorquatus* to the east and *reichenowi* west of it to the Tapajós River, which further separates the latter from the race *sturmii*, which occurs westwards to the Madeira River. These populations differ mainly in bill coloration, and a few other traits. Unfortunately, few series of specimens are available that might show what happens in places where they meet in, as Haffer noted, the upper reaches of these rivers; assuming that suitable habitats exist, they may meet where the rivers are narrower and less of a barrier. A few museum collections reveal that hybrids occur, as in the Cururu Valley of the upper Rio Tapajós, between the forms *reichenowi* and *sturmii*. The differences between these various populations seem not to be significant enough for them to be accorded species status. Similarly, the Ivory-billed Araçari has

three subspecies which are treated by some authorities as species, and which differ essentially in bill markings, but not by very much. These are the nominate race, inhabiting the region between the lower Rio Negro and the Amazon River, *flavirostris* of north-western Amazonia, and *mariae* of south-western Amazonia. The nominate race interbreeds across the Amazon with *mariae*, and up the Rio Negro with *flavirostris*, while the latter interbreeds with *mariae* both across the Amazon-Solimões River and around the Rio Marañon in northern Peru. It seems impossible to accept these subspecies as biological species. In fact, by designating all the above races as full species one would eliminate all subspecies in these taxa.

In the "higher" *Pteroglossi*, no valid evidence of hybridization between the Black-necked and Chestnut-eared Araçaris has been found, their ranges being essentially parapatric, with only occasional, local sympatry. A single hybrid between the Many-banded and the Black-necked Araçari is known from Carapo, on the Paragua River, Venezuela, but no real significance can be attached to this, other than noting the particularly close relationship among these three members of the "Collared Araçari group". That group also includes the Fiery-billed Araçari, which is, with some hesitation, accepted here as a full species, separate from the Collared Araçari; the two do not come into direct contact except casually, and a single hybrid is known from Aranjuez, near the Gulf of Nicoya, in Costa Rica. On the other hand, there appears to be no good reason to elevate to species status the two north-western South American forms of the Collared Araçari, *erythropygius* and *sanguineus*. These are closely similar to each other, differing only in bill colour, and a case might be made for treating the two as forming a single species, separate from the Collared, but they differ less markedly from the latter than does the Fiery-billed Araçari, and, as Haffer has clearly shown, the race *sanguineus* intergrades with the nominate race of the Collared in the region from easternmost Panama to north-western Colombia. It can be added here that *sanguineus* and *erythropygius* interbreed in south-west Colombia and north-west Ecuador; the two converge in bill pattern and colours, and examination of a series of six specimens from Guala, in Ecuador, revealed that all were hybrids. In terms of their vocalizations, these races are

alike, and resemble the nominate race of the Collared Araçari. It is worth noting that the Fiery-billed Araçari, with its fine bill serrations, strongly different bill pattern, broader, more red belly-band and, probably, longer call notes, differs more from the *torquatus* group of races than does either *sanguineus* or *erythropygius*. All of these, including the Fiery-billed, may end up being treated as conspecific when further studies have provided additional data.

Among the toucans of the genus *Ramphastos*, there are three species with distinctive subspecies that some scientists would regard as full species. The Channel-billed Toucan has four well-marked subspecies: nominate *vitellinus* of north-eastern South America north of the Amazon; *citreolaemus* of north-east Colombia to north-west Venezuela; *culminatus* of all of western Amazonia; and *ariel* of south-eastern Amazonia to south-east Brazil. All four have essentially identical vocalizations, and differ in the colours of the bill, bare parts, breast and belly. The subspecies *culminatus* interbreeds with *citreolaemus* in Venezuela, and toucans from the eastern half of the latter's range appear to be essentially all hybrids. Furthermore, *culminatus* intergrades with *vitellinus* across northern Amazonia, from Venezuela to north-central Brazil. To the south of the Amazon, *culminatus* intergrades with *ariel* along that river and between Rondônia and Bolivia, as well as, in the east, between Piauí and São Paulo, a vast area with large populations of apparent hybrids, some of which bear names, such as "*berliozi*" for *vitellinus* × *culminatus*, and "*osculans*", "*theresae*" and "*pinto*i" for *culminatus* × *ariel*. There is no allopatry of these subspecies other than that of *vitellinus* and *ariel*, which are separated by the lower Amazon; they have long interbred where they meet, and it is now quite impossible to draw geographical boundaries between them. Introgression, impeded by rivers and currently by some deforested habitats, affects even extreme populations in Peru, Roraima and Minas Gerais.

The White-throated Toucan is larger than the Channel-billed. Rivers pose less of a barrier to it, and it is more mobile. Its nominate race, which extends from eastern Amazonia to the Guianas, eastern Venezuela and northern Maranhão, includes a morph with an orange-red bill that was once considered a different species, under the name "*Ramphastos erythrorhynchus*" or "*R. aurantirostris*". The western Amazonian race *cuvieri*, occurring from western Venezuela to the fringe of northern Bolivia, is sometimes treated as specifically distinct from the nominate race. These two, however, show fewer differences from each other than do the races of the Channel-billed Toucan, differing mainly in lateral bill colour and in the colour of the uppertail-coverts. Variably intermediate populations occur in a large area from southern Venezuela to Mato Grosso and Goiás, and from the Rio Solimões and Rondônia east to Para, connecting the "pure" parental populations of the far west and the far east. The subspecies *inca* of much of central Bolivia seems to represent a semi-stabilized hybrid population that is closest to *cuvieri*, but with a chestnut-red basal patch on each side of the bill, and redder uppertail-coverts than in either of the above forms. Since intermediates constitute a huge population that both separates and connects the parental taxa, *R. tucanus* is best treated as but one biological species.

Finally, the Yellow-throated Toucan comprises three races, one of which, *swainsonii* of Honduras to north-western South America as far as south-west Ecuador, has been considered specifically distinct from nominate *ambiguus* of the eastern Andes from Colombia to Peru, despite their very close similarity. Compared with the nominate race, *swainsonii* differs in having the sides of the bill less black and more chestnut-red in colour, though sometimes black at the edges, although the black bill of the nominate race sometimes has chestnut near its base. The facial-orbital colour of *swainsonii* is yellow-green to greenish-yellow, but overlapping to a degree with nominate *ambiguus*, in which the colour is blue or pale green or yellow-green. The eyes of *swainsonii* are yellow-green to brown, but with variants showing white, or partly pure green or partly yellow eyes, whereas those of the nominate race are normally grey-brown, green-brown or blue-brown, but vary to yellow and to grey. In view of the variation in these characters, the differences may

be regarded as trivial. There also is the race *abbreviatus* of north-east Colombia and northern Venezuela, with a bill coloration like that of nominate *ambiguus*, but with the face colour as in *swainsonii*. Suggestive evidence of interbreeding between *ambiguus* and *swainsonii* is presented by old specimens from the Cauca Valley, in western Colombia, in addition to which the two forms have the same distinctive song phrases. It should be noted that the traditional separation of *ambiguus* from *swainsonii* has its basis in the fact that the Choco Toucan was for a long period regarded as a race of *R. ambiguus*, being sympatric with *swainsonii*. Only with the realization that the Choco Toucan is, in fact, a distinct species was it possible to recognize the allopatry of *ambiguus* and *swainsonii*, and their very close relationship, as Haffer has demonstrated.

Such taxa as those outlined above, through their population interactions, prove or negate their status as species either by coming to co-exist in sympatry without interbreeding, or by interbreeding with more or less free, but, of course, ecologically conditioned, gene flow. Thus, they demonstrate what they are, if habitat conditions allow them to meet. If not, then it is necessary to study aspects of their behaviour, including vocalizations, and their ecology that will allow some conclusions to be drawn as to their likely interactions were they to meet.

## Morphological Aspects

The long, deep and narrow bill, usually brightly coloured, and with small to large forward-facing serrations, or "teeth", is the hallmark of all toucans. The bill is also very light, with thin bony struts making for much space and little solid substance to the structure beneath its covering, or rhamphotheca. Unlike their relatives, the barbets, the toucans have the bill culmen curving downwards at its tip, often forming a hawk-like hook, and the gonys of the mandible is straight or, more usually, curves slightly downwards along its length, and definitely curves downwards at its tip. The base of the bill has a narrow to broad, thickened area around the sides to the nostrils, often indented forwards from the rear and surrounding the nostrils in front, and then reaching on to the culmen. This vertical base line is unique to the toucans, and is usually conspicuously coloured, often in contrast to the lateral-bill and culmen colours. In species of *Ramphastos*, the line is broad and includes the base of the culmen, the external nostrils having evolved to open backwards and upwards, underneath the rear edge of the top of the bill. This basal line develops slowly and is not present in juvenile toucans; the "teeth" and the patterning of the bill also develop slowly in young toucans. The bill of the large toucans is translucent, although that of the immatures is opaque. The colour patterns of toucans' bills are complex, with broad horizontal or angled marks, vertical bands and splotches, all multicoloured and unlike the patterns of other piciform bills.

Toucans lay their eggs in a natural cavity, or one constructed previously by woodpeckers, or occasionally barbets. Although they can "excavate" pieces of rotten wood from old cavities in very rotten stubs, this is a rare occurrence. The downcurved tip of the bill does not lend itself to excavation. In those pairs of Emerald Toucanets that attempt to create a cavity, it is usually the female, with the shorter and straighter bill, that excavates (see Breeding).

Toucans have a larger area of bare skin around the orbit, extending on to the face and to the lores and even the bill, than do the barbets. The skin and the eye are visible in frontal view, and are usually brightly coloured, even patterned. The iris of several pale-eyed species, of two genera, has dark areas to the front and rear of the dark pupil, sometimes referred to as a "glitch", the whole giving the appearance of a slit-eye, a feature not found in any other piciforms. The gular area of skin is of more or less the same colour as the face. Unlike the barbets, including all those of the Neotropics, the toucans lack bristles around the base of the bill.

The ramphastid tongue is extremely long, up to 14-15 cm, and is laminated along the sides and brush-like towards the tip. The fine villi in the breast feathers of toucans were found by T.

As with other cavity-nesting birds that cannot effectively excavate wood, the availability of mature trees with natural nest-sites is of paramount importance to the striking Rainbow-billed Toucan, and all other members of the family. Suitable cavities are produced where boughs have snapped from trunks of trees or where large woodpeckers have excavated their own nests. The infrequency of such nest-sites in young trees explains the paucity of toucans in secondary regrowth or heavily logged forest. Beyond this requirement the next important limiting factor on toucan numbers and distribution is food. A good supply of fruit is essential for breeding, while spatial and seasonal variations in fruit supply underlie distinct local migrations of toucans.

G. Brom to be more than twice as long as those of the barbets, and longer than in all birds otherwise examined. Other anatomical features of the toucans have been discussed, and compared with those of barbets, by Short and J. F. M. Horne. Höfling found the skull, including the palate and other bones, to be very much alike in all toucans, with various features unique to the family. One structural complex found only in the Ramphastidae involves the modification of nine tail vertebrae, their processes and the spines. The rear three vertebrae are fused, and attach to the others by a fluid-bearing ball-and-socket joint, giving toucans the ability to snap the tail forwards until it touches the head; sleeping toucans appear as a ball of feathers, with the tip of the tail sticking out over the crown. No barbet or any other piciform seems to have these novel specialities, or to sleep in this posture.

In contrast to the American barbets, most of which are distinctly sexually dimorphic, the majority of toucans do not show any sexual dimorphism in plumage and bare-part colours. Moreover, those toucans, mainly species of *Selenidera* and a few of *Pteroglossus*, with plumage differences between the sexes exhibit patterns of dimorphism that are unique to the Ramphastidae and do not resemble patterns found in other piciforms. Most toucans are strongly sexually dimorphic in the length, and thereby in the profile shape, of the bill. Males often have a bill 10% or more longer than that of females. The male bill appears longer and thinner, and the female bill generally seems shorter, deeper and more block-shaped. Such differences in bill size and shape are not evident in the barbets.

In their metabolism, toucans of a number of species show a strong and deadly tendency to store iron in the body, often leading to haematosi. Known by aviculturalists for some time, this unfortunate habit somewhat restricts the fruits that can be fed to them. Toucans die readily from this disease, otherwise unknown in piciform birds.

The flight of the larger toucans is somewhat undulating, with a series of flaps alternating with glides. The smaller species beat their wings faster and fly more directly, some araçaris appearing like bustling, buzzy auklets (*Aethia*) in flight. Generally, when crossing any open areas, toucans fly across one by one, each

waiting for the one ahead to get to a tree before taking off. Their flight is rather weak. Large toucans attempting to cross watercourses gradually lose height, and may not make it to the far side of wide rivers. In savannas with woodland thickets visited by toucans, one technique used by hunters is to run, chasing the toucans from wooded patch to wooded patch, until the birds are more winded than are the runners themselves; exhausted, the toucans fall to the ground and, unable to rise into the air, they are easily picked up. Toucans are alone among piciforms in that they do not display aerially.

Toucans bound and jump, leap or hop, often upwards in tree branches. They can cling to small branches, and, with the long bill, reach fruits unavailable to other fruit-eating birds. The bill is a weapon as well, used in bill-fencing "matches", probably involving dominance hierarchies in groups, but also in securing prey. The toucan is not built like a predator, but the long, hook-tipped bill is an effective device for tearing into nests and snatching out nestling birds and eggs. Some toucans regularly investigate the hanging nests of American blackbirds (Icteridae) and flycatchers (Tyrannidae), tearing into them, and removing anything edible. This predatory capability, given to toucans secondarily as a "preadaptation" following its primary fruit-acquiring function, is probably a very important factor in securing sufficient proteins as nutrients for the young at their early, fast-growing stage.

The huge bill, with its diverse markings, also intimidates other birds, not only those competing with the toucans for fruits in a fruiting tree, but also those avian species the young of which the toucans eat; the bill thereby reduces the mobbing actions of such birds. The late P. Bühler developed a related concept involving secondary use of the bill as an ultimate intimidator, following some points made by H. Sick. Bühler even viewed the highlighting and contrasting patterns of the "teeth" of some toucans as having evolved to enhance the intimidating effects. While these interesting views are respected, there are nevertheless many cases of species with otherwise well-marked "teeth" containing races in which this feature is unmarked or less marked. Further, two closely related species may differ in this character, as demonstrated by, for example, the Collared

Many toucans are usually found in noisy groups, and this is particularly true of *Pteroglossus araçaris*. The Lettered Araçari is typical of the genus, several individuals usually hopping conspicuously from branch to branch or following each other in single file from tree to tree. Larger gatherings of toucans have been reported at plentiful sources of fruit or during eruptive movements. The latter sometimes involve hundreds or thousands of individuals crossing waterbodies, or attempting to cross them, and moving temporarily into previously unoccupied areas.

[*Pteroglossus inscriptus*, Imperatriz, Maranhão, Brazil.  
Photo: Haroldo Palo Jr.]

A relatively large proportion of a toucan's time is spent dedicated to various forms of comfort behaviour. These include tussling and "playing" amongst group members, as well as resting, stretching, scratching, preening and yawning. One of the reasons that this Emerald Toucanet has time available for this is that it takes up to 75 minutes to digest a large fruit. As the digestive tract can be filled in a relatively short space of time, it is often necessary for toucans to wait until digestion is completed before foraging continues.

[*Aulacorhynchus prasinus caeruleogularis*, Costa Rica.  
Photo: Michael & Patricia Fogden]

and the Fiery-billed Araçaris: the former has highly marked, outlined "teeth", while on the Fiery-billed they are smaller and non-contrasting. It would seem that ancestral toucans should have acquired visibly well-marked "teeth" when the toucan bill was evolving; these should not have to evolve *de novo* in species after species. Although there are obvious bill-size diffe-

rences between males and females, the sexes do not vary in bill markings, so these do not have a sexual function. Certainly, the colours of the bill could act as a species-specific feature, and they may in some cases do so, but they do not function in this way in highly variable species the populations of which, despite having different bill colours and patterns, seem to interbreed freely.

The plumage patterns of the toucans are multicoloured and generically distinctive. All toucanets of the genus *Aulacorhynchus* are green with some blue and yellow areas; white, yellow or blue may mark the head, and the colours of the tail tips and the undertail- and uppertail-coverts relieve the general green coloration. These patterns are not found in any other avian family and, moreover, within the Ramphastidae, they are unique to this genus. The green, rusty, black and grey colours of *Selenidera* toucanets are made complex by these species' sexual dimorphism, and are further enhanced by bright rump, undertail, flank, ear-covert and other patches, as well as by the contrastingly coloured tail tips. The species of *Andigena* have general colours suggestive of *Selenidera*, but all have bronzy and grey-blue to whitish-blue in their plumage. Their undertail-coverts are red, and the area of rump and uppertail-coverts tends to be yellow; there is no sexual dimorphism. *Baillonius*, only slightly patterned, is the most uniformly coloured of the genera, resembling no other, although it shares a red rump with the araçaris of the genus *Pteroglossus*. With their black or chestnut and black hood, and their yellow underparts, the latter usually banded with red or with red, black and green, the brightly plumaged araçaris have no counterpart within the Piciformes, or among other toucans; the nape patch occasionally present in the genus suggests *Selenidera*. The large *Ramphastos* species have a black cap, upperparts, tail and belly, setting off the bright throat-breast colour with a red band at the rear, the red undertail-coverts, and the white, red or yellow rump and uppertail-coverts. These patterns, especially when added to the often fantastic bill colours and markings, and the facial and eye colours, are strictly "toucanesque".

However recently the toucans may have diverged from an ancestor which they have in common with the barbets, their array of unparalleled morphological and other characters, the

The size and shape of the toucan's bill precludes grooming of the head except by another individual. It is perhaps for this reason that allopreening is such a frequent year-round activity for members of the family. In this pair of Yellow-throated Toucans, the longer-billed male can be seen preening the crown feathers of his shorter-billed mate.

[*Ramphastos ambiguus swainsonii*, northern Colombia.  
Photo: Art Wolfe]

number of species in the group, their ecology, and their dominant position as Neotropical frugivores are deemed sufficient reasons to accord these highly distinctive birds family status, separate from the barbets (see Systematics).

## Habitat

Toucans range through forested lowlands from north-central Mexico south to western and eastern Argentina, a much greater area than that occupied by Neotropical barbets. Most are strictly forest species, and have trouble crossing rivers that are wide. One genus, *Andigena*, is confined to montane subtropical and temperate forest of the northern Andes, there reaching the tree-line. Another genus, *Aulacorhynchus*, is found essentially in montane forest, although not so high as that reached by some species of *Andigena*, and its members range into lowland forest in northern Central America, and in Peru. Emerald Toucanets sometimes occur in dry montane forest or woodland. The Collared Araçari spills into dry deciduous woodland in Costa Rica and, farther north, in Yucatán. The Toco Toucan is, however, the only ramphastid favouring open country with forest patches, savanna woodland, and forest edges along rivers, both large and small. It also ranges at times into dry upland Bolivian valleys, seeking fruits, and it courses through the Chaco woodlands, mainly along streams, and through thickets and palms of the Pantanal in Bolivia, Mato Grosso and Paraguay.

Most of the forest toucans will enter second-growth forest near primary forest, and some penetrate the *campos* along sufficiently dense riverine forest. The subtropical Atlantic forest, or remnants thereof, is home to several toucans in southern Brazil and adjacent Paraguay and Argentina. These include one essentially riverine araçari, the Chestnut-eared. Lowland-forest toucans ascend to various elevations at the foot of the Andes, in the mountains of Venezuela and the Guianas, and in south-eastern Brazil. Most reach only 1000-1200 m, but the nominate race of the Yellow-throated Toucan occurs in submontane forest at 700-2600 m along the eastern Andes, from Colombia to Peru. Lowland toucans such as the Yellow-throated and

Choco Toucans regularly forage into uplands in western Ecuador. Where the Red-breasted and Channel-billed Toucans meet in south-eastern Brazil, the former breeds in forest on mountain slopes. Although most toucans live in lowland forest, they do vary in their choice of micro-habitats; toucanets of the genus *Selenidera*, for example, prefer forest on higher ground and with a dense middle and lower storey. Even use of the habitat may vary. The big White-throated Toucans sing from exposed perches emerging above the forest, whereas the smaller Channel-billed Toucans sing from perches beneath the canopy, usually hidden from view.

A critical aspect of habitat is the availability not, as with the barbets and woodpeckers, of trees suitable for cavity excavation, but of suitable cavities themselves. The toucans, generally unable themselves to excavate (see Morphological Aspects), require pre-existing cavities for nesting and, in the case of some of the smaller species, also for roosting. Such facilities are provided by the holes of large woodpeckers, either abandoned or occupied, and large natural cavities, mostly those which sometimes form where major branching occurs, and those created by rot where large branches have broken off and fallen. One reason why second-growth forest cannot be utilized fully by toucans is the usual lack of such large cavities in new, young trees. On the other hand, trees isolated from the forest, standing in nearby pastures or on trails alongside forest, often have cavities. These are the result of exposure to the elements of a tree that was once part of the forest, and to woodpeckers seeking out such trees for their holes because they are subject to less predation from arboreal animals.

So far as is known, the greatest degree of sympatry among toucan species occurs in south-eastern Peru. There, at Tambopata Reserve or Manu National Park, one can observe the co-existence of eight species of toucan, about as many as the number of barbets occurring together in African forest. These include one species each of two genera, two species of *Ramphastos*, and four of *Preroglossus*. The last genus involves three species, the Ivory-billed, Lettered and Chestnut-eared Araçaris, that tend to favour floodplain and river-edge forest, and the more generally distributed Curl-crested Araçari. All four may eat fruits of the same

Toucans are in general very noisy birds, most often heard delivering simple repetitive yelps, croaks or squeals. Ramphastos species call for long periods on exposed perches, their "songs" being one of the dominant background sounds of lowland forests in South America. Although toucan repertoires seem very small, quite a variety of notes are given. The Chestnut-eared Araçari, for example, gives a series of piercing notes, or three or four whistled "weets", and also a woodpecker-like "pyee-tyee-tyee-tyet" call, the last possibly being a form of song. Toucans often cock their tails, and araçaris often twitch and cock the tail and throw the head about when calling.

Oxford Scientific Films]

As with other members of the genus *Aulacorhynchus*, the closest that the Groove-billed Toucanet comes to singing is a slow, monotonous series of up to about 20 growling, croaking or barking notes, variable in quality. In this genus, the members of a pair often call together, the male at a distinctly lower pitch than the female, and neighbouring pairs may countering in response. At least some of these toucanets also rattle or clap the bill, and the voices of some other bird species may on occasion be imitated.

tree, but usually not all together; rather, one species leaves as another group of a different species arrives.

Fruiting trees are of vital importance to toucans (see Food and Feeding), and a regular supply within a limited area is essential for breeding. That fruits may not always be available, even under natural conditions with no human modification of forest, is suggested by old accounts of widespread influxes of toucans into areas around major rivers, such as the Amazon; as Sick reported, these can involve up to 1000 individuals of some species. Toucans supplement natural foods by invading fruit plantations accessible to them, often seasonally, and by making local movements, such as shifting downslope, as do some Yellow-eared and Emerald Toucanets. The Grey-breasted Mountain-toucan lives in the high Andes of north-western South America, in temperate forest that abuts treeless, open *páramo*. It is resident at these altitudes, and must secure enough fruits to be able to live there.

The large size of toucans and their need for substantial quantities of fruits preclude their expansion northwards into North America, although lack of appropriate forest habitat in the north of Mexico and the south-western USA may also be current factors of relevance. Toco Toucans extend beyond the tropics as far south as forested areas of Tucumán, in north-west Argentina, and the riverine woodland and forest of Chaco and Corrientes in the north-east of that country; in the past they probably wandered farther, even to Buenos Aires. Here, it may be lack of habitat in the *pampas* and insufficiency of fruits farther south in forest and *monte* scrub along the Andes that prevented further southward expansion.

As is the usual situation, closely related species tend not to live in the same area. This is demonstrated by the Yellow-throated and White-throated Toucans along the eastern slopes of the Andes, where the Yellow-throated occurs on mountain slopes; and, as Haffer showed, by the Choco, Rainbow-billed and Channel-billed Toucans in northern Colombia. In the Andes, the mountain-toucans are allopatric: in the north, the Black-billed Mountain-toucan, while not a member of a superspecies with the Grey-breasted Mountain-toucan, occurs generally below the latter, but the two do overlap somewhat. There may even be

altitudinal replacement of species of *Aulacorhynchus* by mountain-toucans. For example, the very local Yellow-browed Toucanet in Peru occurs at 2100-2500 m, below the Grey-breasted Mountain-toucan and, incidentally, above the Emerald Toucanet; and the Hooded Mountain-toucan of the Bolivian Andes lives above 2400 m generally, and thus usually at a higher elevation than the Blue-banded Toucanet, below which live the Chestnut-tipped and Emerald Toucanets.

Amazonia is the centre of distribution of the toucans, even including the mountain-toucans and the green toucanets, most of which occur in highlands adjacent to western and north-western Amazonia. Colombia, with its great diversity of habitats, may have been the site of origin of a number of species, even of those, such as the Yellow-throated Toucan and the Yellow-eared Toucanet, which currently have their major range in Central America. Colombia is today home to 21 members of the family, 62% of all toucan species, although none is endemic to that country. Certainly, the Fiery-billed Araçari originated in Central America. So also, perhaps, did the Emerald Toucanet and the Rainbow-billed Toucan, as invaders from South America, later isolated and evolving in Central America, then re-entering South America; alternatively, they could have evolved in Colombia, and later invaded Central America. To the south-east, in the Serra do Mar subtropical forest centre in eastern Brazil, the genus and monotypic species of the Saffron Toucanet probably evolved as an ancient offshoot of an ancestor in common with *Pteroglossus*. The Red-breasted Toucan seems likely to have evolved there long ago, but the Spot-billed Toucanet is thought to have reached that region from Amazonia more recently, perhaps during a wet cycle, along rivers to the west and north, deriving from an ancestor in common with the very closely related, possibly even conspecific Gould's Toucanet. All the modern genera of toucans, with the exception of *Baillonius*, would seem to have originated in Amazonia.

No toucans or barbets appear to have reached the West Indies. The toucans are poor candidates for avian water-crossing species. The occurrence of Channel-billed Toucans on Trinidad is very likely due to the connection of Trinidad to Venezuela in the geologically recent past, rather than to over-water invasion.

## General Habits

For perhaps most of the time, the majority of toucans live in groups. Exceptions are some of the green toucanets, several species of *Selenidera*, some mountain-toucans, and the Green and Lettered Araçaris. Large gatherings of some toucans occasionally occur in migratory or eruptive movements, and at large fruiting trees with many ripe fruits. Examples include flocks of up to 20 Emerald Toucanets, twelve Plate-billed Mountain-toucans, and 22 Rainbow-billed, over 20 White-throated and 20 Yellow-throated Toucans. Most toucans breed in pairs, some retiring to part of a group home range; they then form family groups, or rejoin their own social group accompanied by their young. In all probability, only some of the araçaris regularly breed in small groups of three or four individuals.

The smaller toucans appear to roost in old nesting cavities or old woodpecker holes. Guianan Toucanets kept in captivity roost alone, in separate cavities if more than one of these is available; if there is but one, the male roosts in the cavity and the female outside it. The green toucanets roost in pairs in cavities. After breeding, araçaris sometimes roost in groups, or as many as will fit into one cavity, the remainder using another. Big *Ramphastos* toucans roost in groups, clustered beside one another, on a branch of a dense tree. The cavity-roosting species may attempt to take over the roosting holes of woodpeckers, harassing them regularly.

In the heat of the day, many toucans simply sit, often in a fruiting tree, in which case they may "control" access to the fruits. Others may sleep, occasionally in the full sleeping posture with tail pulled up forwards to the head (see Morphological Aspects). The daily routine can mean early visits to the neighbourhood's fruiting trees, or more lengthy foraging trips in search of new sources of fruit. The large toucans often spend some time in calling, an activity that is sometimes repeated late in the day. In the case of araçaris roosting together, there may be much calling and displaying among group-members before they take to the roosting cavity for the night.

"Play", involving "sparring" or "duelling" with the bill, has been observed in several ramphastid species of different genera. The birds approach one another and whack their bills together, or they clasp bills and push and tug. These bouts may involve contests between members of a group relating to dominance of the individuals. Paired birds at times reinforce the pair-bond by gentle, pushing "duels". Tag-chasing around and around, with repeated supplanting, among members of a group may also be concerned with the dominance hierarchy, and, moreover, group-members sometimes "play" at throwing a fruit from one to another, the fruit presumably being finally eaten.

Activities such as "play", various interactions, and even singing and sexual behaviour, may take place during the periods of time required for the digestion of large fruits by the toucans, as N. T. Wheelwright has shown. Because such fruits can take up to 75 minutes to digest, the presence of several of these in the digestive system may preclude further consumption of fruit. The "free" time during digestion can therefore be used for various of the birds' other activities.

Comfort behaviour involves a number of different activities. Moulting toucans scratch more often than do non-moulting toucans. For the head, scratching is by the direct method, over the wing, using one leg or the other. The bill is wiped at intervals during feeding. Perhaps because of the long bill, paired adults of the large toucan species allopreen all year, and even other members of a group sometimes preen each other's face, carefully, with the tip of the immense bill. Preening is frequent, and so, too, is stretching and yawning. A Plate-billed Mountain-toucan, for example, stretches one leg down and extends the wing of the same side upwards, the tail being spread to the opposite side, and then repeats this with the other wing and leg; finally, both wings are stretched and, often, the toucan yawns. Sunning occurs especially after rain: this is performed by spreading the feathers on the side facing the sun, sometimes with the head turned over, the body draped over a branch, so that one side, including the wing, and the throat skin are in the sun. Toucans also pant, holding the bill open, and probably cool themselves by evaporation of water from

the long, brushy tongue and the mouth-lining (see Morphological Aspects). Bathing occurs, probably often, in the water that collects in arboreal crevices. All the large toucans seem to bathe, as do the well-known species of araçari, such as the Collared and Fiery-billed Araçaris. Captive mountain-toucans and Spot-billed Toucanets bathe regularly.

Despite the presence of liquids in the fruits which they consume, those toucans observed frequently are known to drink. They usually take water from a tree crevice, or that held in bromeliads. Often, the water is not "gulped"; the toucan puts its bill deep into the water, and then holds the bill only slightly above the horizontal, allowing water to trickle or flow into the oesophagus.

Aggression varies considerably among toucan species, but one can assume that the adopting of a face-on posture signifies aggression. Otherwise, a number of different stances and movements are used, depending on the species. In the green toucanets, aggressors lash the tail and cock it, lean, peer, and make side-to-side movements with the head and bill forwards. *Selenidera* toucanets raise the head and hold it up, go into a horizontal posture, and call. One female Guianan Toucanet, kept in a cage with another female, pursued the latter, forcing allopreening upon it. Gold-collared Toucanets flap the wings and thrash the tail, and spread the red feathers of the undertail-coverts. The Plate-billed Mountain-toucan bobs its head, flips its tail up and down and, similarly, erects the red undertail-coverts. Green Araçaris hold the head up and swing it from one side to the other, shake the tail from side to side, and then cock the tail and twitch it. On the other hand, Black-necked Araçaris bow, erecting the head to one side, then dropping it down to the other side, often cocking the tail forwards as far as the back. Collared Araçaris stretch the head, bow, nod, and jerk all about; a dispersing araçari trying to join a group was held by the bill, and pecked by various group-members, becoming bloodied. Curl-crested Araçaris bow very deeply up and down, jumping from perch to perch and giving "krek" calls. Aggressive Red-breasted Toucans raise the nape feathers, swing the head from side to side, and lean forwards. In conflicts, a submissive Choco Toucan erects the crown feathers and spreads the tail, while the aggressor holds the bill low, with crown feathers sleeked, and the tail closed, showing more of the white of the uppertail-coverts. In the case of Toco Toucans, the attacker directs its bill forwards, rattles, pecks forward and grabs, and bangs the bill loudly on a branch. White-throated Toucans point the bill at an opponent and switch the tail from one side to the other.

Interactions between different species of toucan are frequent in occurrence, although the smaller toucans usually keep their distance from larger ones. Emerald Toucanets sometimes chase Collared Araçaris, which may return the chase, with several group-members attacking. Collared Araçaris are aggressive towards single Choco Toucans, "buzzing" the Choco and flying at it when it is airborne. The Black-necked Araçari and other *Pteroglossus* species tend to stay well away from White-throated Toucans, as do Channel-billed Toucans. Red-breasted Toucans supplant Chestnut-eared Araçaris, and one or two of the former together can keep groups of Saffron Toucanets out of a fruiting tree. Interestingly, even though Rainbow-billed Toucans will nest close to Yellow-throated Toucans, they are frequently supplanted by the latter species at food sources. Among the araçaris, it is simply the larger or more numerous species that is dominant: for example, five Chestnut-eared Araçaris were seen to drive four Lettered Araçaris from a potential nesting cavity, the former later nesting in the cavity.

Larger toucans and araçaris are often mobbed by calling birds, and are attacked in flight by various tyrant-flycatchers. The highly predatory White-throated Toucan, when alone or in pairs, is readily mobbed by several species of tyrant-flycatcher (see Food and Feeding), and in flight the toucan may even suffer the indignity of having a flycatcher land on its back. Not surprisingly, hunting araçaris, when they skulk about in dense bushes or trees, are mobbed by various small birds. That the mobbers have reason to fear toucans is evidenced by the fact that *Selenidera* toucanets are clearly attracted to birds caught in mist-nets; they will attack and eat birds that are trapped in this way.

Toucans are primarily frugivorous, consuming a wide variety of arboreal fruits; Emerald Toucanets have been recorded eating 115-120 fruit types from around 50 families of plants. They tend to eat smaller, more carbohydrate-rich berries early in the day, later moving to high-nutrient fruits. In the dry season food supplies are scarce, and individuals need to feed for longer periods on berry-like fruits and make longer-distance forays from one food source to another. Most members of the family, however, are opportunistic omnivores. Although this Guianan Toucanet is consuming berries, it will take insects encountered while foraging; indeed, in captivity *Selenidera* toucanets can be maintained on an all-insect diet, and will actively hunt insects in their cages. Moreover, members of this genus are known to be quite carnivorous, sometimes attacking small birds trapped in mist-nets and often being mobbed by passerines.

Despite their rather clumsy appearance, toucans are very agile in trees and are adept at stretching acrobatically to reach food. Even the largest species, the Toco Toucan, can hang daintily to pluck small fruits with its long bill. It can twist them off by swivelling its bill and can detach them by tugging with considerable force. In their range, toucans are generally responsible for consuming the majority of fruit at major fruiting trees and are thus extremely important vectors for seed dispersal in Neotropical forest ecosystems.

[*Ramphastos toco albobularis*, Iguazú National Park, Argentina.  
Photo: Günter Ziesler]

On the other hand, the toucans, although kings of the frugivores at a fruiting tree, are hardly without enemies of their own, including human hunters (see Status and Conservation). Various forest eagles, hawks and eagle-owls are major predators of toucans. Ornate Hawk-eagles (*Spizaetus ornatus*), White Hawks (*Leucopternis albigollis*) and Collared Forest-falcons (*Micrastur semitorquatus*) prey on Collared Araçaris in Central America. The Ornate Hawk-eagle and the Great Horned Owl (*Bubo virginianus*) prey on Channel-billed Toucans, including those roosting on branches of trees, and in Tikal National Park, in Guatemala, the Rainbow-billed Toucan is commonly eaten by Black Hawk-eagles (*Spizaetus tyrannus*), as well as by Ornate Hawk-eagles. In some species, such as the Channel-billed Toucan, the social group will sometimes follow larger, noisier falconiform groups, particularly Red-throated Caracaras (*Daptrius americanus*), as a measure to lessen the chances of predation.

## Voice

Acoustical displays are important in the Ramphastidae. The non-vocal sounds produced by toucans range from bill-tapping to bill-clattering and loud rustling of the wings during interactions. Wing-rustling is often surprisingly noisy, and is especially notable in the *Ramphastos* toucans with their emarginated outer two primaries. Although it is not apparent from their often very repetitive songs, most toucans have a large vocal repertoire. It should, however, be noted that what recordists call "small sounds" are unknown for many toucans. Indeed, what might be termed "songs" in the classic sense are not well understood in the case of some species, mainly the araçaris.

Sounds resembling bill-snapping are evident as single, mechanical sounds, and are associated with the calls of some green toucanets, the *Selenidera* toucanets, the mountain-toucans, the *Ramphastos* toucans and some araçaris. They are most obvious in the songs of the large mountain-toucans and the *Ramphastos* toucans, and can be dominant in some notes. Because some calls

with the snaps, as well as some of the rattle calls with very mechanical sounds, are uttered with the bill closed, it may be that they are produced by the tongue hitting against the inside of the bill; on the other hand, they may, indeed, be vocal. Bill-whacking in aggression is an obvious sound, the toucan hitting a branch with the bill, while loud wiping of the bill is a further aggressive activity in interactions. In addition, many toucans tap the bill rapidly against the entrance to the nesting cavity, and some do so inside the nest, effectively "drumming" in the manner of woodpeckers and some barbets.

Growling, grunting and barking notes, variable in minor detail and in their length and the tempo at which they are given, make up the often monotonous, long "songs" of the green toucanets of the genus *Aulacorhynchus*. Paired individuals may sing simultaneously, the male at a lower pitch, often stimulating countersinging by neighbouring pairs. These are typical sounds of montane forest.

Four closely related species of *Selenidera*, the Tawny-tufted, Gold-collared, Gould's and Spot-billed Toucanets, during their essentially identical visual bowing displays, utter growl-like "krowk" or "krrawk" notes more or less with each bow; these vary in tempo among the species. Of their two congeners, the Guianan Toucanet has, instead, a series of rattle-squawks, and also gives series of screams very like those of the mountain-toucans, while the song of the Yellow-eared Toucanet is, by contrast, a "tik-kit" series. Usually, the songs are uttered separately by males and females, but sometimes the sexes sing simultaneously.

The mountain-toucans utter braying series of "eeeeeah" notes, sometimes compounded with bill-snapping sounds; snaps may lead into the song. These are given with accompanying bows like those of *Selenidera* toucanets. The song notes of the Grey-breasted Mountain-toucan are the longest recorded for any piciform, up to two seconds or more in length. The Saffron Toucanet utters a "tee-ee-up" series, without such obvious displays as those of the two previous genera.

Araçaris vary in their calls, with songs, as such, not known for most species. Some have "kek" or rattle calls, for example the Green, Lettered and Red-necked Araçaris. The Ivory-billed

Toucans "monitor" regular fruiting trees to assess the food supply, and individuals are known to guard productive fruit sources, driving off other frugivores, even a mate.

Nevertheless, their foraging requirements are not entirely met by forest fruit. Several species visit gardens or plantations to feast on fruit such as bananas and papayas, as illustrated by this Collared Araçari and Red-breasted Toucan. They dig into large fruit, returning repeatedly to the known resource, and some species drop to the ground to feed on fallen fruit. The form of Collared Araçari shown here is often treated as a separate species, the Pale-mandibled Araçari, a restricted-range near-endemic of western Ecuador; however, regular interbreeding occurs with the race sanguineus of Collared Araçari in north-western Ecuador and also in extreme south-western Colombia, suggesting that only one species is involved.

[Above: *Pteroglossus torquatus erythropterus*, Tinalandia, Ecuador.

Below: *Ramphastos dicolorus*, Itatiaia National Park, Brazil.  
Photos: Kevin Schafer]

Araçari has a wailing song of "waaaa" or "traaa-at" notes in series, not unlike that of the Saffron Toucanet. All five members of the "Collared Araçari group" utter very similar, short "peeent" or "sneep" notes in irregular series, but they seem to have no song as such. Curl-crested Araçarís give deep "rrek" to grunting notes, the latter like those of the green toucanets; these are delivered in irregular series with intermingled bill-snapping sounds.

The big *Ramphastos* toucans can be divided vocally into two groups. The first is the croaking, honking group of five species, which utter calls in long or short, regular or irregular series. The notes have both noisy and clear elements, these being either muted or enhanced. Thus, the notes of the Red-breasted Toucan are "grrek"-like, those of the Rainbow-billed vary from "bbrrik" to "ggrrr", and the notes of Choco Toucans sound like "tyeerp" to "tree-ak". Channel-billed Toucans usually have clearer "keee", "kerrrk" or "kee-ark" notes, and the Toco has the deepest, grunting "groomkk" sound. These vocalizations are "sung", the female's higher-pitched, sometimes clearer notes at times given simultaneously with those of the male, eliciting countersinging by other individuals. The other two *Ramphastos* species, the White-throated and Yellow-throated Toucans, sing in yelping sets of more musical notes, phrased more or less as "Dios-te-de"; more like "keeow-yelp-yelp" in the White-throated, and more double-noted, "Dios, te-de", in the Yellow-throated. The numbers of yelps following the initial note of a phrase can vary. The sexes of these two species, females of which again have higher-pitched voices, sometimes sing together on exposed perches, their sounds being a dominant feature of the background ambience of Neotropical lowland forest. Most of these vocalizations are represented on a useful cassette produced by J. W. Hardy and colleagues in 1996.

The singing postures of toucans vary a great deal. That of the green toucanets is simple, the upright bird perhaps twitching its tail below the often half-erected rump feathers. Most of the *Selenidera* toucanets flare their ear-tufts and red undertail-coverts, bow deeply, with the tail usually moving downwards, and then raise the head and tail high more or less in time with

the notes of the song, or the tail may be held cocked and twitched. In the Yellow-eared Toucanet, however, the head is tossed up to one side, the semi-cocked tail flopped to the opposite side, and the bird then bows, following this with a toss of the head and a switch of the tail to the opposite side. Song postures of mountain-toucans are generally like those of species of *Selenidera*. There is no described singing posture of the Saffron Toucanet, and the araçaris have no precise posture when uttering their calls, although they often switch and cock the tail, and toss the head about.

In the "croaking group" of *Ramphastos* toucans, the singer stretches the head out and up and swings it in a smooth or jerky arc from side to side, dipping but not bowing deeply. Some species drop the cocked tail with each note, and then, after five or six notes, swing the head to the other side and cock the tail again; sometimes, the head is held erect throughout and the tail is twitched. The two species comprising the "yelping group" raise the head upwards, either vertically or to the side, gradually lowering it with the notes until the posture becomes a more or less deep bow, and then swing the head upwards, or out and upwards, to the other side, the tail moving up and down with the head. The incorporation of swinging and bobbing-bowing movements is a feature of the displays of toucans, barbets, woodpeckers and some honeyguides, and is not necessarily associated with "singing".

The many other sounds made by toucans include predominantly rattling calls and bill-rattling, along with growling and grating notes, and begging notes, such as the "cha-cha-" uttered by Emerald Toucanets. Also heard are "ark" notes in interactions, soft rattling "intimate" calls such as "un", "ik", "eh", "tut", "wek", "eee", "perp", "rak" and "tweah", chatters, croaks, a piping "zneep", and a grunting "tuk" and other low calls. Araçarís and Saffron Toucanets have low purring calls. Young toucans in the nest generally utter peeping, squeaky, whining, buzzy or wailing notes in series. Collared Araçarís have a little-known "pee-yew" alarm call, and emit an aggressive "arghr", as well as loud "pit" notes in alarm; other toucans utter "kyeek" or squeak-like alarm calls. Chestnut-eared Araçarís are known to give three or four whistled "weets", and a woodpecker-like "pyee-tyee-tyee-tyee-tyet" call, possibly a song.

Toucans augment their fruit diet with a variety of other items. Some species are known to hunt and consume small mammals; others eat lizards, sometimes hunting them co-operatively; others eat roosting bats, or frogs, toads and snakes. Some species follow army ants, normally positioning themselves close to the front edge of the column, and dropping onto or chasing insects flushed by swarm. As an indication of their carnivory, captive individuals of some species, including White-throated Toucans, are said to prefer meat to fruit, even hunting and eating small birds that enter their cages.

Ardea]

This male Toco Toucan is delivering a stolen egg to his chicks inside their cavity nest. This illustrates an important aspect of toucan foraging strategy: more than half the toucans of five genera are known to steal eggs and young from nests of other species, and it is very likely that the remainder do so at least occasionally. Some species are very bold, chasing other species (even birds of prey) from their nests to steal the contents.

Most of the sounds made by toucans are unique to the family. Those sounds that are similar to calls of barbets also resemble those of other piciforms.

### Food and Feeding

These large birds are primarily frugivorous. They seek out and "monitor" fruiting plants of a wide range of species. The fruits that they eat, although diverse, tend to be red, red and black, orange, purple, black, green, brown and yellow in colour. A single species, such as the Emerald Toucanet, will consume fruits of 115-120 species, representing about 50 families of plants. A dominant large toucan at a fruiting tree, say, the Yellow-throated Toucan at a tree of *Viola sebifera*, may take 45% of the tree's fruits, each of which yields about 825 calories. The toucans, therefore, play a very major role in the dispersal of seeds of many fruiting trees.

Important families of fruiting plants, mainly trees, are the Lauraceae, Moraceae, Cecropiaceae, Melastomataceae, Solanaceae, Myrtaceae, Clusiaceae, the palms Arecaceae, Rosaceae, Urticaceae, and many others. Of especial importance are species of *Beilschmiedia*, *Caesaria*, *Cecropia*, *Coussapoa*, *Didymopanax*, *Ficus*, *Inga*, *Nectandra*, *Neea*, *Ocotea*, the palms *Euterpe* and *Oenocarpus*, the peppers *Capsicum* and *Piper*, *Phoebe*, *Protium*, *Prunus*, *Rubus*, *Steicula* and *Viola*. The ramphastid diet thus includes berries, arils of various sizes, fruits with seeds that pass through the digestive tract, and large-stoned drupes such as avocados, the seeds or stones of which must be regurgitated, as well as large, pod-like fruits such as *Cecropia*, or *Piper* peppers, that must be held in the feet and broken open. These frugivores also eat nectar and flowers of species of *Clusia*, *Combretum*, *Erythrina*, *Mcclenia*, *Quararibea*, *Saurauia* and others. Captive toucans accept apples, avocados, bananas, cooked beets and carrots, blueberries, cantaloupes, watermelons and other melons, chopped cabbage and lettuce, grapes and raisins, guavas, frozen maize, papayas, peaches, pears, peas, raspberries,

and cooked zucchini. Because of these birds' propensity for storing iron (see Morphological Aspects), however, oranges and other high-iron foods are to be avoided.

Wheelwright showed that Emerald Toucanets eat smaller, more carbohydrate-rich berries early in the day, and that they monitor fruiting trees, later moving to high-nutrient fruits. Fruit availability is important. In the dry season, this toucanet has to feed for a longer period, lower down, on smaller-seeded fruits, and it has to move greater distances from one food source to another. Generally, a toucanet made feeding visits lasting two to eight minutes, took an average of two fruits totalling 26 g per visit, and took 24-70 minutes to digest the fruits; larger fruits require more regurgitation to facilitate digestion. C. M. Riley and K. G. Smith, in their study of the Emerald Toucanet, found that the sexes fed on the same fruits and used the same foraging modes; they also found that the diet shifted to about 21% animal matter when the adults were feeding nestlings.

The dispersal strategies of the plants may vary. Several toucan species feed on fruits of the palm *Oenocarpus*. As Bühler pointed out, this palm produces large-stoned fruit with little, but nourishing, flesh; the fruits ripen a few at a time, on long filamentous stalks that hang down. It is difficult for toucans to gain and maintain a perch, and so they leave after eating few fruits, thus facilitating dispersal of the seeds away from the trees. Incidentally, in addition to seeds, the legs of small passerine birds and the legs and tails of mice fed to captive Red-breasted Toucans also pass through the digestive tract.

Toucans are also opportunistic omnivores, and they need to capture insects or other animal foods for their young in the early nestling stages. Since toucans tend to breed when many small birds are nesting, opportunities are available to secure eggs and young of birds, and nearly half the toucans of five genera are known to do so. Indeed, in parts of Brazil, Red-breasted Toucans are persecuted for this habit. At least seven species eat lizards, and paired Yellow-throated Toucans will at times hunt these co-operatively. Three species of the genera *Andigena* and *Ramphastos* are known to hunt for and eat small mammals, while

This Red-breasted Toucan is caught in the act of plundering a Great Kiskadee (*Pitangus sulphuratus*) nest situated in the trailing branches of an *Araucaria* tree. In such cases, toucans prise open the nest, often ignoring the entrance, and eat the chicks or eggs. At least seven species in the family have been recorded opening the suspended nests of caciques or oropendolas (*Icteridae*). It is because of this predilection that toucans are often mobbed by smaller birds. The efficacy of this defence behaviour is limited, however, because of the persistence of toucans: one species was observed stealing flycatcher eggs despite being mobbed by twelve flycatchers of three species at the time!

[*Ramphastos dicolorus*, Rio de Janeiro, Brazil. Photo: Gustavo Banhara Marigo]

Channel-billed Toucans take roosting bats, and also eat frogs and toads. Snakes are captured and eaten by six species.

Insects are taken at least occasionally by a number of toucans, with orthopterans such as cicadas and grasshoppers the most frequent prey. Beetles, homopterans, caterpillars, flies, bees, ants and flying termites are eaten, the Toco Toucan being one of at least three ramphastids that will "fly-catch" for aerial insects. Rainbow-billed, Choco and Channel-billed Toucans follow army-ant columns, seizing insects and vertebrates flushed by the ants, while the Gold-collared Toucanet and the Grey-breasted Mountain-toucan take insects while foraging as members of mixed-species flocks. In captivity, Plate-billed Mountain-toucans and Red-breasted, Toco and White-throated Toucans systematically hunt and eat small birds that enter aviaries. Interestingly, Toco and White-throated Toucans kept as pets are said to prefer meats to fruits, and these species have been fed on a long-term basis on boiled eggs, meat, bread and a small bird per day. Captive *Selenidera* toucanets can be maintained on an all-insect diet and, indeed, will forage for insects in their cages. Centipedes and spiders are other toucan foods.

Groove-billed Toucanets are well-known nest-robbers, and several other species have been seen to indulge in this type of behaviour. Emerald Toucanets attempted to enter a barbet nest with calling young, and Yellow-throated Toucans tried to reach Collared Araçari nestlings in a cavity. At least seven toucanets, araçaris and toucans have been recorded opening the suspended nests of Yellow-rumped Caciques (*Cacicus cela*) and oropendolas to get at the contents. In a study in Manu National Park, Peru, it was found that, of 41 attacks by Chestnut-eared Araçaris on cacique colonies over a three-month period, 24% were successful. Four Lettered Araçaris regularly raided cacique nests; they also took two young from pigeon (*Columbidae*) nests, ate young finches (*Fringillidae*) from cavity nests, and were successful in obtaining eggs or young from three swallow (*Hirundinidae*) nests. White-throated Toucans, although being mobbed by twelve flycatchers of three species, still managed to steal eggs from a flycatcher nest, and Yellow-throated Toucans ate the young of three flycatcher species. One of those Yellow-throated Toucans even

chased a female Double-toothed Kite (*Harpagus bidentatus*) from her nest and ate the young. White-throated Toucans achieved a success rate of 36% in raids on cacique nests; and, in attempts to obtain young flycatchers from nests, their success rates were 20% for *Pitangus* flycatchers, 50% for *Myiozetetes* species, and 33% for *Megarhynchus* flycatchers. In view of the degree of nest predation by toucans, it is no surprise that they are frequently mobbed by other birds.

When foraging, toucans fly one at a time into a fruiting tree and quickly jump into positions for grasping, tugging and pulling off ripe fruits. They are very agile, the immense bill not deterring them from hanging and reaching, twisting the neck about, and seizing fruits. The length of the bill enables them to reach far from their centre of gravity, and the hook tip and jutting serrations give them certain purchase. Even Toco Toucans can hang and daintily pluck small fruits. On one occasion, a semi-tame Toco rifled the pockets of the observers, hanging upside-down as it turned out pocket-linings; pulling against the bird's tugs resulted in terrier-like shaking and fast back-and-forth twists with power. Red-breasted Toucans can keep numbers of Saffron Toucanets from a fruit tree, and Yellow-throated Toucans sometimes guard a tree, evicting any other frugivores, even a mate. The last species descends to the ground to eat fallen bananas, and Channel-billed and Toco Toucans also drop down to feed on fallen fruits, the latter making fast, 70-cm hops on the ground.

Large fruits, pods, and insects and vertebrates are held in one or both feet and broken up; in the case of a mammal or snake, the food is "mandibulated", meaning that it is worked over by the serrated "teeth" of the bill.

When hunting animal food, toucans skulk with the head held low, looking all around constantly. Working in tandem to catch a lizard, one goes after the prey bill first, while the other perches close by or flies to the other side of a tree trunk, ever ready to snatch up the reptile. Various toucans probe into epiphytes for insects or frogs. Gold-collared Toucanets carefully ply the bark of trees, along the trunk, out on to branches and in foliage, probing into debris, mosses and crevices. Like hawks

Despite the liquid content in fruit, toucans frequently drink. They usually take water trapped in tree crevices or in bromeliads, drinking by closing the bill as deeply as possible into the water, then raising it just above the horizontal so that the water trickles down the inside of the bill. It is thus possible that this Rainbow-billed Toucan is visiting this bromeliad for the purpose of seeking water, but it might also be looking for insects or frogs; toucans are known to prise open bromeliads for this purpose.

[*Ramphastos sulfuratus*.  
Photo: Carol Farneti/  
Planet Earth]

(Accipitridae) and small owls (Strigidae), the toucanet gravitates towards sounds of birds in trouble, such as those trapped in mist-nets. Toucans following army ants move low above the leading edge of the ant column, peering, dropping down to pick up prey, or even chasing it.

## Breeding

The mountain-toucans and the toucanets of the Andes breed mostly from January to July, or somewhat later, in the north, and from June to December farther south, in Peru and Bolivia. It is during these periods that the greatest numbers of plants are fruiting. Amazonian toucans have a long breeding season, this being possibly due in part to the occurrence of reneesting. In northern Central America, the breeding season is approximately the same as that in southern North America, namely from January to July. Paraguayan, Argentine and south Brazilian toucans follow a typical austral regime, breeding usually from August to February, with some commencing earlier and a few nesting later. The widespread Channel-billed Toucan breeds from June to November in north-eastern South America, but from November to July in Venezuela, August to March in western Brazil and October to April in south-central Brazil, while some breeding takes place in most areas in the months of February to July. Such seasonality has not been evaluated with regard to the seasonality of fruits on which these toucans depend, except in the far north and south of the overall range; at those extremes, the appropriate spring-summer period is the flowering and fruiting time of the year.

Details of toucan territories and their sizes are little known, and from only few locations, and the relationship between home range and territory is poorly understood. Territories may vary seasonally, or be partitioned between the primary pair and the rest of a social group, and they are readily abandoned under adverse fruiting conditions. Often, territories are smaller in a preferred habitat, and larger elsewhere.

At Manu, in Peru, Emerald Toucanets have been found to occur at two pairs per 100 ha of successional *Ficus/Cedrela* for-

est along lakes and rivers, and at 1.5 pairs per 100 ha in mature forest. Gold-collared Toucanet pairs live mainly in mature forest, each pair having a home range of 100 ha, of which about 35 ha represent the territory. In the same area, Lettered Araçaris are found along rivers, at a density of less than one pair per 100 ha. Ivory-billed Araçaris living in the same early successional stages of riverine forest occur at two pairs per 100 ha, a pair using perhaps 20 ha of a 50-ha home range; in very late successional stages, and in mature forest, 200 ha hold just a single pair of that species. Chestnut-eared Araçaris in this riverine habitat are less common, at one pair per 200 ha, than are Lettered or Ivory-billed Araçaris. The Curl-crested Araçari, however, favours mature forest, where one pair or group uses 20-25 ha, but in riverine late successional stages it requires 50 ha or more.

The existence of suitable nesting cavities is a prerequisite for a usable territory. In the 1920's, J. Van Tyne apparently found ideal conditions on Barro Colorado Island, in Panama, for in 16 ha of mature forest there he located nests of three pairs/groups of Collared Araçaris, four pairs of Rainbow-billed Toucans and two pairs of Yellow-throated Toucans. The Plate-billed Mountain-toucan in Colombia was found to have a group home range of 8-9 ha; the pair nests alone within that range, which may be deserted by the group in poor years. In south-eastern Brazil, Saffron Toucanets appear to maintain a territory of approximately 40 ha per pair. G. R. Bourne found White-throated Toucans in groups in very large home ranges for much of the year; the primary pair defends a small territory in this range for the breeding season, and then rejoins the group, along with any young that are raised. In a study in Peru, White-throated Toucans had territories that varied from about 30 ha in late successional riverine forest to some 50 ha in mature forest; they were more numerous than Channel-billed Toucans, which occupied territories of 40-67 ha.

In those cases in which the toucans live mainly in groups, the more mature, but still non-breeding, individuals comprise "floaters" within the population. From these, a breeding toucan losing its mate would presumably select a new mate. To the extent that the groups are composed of subadult and immature

individuals they are not potential breeders, and they can give the impression to the observer of a greater effective population than really exists. More needs to be learned about group composition, home-range size, and the relative availability of suitable nesting and, for some species, roosting cavities.

Breeding sociality is not common generally. Green toucanets seem to clear their territory of group-members and to breed as pairs. *Selenidera* toucans seemingly do the same, although there is a record of a nesting trio of Guianan Toucanets. Breeding mountain-toucans occur as pairs. Even among the generally social araçaris, most species breed in pairs, with trios known for the Lettered, Ivory-billed and Fiery-billed Araçaris. Red-necked, Black-necked and Curl-crested Araçaris are likely to nest in social groups of three or four individuals, and Chestnut-eared Araçaris may occasionally do so. Collared Araçaris nest in groups of up to five or six, but the primary pair keeps the others from the nest during egg-laying and incubation; after the eggs have hatched, they rejoin the parents and nestlings, roost in the nest, and feed the young. The large toucans seem to breed strictly in pairs, and in captivity, once breeding commences, they usually kill any conspecific toucan caged with them.

Although no toucans appear to breed colonially, nor do two or more females of a group seem to breed, there are numerous cases of pairs of both large and small species nesting rather close together, as happens with some barbets. These cases have not, however, been studied in any detail. It seems likely that pairs of conspecific toucans, having happened to find nesting cavities within 100 m or less of each other, then regulate their foraging and other activities in opposite directions, away from one another.

It is probably rare for a toucan, even a small one, to breed in its first year. Yearlings are likely to make up the bulk of groups cast out of territories by pairs of green toucanets and mountain-toucans. *Ramphastos* toucans may barely be adult at one year old. Avicultural information suggests that most large toucans nest successfully only when they reach three or four years of age, and, in any case, not until two years. Captive male Red-breasted Toucans first bred at 34 months and captive females at 21 months, suggesting that, under some conditions, females can breed at two years of age. If nesting cavities are at a premium, it is unlikely that young, newly formed pairs, or pairs with young replacement individuals of one or the other

sex, will be able to compete with older, experienced pairs. Finding, or taking over from other hole-nesters, a suitable nesting cavity would presumably be difficult for young adults. If the suitable cavities are already taken, the available habitat would be saturated, and entry into the breeding population by younger adults would be impossible. Indeed, Plate-billed Mountain-toucan pairs, whatever their age, may not breed yearly.

Most toucans are unable to excavate a nesting cavity, although a few green toucanet pairs do so. Yet aviary experience and several field observations suggest that some excavation, by one or both pair-members, is an essential part of pair formation and maintenance, and probably important for physiological synchronization of their breeding. The normal procedure is for the toucan to find a vacant cavity or to take over one already occupied. Fiery-billed Araçaris, for example, use old or usurped cavities of the relatively large Lineated Woodpecker (*Dryocopus lineatus*) and Pale-billed Woodpecker (*Campephilus guatemalensis*). The smaller toucans may exert themselves to drive out occupants of usable cavities. Repeated attempts to usurp a cavity could interfere with the nesting woodpeckers or other birds, allowing a take-over by the toucans. Large toucans that are successful ordinarily return to the same nest early in the next breeding season, and begin clearing it and preparing it for laying. The height of the cavity often seems not to matter, the securing of a cavity being more important than is its location. Toco Toucans, for instance, even nest on or inside termite mounds on the ground, often in those where Campo Flickers (*Colaptes campestris*) have previously excavated a nest.

The Emerald Toucanet, especially the female with its shorter, straighter bill, can excavate or "bite" out wood if the wood is very rotten, and it will even use the tail, soft though it is, as a "prop". The toucanets drop the pieces of wood away from the nest. Araçaris at times tear out the rotted centres of cavities that they occupy, whether natural or woodpecker-made; they frequently use holes with very narrow entrances into which they must squeeze, as they are unable to excavate hard bark and underlying wood. Spot-billed Toucanets will also tear into well-rotted wood, and may start and complete some excavations; old woodpecker cavities are apt to be safer, in harder wood. Plate-billed Mountain-toucans do some excavation, and may on occasion have to work for six weeks or so to complete a nest, some excavating continuing during incubation. Their nests may be

Although many species of toucan spend the non-breeding season foraging in groups, breeding sociality is not common. Certainly all of the larger toucans, such as the Toco Toucan, always nest in pairs; indeed, when a breeding pair is held captive with another conspecific, the members of the pair generally kill the third bird. Even in the highly social araçaris, while the group may stay essentially integrated during the breeding season, the nesting pair will usually keep the other group members away from the nest during the egg-laying and incubation periods. After hatching the group reassembles to roost in the nest cavity and share parental care.

[*Ramphastos toco*, Brazil.

DRK Photo]

Although most species of toucan use only available cavities, some are capable of digging out a nest in soft substrate. The Emerald Toucanet, for example, often excavates or bites through soft rotten wood, and carries the debris away from the nest. It tends to be the female that performs this task, perhaps because her bill is shorter, straighter and thus more sturdy, but also because the female performs the greater part of nest duties. One of the other chores is that of nest sanitation, involving the removal of faecal material mixed with shreds of rotten wood.

[*Aulacorhynchus prasinus caeruleogularis*, Costa Rica.  
Photo: Michael & Patricia Fogden]

nearly 2 m deep. This species often excavates nesting cavities in well-rotted, perhaps over-rotted, stubs or dead trees that may fall down at any time. At other times it usurps a cavity from Toucan-barbets (*Semnornis ramphastinus*) that have chosen to carve a nest in a tree sufficiently broad to allow use by the larger toucan.

The big *Ramphastos* toucans not only clean out debris, but also tear into rotted wood at the bottom of the natural cavities that they use. Cavities used for consecutive years become deeper and deeper, to 2 m on occasion, with each year's cleaning. The nests of these species are 2-30 m or more above the ground. The toucans seem to seek out cavities with narrow entrances, but to a great extent they have to accept them wherever and however they are situated. Nest-sites are selected and visited for one to two months before they are occupied. Most end up with a lining of fruit stones up to 7 cm or more in depth. Sometimes the eggs are not laid until two weeks after the cavity is ready.

Smaller toucans may select cavities in isolated trees in pastures, as an anti-predator strategy. Once occupied, the nest is rather conspicuous, although the adults approach quietly, and often in a roundabout way. The toucans will defend the nest, and even mob certain predators, but they are wary and often watch the predator at a distance. Interestingly, Yellow-throated Toucans were seen to chase away a kinkajou (*Potos flavus*), an arboreal mammal, rattling the bill at it.

As might be expected where pair-bonds tend to be long, the courtship displays of toucans are not elaborate, and copulation can occur without prior ritual. The plumage and bare parts, the wherewithal for display, appear not to change seasonally, and are, rather, determined by age, sex and condition of the toucan. Colour patterning and markings, such as red undertail-coverts, coloured marks over the eye or on the ear-coverts, and the frontal and lateral patterns of the head and bill, are likely important, and can be shifted by movements and by erecting and lowering of the feathers. The most prevalent courtship displays are courtship feeding and allopreening, the latter especially about the face and eyes, although this can occur to an extent throughout the year in large toucans. Some species, such as the Plate-billed Mountain-toucan, courtship-feed only in the vicinity of the nest. Courtship feeding is known to occur in all genera of toucans, while delicate allopreening is most frequent in *Ramphastos*, but is also performed by green toucanets, *Selenidera*, *Bailloni* and a few aracarís.

Plate-billed Mountain-toucans display by jumping about, the male calling with tail cocked, and both sexes erecting the red undertail-coverts and the yellow-gold flank mark. During this, the moving bill and face colours are, of course, a notable feature. In Saffron Toucanets, courtship feeding is carried on to the extent that the "gifted" fruit is passed back and forth, while there is extended allopreening of the female's face by the male, and both sexes tap-drum at the nest. Very little information is available on courting aracarís; apparently, the pair-members bob and bow at one another repeatedly, a possible effect of this being that the shorter bill of the female is displayed differently from the male's against the pattern of the underparts. In Red-breasted Toucans, allopreening is carried to the point of feeding-chases of the female by her fruit-carrying mate. The male Toco Toucan cocks the tail and spreads the red undertail-coverts, leaping about the female, and in captivity the male can become too aggressive towards its mate for breeding to occur. Allopreening male White-throated Toucans softly "chew" or "nibble" on the female's face with the tips of the mandibles. During the courtship period, Yellow-throated Toucans regurgitate one fruit after another, up to five at one feeding. The male of this species, which sometimes keeps even its mate from a fruiting tree, will often come to allow her to feed in it with him, at a distance, or he may turn over the tree to her control, moving himself to another nearby.

One to five white eggs are laid by green toucanets, two to four by *Selenidera*, two or three by the Plate-billed Mountain-toucan and by *Bailloni*, two to five by aracarís, and one to five by *Ramphastos* toucans. These are laid at daily intervals, incubation commencing with the last egg in the case of the Rainbow-billed Toucan, but starting with the first egg in White-throated Toucans. Copulation continues through the laying cycle. In the Plate-billed Mountain-toucan, the female solicits and the male mounts as she crouches; he puts his head over her nape and holds her nape feathers as she partly spreads her wings and tail, copulation lasting for 15-20 seconds. In Yellow-throated Toucans, there appear to be no preliminary displays prior to copulation. Female White-throated Toucans droop the tail and body, with wings held out, and then raise the tail, whereupon the male mounts, and he may stay thrusting atop her for up to 35 seconds.

The female often incubates more than the male, and incubates at night in the cases of the well-studied Emerald Toucanet

and the Plate-billed Mountain-toucan. Both parents incubate during the day. In White-throated Toucans, the female sits at night, and, while incubating during the day, is fed on the nest by the male. Incubation stints recorded for Rainbow-billed Toucans last from four to 86 minutes, and those of Fiery-billed Araçaris are two to 102 minutes, averaging 25-28 minutes. Data on incubation period are available for eleven species, representing all genera, and these give an average of 16.3 days. The incubation period is 15-17 days in the toucanets, araçaris and mountain-toucans, and 15-18 days in *Ramphastos* species.

At hatching, the young are blind and naked, with a long neck, strongly tubercled heel pads, a misproportioned bill with the lower mandible longer than the maxilla, which bears the egg tooth, and an uptilted uropygial area at the tail base. They perch on a tripod formed by the two hypotarsal heels and the belly, with feet in the air and with upward-pointing uropygium. The rapid incubation, typical of piciforms, is followed by a long nestling period with an initial phase of fast growth lasting about two weeks, during which proteins and other nutrients are essential. At this stage, Collared Araçari pairs allow members of the social group back into the nest for roosting, and to feed the nestlings. The chick's feathers begin to appear at two weeks, the eyes begin to open in two to four weeks, and at four to five weeks the chick is well feathered. Nevertheless, in none of the toucan species are the young known to fledge before 40 days. Those of two very large toucans, the White-throated and Yellow-throated, fledge in 43 and 45 days, respectively, so size matters little. For some species, the nestling period covers a wide range: 43-52 days have been recorded for the Channel-billed Toucan, and 46-60 days, with an average of 50.3 days, for Plate-billed Mountain-toucans. Broadly, then, 40-60 days is the range of toucan nestling periods.

Toucans are generally wary and easily disturbed. In aviary conditions, Green Araçaris sometimes eat their young if disturbed; two nestlings were saved from their parents by fostering them with a pair of Spot-billed Toucanets, which raised them successfully. At first, the naked young must be brooded at cool times, as during rain. Both parents brood, the female more so in several species. Both also feed the tiny hatchlings, in some cases by regurgitation. Feeding rates are lower than those recorded for the barbets, but toucans can hold several

items at once in the bill, and the oesophagus. Two feeds in an hour is perhaps the average rate. In one study, White-throated Toucans fed the chicks 1.8-6.4 times per hour, the male averaging fewer feeds; the combined hourly rate of 6.4 occurred late in the nestling period, on a day when both parents made a total of 32 feeding visits in 15 hours. Both sexes of the Plate-billed Mountain-toucan feed the brood regularly at first, but after two weeks the female, which stays closer to the nest, feeds them more often. In Channel-billed Toucans, feeds may number about 29 per day, but occasionally there is a gap in feeding of up to nine hours. Animal food items are brought more often early in the period, and mostly by males.

The nest-cavity is usually kept clean, a task carried out by both adults. Occasionally, females undertake more of this burden. In Collared Araçaris, adults were not seen to carry away faecal material until the fourth week; the chicks' droppings are perhaps eaten at first, and carried away only as the young grow larger, or, more probably, the material is carried within the bill. Wood chips are mixed with the faeces, and this may account for the excavating work performed by incubating adults, designed to produce more chips.

Fledging has rarely been observed. One Fiery-billed Araçari fledged as long as three days after others of its brood, but no comparable data are available on other species of toucan. Except in the case of some araçaris, fledglings are generally not led back to the nest. White-throated Toucans, for example, lead their fledged young to join the group within the home range, and away from the nest. In captivity, the young sometimes beg over a lengthy period, but they can feed themselves rather quickly. Crimson-rumped Toucanets feed the fledglings for about two weeks, while a young Spot-billed Toucanet was fed to some extent for 55 days. Some green toucanets and mountain-toucans raise a second brood on occasion. Plate-billed Mountain-toucans can also raise two broods, but they may not nest in some years; they feed the young of the first brood for 20 days or so, but then drive them from the territory. Young Toco Toucans soon learn to feed themselves in aviaries, where the pair may raise two broods in a season. In contrast, Fiery-billed Araçaris which lose their young, or eggs, are not known to re-nest in the same year. Fledged araçaris often accompany their parents and any helpers for a lengthy period, and young Lettered Araçaris may remain with their parents until the following breeding season.

Nest failures are perhaps most often due to the collapse or fall of the nesting stub or tree, which sometimes breaks off through the nest. In addition, nests can be taken over by mammals, by other large birds, even other toucans, or by reptiles, bees and other animals, and a further problem is that rainwater can flood the cavity.

Toucans suffer various degrees of predation and nest parasitism during the breeding season, and they are often taken by raptors (see General Habits). Individual hawks or falcons sometimes specialize on toucans: for example, the "extra" Collared Forest-falcon forming a trio at the nest of a pair of these raptors brought 27 Rainbow-billed Toucans to the nestling falcons in a period of ten weeks. Furthermore, monkeys such as the white-throated capuchin monkey (*Cebus capucinus*) are known to take the eggs and young of White-throated Toucans, and probably those of other ramphastids, too. Snakes, and mammalian predators such as various weasels (*Mustelidae*), no doubt also raid toucan nests. Moreover, young, recently fledged toucanets and araçaris, and even young fledglings of the large species of toucan, when they are not yet flying efficiently, are probably very vulnerable to adult avian predators.

Information on breeding success is virtually lacking, but it is considered doubtful whether most pairs of toucans manage to raise one young bird to independence yearly.

Although there are no data available on the longevity of toucans in the wild, these birds can live for a long time in captivity. Twenty years is probably not an unusual age. J. Jennings reported on a pair of Channel-billed Toucans, already adult when he obtained them; they bred two years later, and continued to do so, successfully, for 14 consecutive years, by which time they must have been at least 18 years old. Many of those toucans bred in captivity are eight to twelve years old. Extensive field studies of

*Toucans are often limited by nest-site availability, preferring cavities in secure locations but utilizing low or insecure sites if there is a shortage of options. If available, nests with narrow entrances are preferred; the Green Araçari, like several of its relatives, prefers disused woodpecker holes. Smaller toucans regularly position their nests in isolated trees, in agricultural land alongside forest, for example, and it is possible that thus situated they confer some protection against arboreal mammalian and reptilian predators. Nest occupants tend to mob predators that approach the nest, often clattering their bills as a sign of aggression.*

[*Pteroglossus viridis*, Amazonia.  
Photo: E. & D. Hosking/  
FLPA]

The female Emerald Toucanet, as in most toucans for which data are available, generally contributes more time to incubation than the male, and tends to incubate during the night. Taking an average of those species for which information has been gathered gives an average incubation period of 16.3 days for the family, being slightly shorter than this for the smaller toucanets and aracarís and slightly longer for the larger Ramphastos toucans. Pair-bonds in toucans are protracted and it is thus not surprising that breeding displays are modest, copulation often occurring without display as a precursor. Courtship feeding is common, however, with regurgitated fruit regularly offered by the male.

marked individual birds are required in order to ascertain whether or not such ages are attained in the wild.

## Movements

Regular migrations and long-range dispersal are little known among the toucans. Emerald and Yellow-eared Toucanets in Central America do undertake downslope movements after the breeding season, or late within that period. It is possible that these involve mainly subadult and yearling birds, and therefore perhaps only one such movement would occur in a lifetime. Information is needed on whether or not breeding adults participate in these movements, and, if they do, to what extent. Similar downslope movements are made by Andean Plate-billed Mountain-toucans, in some numbers at times, and adults may be among those "migrating".

In south-eastern Brazil and adjacent Argentina, Red-breasted Toucans and Saffron Toucanets sometimes invade plantations of fruiting trees and coffee farms in mid-winter. These species often breed on mountain slopes, and it is likely that they move to lower elevations after breeding. Whether these are truly yearly migrations or whether they occur only in certain years is not known. Chestnut-eared Araçaris may make similar displacements.

Significant eruptive movements were formerly a feature of Toco and White-throated Toucans, and possibly Channel-billed Toucans, in the region of the Amazon and Oyapuk Rivers in northern Brazil and adjacent French Guiana. These involved hundreds or, at times, even a thousand or more toucans, often during June, and at Belém, on the lower Amazon, the birds moved from south to north. Such movements possibly occur as a result of the periodic failure of whole crops of forest fruits. Little is known about these eruptions; when reaching towns, the birds were often slaughtered. Any such movements that take place nowadays should be observed and monitored, since one effect of widespread clearance of forest in Amazonia is a shift

in climate, especially in rainfall, which could have wholesale impacts on fruiting trees, the size of their crop, and the seasonality of fruiting.

The normal dispersive movements of the Ramphastidae are likely to be not very great, although they could be so in the non-forest Toco Toucan. Data on dispersal are, however, minimal.

## Relationship with Man

The "banana-billed" Toco and Rainbow-billed Toucans are among the most familiar of Neotropical birds to people everywhere. Indeed, toucans are among the best-known of all bird species, their general appearance making them instantly recognizable even to people whose knowledge of birds and ornithology is virtually non-existent. They are noted for their colours, and they cause amusement with their antics and the absurdly long and deep bill that they possess.

The fact that Gould devoted two editions, the second very much revised, to a monograph of the Ramphastidae, with excellent plates and a surprisingly detailed verbal account, attests to the long-term popularity of the family. At least their conspicuousness and uniqueness resulted in several species of *Ramphastos* and one araçari having been named by Linnaeus himself, in 1758, making the toucans' taxonomic debut as old as that of the woodpeckers, and older than that of the barbets and honeyguides.

Certainly, these amazing birds were long known by Amerindian tribes and by early European colonists, who hunted and captured them. Being naturally inquisitive, toucans are easily attracted by imitation of their whistles. The birds were then either eaten or maintained as pets. At least one toucanet, several araçaris and all the large *Ramphastos* toucans have suffered from man's hunting for food. Like piciforms generally, toucans are probably "good eating".

Because of their unusual appearance, toucans were, and in places still are, prized as trophies. Toco Toucans often nest in

Cavities with small entrances are generally preferred, usually those just large enough to admit the passage of the occupant. Small holes are an advantage because nests are vulnerable to predation by arboreal mammals, snakes and even other toucans; indeed, a Yellow-throated Toucan (*Ramphastos ambiguus*) was observed trying to reach Collared Araçari nestlings in their nest cavity. The Collared Araçari, pictured here, lives in groups that roost together in a tree cavity until breeding commences, at which time the nesting pair will monopolize the cavity and the other group members have to roost elsewhere.

[*Pteroglossus torquatus erythrozonus*, Belize.  
Photos: Steve Kaufman/  
DRK Photo]

In toucans, as with most piciforms, the short incubation period is followed by a lengthy nestling stage, usually between 40 and 60 days, before fledging occurs. Like all young toucans, this nestling Toco Toucan hatched blind and naked. It stands on the callused heel pads typical of piciforms with its feet in the air, balancing on its belly, and awaiting deliveries of food from its parents. By two weeks old, the feathers have broken through; between the second and fourth weeks the eyes open; and at four to five weeks the chick is well feathered.

[*Ramphastos toco toco*,  
Aporé, Goiás, Brazil.  
Photo: Haroldo Palo Jr.]

earth banks, where they are easily captured. In some areas, the person, usually a child, who discovers the nest is deemed then to be the owner of both the nest and its occupants, and is therefore entitled to take and sell the nestlings. In former times, toucans and araçaris were so abundant that they were frequently offered for sale in the markets of large cities, such as Rio de Janeiro. Hunting of toucans is still practised today in some areas (see Status and Conservation).

The bright feathers of the toucan's plumage, especially those of the rump, were valued by many Amerindian tribes, which used them in their adornments, a practice documented as long ago as the sixteenth century. A photograph in Sick's 1993 avifauna on the birds of Brazil depicts a tribal woman's collar from the Rio Gurupi region of Maranhão; the collar itself is made from feathers from the upper breast of the Channel-billed Toucan, the insect-shaped pendant consisting of feathers from two species of cotinga (Cotinginae). In earlier times, Brazilian rulers, notably the Emperors Pedro I and II, had magnificent official robes made from the breast feathers of, primarily, Channel-billed Toucans, and it is likely that some tribal peoples used these feathers for similar purposes.

The extraordinary bill of the toucan must have intrigued numerous people over many generations, and fired their imagination. Medicinal remedies used by native peoples as a cure for a number of ailments have not infrequently included toucan parts, especially the bills, presumably ground into a powder. The efficacy of such concoctions is perhaps debatable, but the ramphastid bill is not known to contain any constituent item that could be of benefit in treating sicknesses of any kind.

Similarly, these birds' outlandish appearance has led to their being used as attention-catching and memorable logos in advertising. One advertisement for a well-known Irish stout-beer used the image of a *Ramphastos* toucan in a long-running campaign, although this has since been superseded by a more modern, *avant garde* approach to promoting the product. In that example, it was supposedly not only the toucan's eye-catching bill, but also its general black-and-white appearance, mirroring the colour of the stout, that appealed to the advertiser's designers.

It is, perhaps, not really surprising that the toucan's bizarre looks have also resulted in less favourable "motives" being attributed to it. One Brazilian legend tells how the toucan, endowed

with its enormous bill, had desires to be regarded as the king of all winged creatures. The toucan concealed itself inside a tree trunk, as indeed it would when nesting, so that only its bill was visible. Other birds, on seeing the bill and its obvious great size, were ready to accept the toucan as the king. When the toucan left the tree cavity, however, and revealed its whole self, a thrush immediately cried out "He's nothing but nose!". The toucan's cover was exposed, and it left in a demoralized state.

At times when wild fruit crops are scarce or difficult to come by, toucans often visit commercial crops and gardens with fruit trees. In some parts of Central and South America where toucan populations remain healthy, the birds can cause serious damage in orchards and other fruit-growing sites, and are regarded as pests.

### Status and Conservation

As large as they are, being the largest species of the order Piciformes, the toucans are perhaps fortunate to have their centre in Amazonian South America rather than in Malaysia or Central Africa, where the survival of forest tracts is more uncertain. This is not to say that there is any reason for complacency. Toucans, since they are relatively large birds, are more thinly distributed and less abundant, and therefore require larger areas to ensure the survival of their populations than do, for example, the barbets. Illegal removal of timber, accounting for perhaps 80% or more of the logging in Amazonian Brazil, where this activity has generally increased two-fold to three-fold since 1990, heightens our concern for these essentially forest denizens. The fact that major new roads, under construction in several parts of Amazonia, carry along with them a broader band of forest clearance than would simple "rights of way" is especially alarming, because their width of over 1 km almost precludes the crossing of these sterile tongues of "progress" by toucans. There seems little doubt that forest clearance and fragmentation are now the major threats to the long-term survival of these forest frugivores, the plight of which is such that it makes them ideal "flagship", or "keystone" or "indicator", species in the efforts to preserve large, intact blocks of habitat.

The rapid provision of accurate information to human inhabitants, both adults and youngsters, of large cities and of the towns near major areas of forest removal is essential. The well-

known toucan species can be used to help demonstrate to people how forests function ecologically, and to illustrate the need for diversity, and the importance of dispersal, both of tree seeds and of toucans, to the continued existence and health of tropical forest. The Plate-billed Mountain-toucan has been used rather as a flagship species in montane southern Colombia, and the Rain-

bow-billed Toucan is a now widely known symbol of the huge upswing in conservation attitudes in Belize.

On top of the obvious threats to their habitats, the hunting of toucans continues today in parts of Central America, Amazonia and Paraguay. Amerindians of the Amazon often have cultural bases for hunting certain animals, and whole tribes may specialize on a few types of birds, such as toucans and guans (Cracidae). That hunting can be significant in reducing the numbers of toucans is suggested by the fact that village hunters killed 57 Yellow-throated Toucans in a two-week period, and by reports from Brazil of a single hunter killing 150 Black-necked Araçaris in one day. The ease with which toucans can be taken by gun is indicated by the following episode. When hunters of a group of five Lettered Araçaris killed one young bird, the others of the group circled the hunters, "mobbing" them; two more were shot, and a fourth continued calling and flying close to the hunters, who then shot and killed that one; the single remaining araçari stayed near the spot for the rest of the day, calling frequently. The calls of some toucans can be mimicked, thereby drawing the birds to the hunters. Araçaris are killed locally because of their fruit depredations, and Red-breasted Toucans are sometimes killed as predators of smaller birds, while in some places a belief in the value of toucans in medicine has accounted for the killing of Choco and Channel-billed Toucans (see Relationship with Man).

Many are also captured for the live-bird trade and as local pets. Even in modern times, some homes in Brazil and Venezuela have pet toucans, and others have realistically mounted, stuffed specimens. Most zoos and bird collections of aviculturalists in the Neotropics have toucans on display, often in fairly large numbers; all of these come from the wild, for until the 1990's there were no toucans being bred in captivity in the region. Probably more toucans are taken today as pets in areas surrounding major population centres than are hunted for food.

In fact, although only one species of Ramphastidae is currently considered globally threatened, and three are currently listed as Near-threatened, others and, in particular, certain subspecies could well come under threat very soon. The montane Yellow-browed Toucanet, with a very restricted range, is considered Endangered. The three Near-threatened species include two of the four mountain-toucans that comprise the genus *Andigena*, and the Atlantic forest Saffron Toucanet, the sole mem-

*The excrement of nestlings being semi-liquid, faecal material is difficult to clear from the nest, and yet the nest is invariably kept hygienic. While both adults carry faecal material away from the nest, this sometimes appears not to happen until well after hatching. It might be that adults carry it hidden within the bill during early stages. This Gold-collared Toucanet is seen carrying faecal material mixed with wood-chips: the need for a layer of absorbant wood-chips perhaps dictates the adults' behaviour of partially excavating in cavities before nesting, and for the gradual deepening of nest-chambers after a series of breeding attempts.*

[*Selenidera reinwardtii* langsdorffii, Tambopata Reserve, Peru.  
Photo: Mark Jones]

*Young Channel-billed Toucans fledge between 43 and 52 days after hatching, this wide variation presumably being dependent on environmental factors such as temperature and food supply. No toucan has been recorded fledging in under 40 days, and the duration of the fledging period is unrelated to species size. After fledging, young toucans usually beg for a few weeks but can feed themselves after only a few days.*

[*Ramphastos vitellinus* culminatus, Aguarico River, Ecuador.  
Photo: Art Wolfe]

As they are so immediately recognizable to non-ornithologists, and because of their need for large tracts of relatively uninterrupted forest, toucans make ideal "flagships" for regional conservation programmes.

The stunning Plate-billed Mountain-toucan, for example, has been used for some time as a logo for conservation organizations and projects in Ecuador and Colombia.

This species is currently categorized as Near-threatened because it occupies a restricted range in the Andean cloudforests of those two countries, a habitat that is continually shrinking in extent because of clearance for agriculture and settlements.

The species is still relatively common in many areas, however, even in quite disturbed and degraded forests, such that its population is not thought small enough to justify its being classed as threatened.

[*Andigena laminirostris*,  
La Planada, Colombia.  
Photo: Patricio Robles Gil]

ber of the genus *Baillonius*. Until recently, all four of these species, along with the other two *Andigena* species, the Hooded and Black-billed Mountain-toucans, were listed as Near-threatened.

Of the mountain-toucans, those of lower montane forest, where clearing is severe and sustained, are possibly the most directly threatened. These are the Plate-billed Mountain-toucan and perhaps one or another subspecies of the Black-billed Mountain-toucan. The latter has a restricted range as a species, to say nothing of its three subspecies. Efforts aimed at informing the local human population, together with direct attempts at conservation of the Plate-billed Mountain-toucan, are under way in Ecuador. It is hoped that more information will soon be forthcoming on the situation of the Peruvian Yellow-browed Toucanet now that guerrilla activity has lessened in the region to which it is restricted. The threat to the Saffron Toucanet in Paraguay, south-east Brazil and adjacent north-east Argentina is mainly in the form of fragmentation of its habitat in the relatively heavily human-populated areas where it exists. It is doubtful whether even the dual national parks and forest reserves around Iguazú Falls in Brazil and Argentina together hold a sufficiently large population to guarantee its survival in the short term. The human-disturbance factor may be important to the conservation of secretive, shy species such as the Saffron Toucanet. An emphasis on protection of the watershed and on flood-control is important to the conservation of all of these toucans.

Other ramphastid species not currently considered to be threatened or near-threatened may be deserving of a reassessment of their conservation status. The Tawny-tufted Toucanet has a relatively small range in northern Brazil and adjacent southern Venezuela in which it shows a preference for white-sand riverine habitat. Its habitat could be cut in two by the already approved, massive road scheme linking Manaus, in Brazil, to Venezuela, and further encroached upon by the associated opening of land to settlement. To the immediate south of that toucanet, the nominate race of the Ivory-billed Araçari has a restricted range within the wedge formed by the Rio Negro and the Amazon. It seems to prefer river-edge habitat within this range, and any major fragmenting of forest there could bring it under threat. The narrow montane range of the Yellow-eared Toucanet is highly fragmented in Central America, populations in which have no contact

with those in western Colombia and north-west Ecuador, yet forested areas continue to be cleared. The problems are exacerbated by the need for connecting corridors of forest that permit the species' downslope movements and return (see Movements). Another species to watch is the Red-breasted Toucan of south-eastern South America, which lives in somewhat similar habitats to those occupied by the Saffron Toucanet. It is, however, larger, and thus probably has a smaller population that is becoming even more fragmented, in addition to which it is a shy, easily disturbed toucan.

Several subspecies could be of concern regarding potential threats to them. The Groove-billed Toucanet, restricted as a species to north-east Colombian and northern Venezuelan mountains, has a race, *erythrognathus*, confined to the north-east corner of Venezuela, where habitat is fast disappearing. It should be monitored. The central, nominate race of that species could also come under threat as the human population rises and land is cleared. Also in need of monitoring, and about which little is known, is the distinctive, isolated race *osgoodi* of the Chestnut-tipped Toucanet, the smallest member of the family and restricted to the Acary and Wilhelmina Mountains in the Guianas. An eye should be kept also on the race *abbreviatus* of the Yellow-throated Toucan, found in north-east Colombia and the mountains of northern Venezuela. This subspecies requires large forest tracts in areas where fragmentation of forest is ongoing.

As alarm bells are sounded about the conservation of rarer, possibly threatened species and races of toucans, it should be noted that the gouging-away of Amazonian forest will probably create subpopulations of many of the more common toucan species and subspecies. In the case of the Channel-billed and White-throated Toucans, middle Amazonian populations are diversely hybrid, tending more or less towards one or another of the subspecies. As these populations inevitably become fragmented with clearance of the forest in one area after the other, it seems wise to give attention to the preservation of the isolates, for they are patently adapted to the habitats that they occupy. Furthermore, the genetic potential which they represent could benefit their species, helping those species to persist. There appears no reason why concern should be expressed with regard to any genetic "impurity", against which some environmentalists tend to discriminate when dealing with primary "pure" species.

Will any toucans benefit, or are they benefiting, from current deforestation and colonization by man? The Toco Toucan, with its preference for forest edges, riverine forest and woodland, and wooded patches in savanna, may be one such species. It is probably moving into partly cleared areas of Amazonia from its river-side habitats. So long as some patchy forest and sufficient fruiting trees remain, the species and its populations could expand. On the negative side, these expanding populations will be in close human contact, and losses of nests and of young birds taken as pets will hamper the expansion. Elsewhere in its range, complete removal of forest and woodland, as in the Chaco, eliminates the species, as tiny fragmented subpopulations are exposed to intense human pressure in the form of disturbance, hunting, and the taking of nestlings. Moreover, the recent intensive use of land bordering the Paraguay River, along which Toco Toucans have long moved, has meant that, at intervals, forest, woodland and, in fact, any tree cover are now lacking for several kilometres or more. This must restrict the species' movements further, to its detriment.

It seems imperative that the capturing of toucans in the wild be considered an unlawful act. Where such laws exist, it is important that they be enforced; where they do not, the exactment of them should surely be a priority. Given the conspicuousness of toucans, particularly as their habitats become ever more fragmented, increasing numbers of local people may well desire a toucan as a pet, and bird-catchers will attempt to take these birds, legally or illegally, in order to funnel them into the lucrative trade in cagebirds. It is essential that people, and especially young people, be made aware of the threats to their local wild birds, and of the fact that these are best left in the wild. Efforts such as those in Belize, which bring whole communities into an understanding of ecological matters and instill in them a pride in their wild birds, demonstrate that progress can be made, rapidly, in halting the capture of nestling birds. To the extent that suitable veteri-

*The Fiery-billed Araçari has a restricted range that falls within the South Central American Pacific Slope Endemic Bird Area of Costa Rica and Panama. Despite this, and a certain contraction of its range in Panama, the species is not considered to be of conservation concern because it remains common in certain localities and its overall numbers are thought to remain sufficiently high at present.*

[*Pteroglossus frantzii*, Corcovado National Park, Costa Rica.  
Photo: Manfred Pfefferle]

*Bailloni* is the only modern genus of toucans that appears not to have originated in Amazonia. It is erected solely for the Saffron Toucanet, an anomalous yellowish species that inhabits the Atlantic Forest of south-east Brazil, northernmost Argentina and eastern Paraguay. The swathe of forest in this region was once vast but is now broken up into shrinking fragments under constant pressure from logging and clearance for agriculture. While this species is still too widespread and numerous to be counted amongst the many threatened birds restricted to the Atlantic Forest, it may well join them if habitat destruction in this region continues.

[*Bailloni bailloni*, Espírito Santo, Brazil.  
Photo: Michel Gunther/  
Bios]

nary and other expertise can be brought into the local milieu, centres for the rehabilitation of toucans can assist in their conservation and in the informing of the people.

The provision of accurate, reliable information is the keystone for bird preservation. People generally should be made aware of why exotic trees are essentially worthless to birds, especially toucans. This is not to say that the planting of exotic, fast-growing trees may not be useful as a source of firewood, and for local construction, as it can reduce the loss of indigenous forest trees. Even for such purposes, however, indigenous trees are still a better choice, although more needs to be known about the planting, growth and tending of local trees. There is no question that firewood trees are essential, at least until such time as technology has provided cheap, readily available alternatives locally for heating and cooking in developing tropical countries. Zoos and botanic gardens in tropical America can help by planting fruit trees among their exhibits, attracting and helping to save toucans. A good example is the Catharine and Robert Wilson Botanical Garden, near San Vito, in south-western Costa Rica, which is now a paradise for wild toucans. Orchardists should be encouraged to plant some fruit trees "for the birds", especially on the orchard edges nearest to forest remnants. Park authorities could usefully plant fruiting trees around their headquarters and other buildings. Toucans are among many birds that come to these, and they are attractions to visitors; the birds often become tame, and observable.

It is well worth experimenting with nestboxes for use by toucans. The success in breeding toucans in aviaries, and the use of various pre-cut logs and palms and other log-boxes, indicate that the provision of nestboxes would be a positive strategy, particularly in secondary forest, forest patches and parks, and on private property. Some boxes will be used by other bird species, mammals and other animals. If designed for one or several of the local toucans, however, they could become a successful tool in improving the quality of habitats that may already provide sufficient fruits and other foods, but not enough appropriate sites for nesting.

Toucans do breed in captivity, but with certain difficulties, such as the large amount of space required by the large toucans. A captive-breeding centre for toucans has been declared by the United States Fish and Wildlife Service at the Fallbrook, California, avi-

aries run by Jennings, who has bred more species of toucan than anybody else. Some North American and European zoos, and a few private aviculturalists, have experience in breeding certain of the species. It does seem essential that the main breeding centres be established within the countries in the Neotropics where toucans occur, or formerly occurred, naturally. To this end, Jennings has helped spearhead endeavours, particularly in Brazil. It is likely that, once techniques have been "fine-tuned", many of the smaller toucans could be bred in numbers sufficient to allow their effective re-establishment in the wild, as and when this becomes necessary. In such cases, captive-bred toucans might require supplemental feeding of fruits for some time after release.

Of course, even a fine, viable captive-breeding programme is no guarantee of the long-term survival of toucans. This depends pre-eminently upon the occurrence of suitable habitat, including a sufficient diversity of fruiting trees to meet the birds' nutritional needs throughout the year. The principal requirement for the conservation of these unique and significant birds is, therefore, the preservation of their habitat.

*Aulacorhynchus prasinus*

**French:** Toucanet émeraude      **German:** Laucharassari      **Spanish:** Tucanete Esmeralda  
**Other common names:** Blue-throated Toucanet (*caeruleogularis*)

**Taxonomy.** *Pteroglossus prasinus* Gould, 1834, Valle Real, Mexico. Related rather closely to *A. sulcatus* (especially race *calorhynchus*), and also, less closely, to *A. derbianus*. Of the many races, several are sometimes considered to represent separate species, especially *wagleri*, *caeruleogularis*, *albivitta*, *phaeolaemus*, *cyanolaemus* and *atrogularis*; these, however, are all similar vocally, bill pattern varies relatively little, and all interbreed with each other or with other races wherever they meet; also, mosaic evolution evident among white-throated and blue-throated races. Races intergrade widely, notably *virescens* with nominate. Race *cognatus* possibly inseparable from *caeruleogularis*. Of other races proposed, *chiapensis* (SE Mexico) and *stenorhabdus* (W Guatemala, N El Salvador) considered synonymous with *virescens*, probably showing only clinal differences; *maxillaris* (Costa Rica, W Panama) with *caeruleogularis*; and *petax* (W Andes of Colombia) with *phaeolaemus*. Fourteen subspecies currently recognized.

**Subspecies and Distribution.**

- A. p. wagleri* (Sturm, 1841) - SW Mexico (Sierra Madre del Sur, in Guerrero and SW Oaxaca).
- A. p. prasinus* (Gould, 1834) - E Mexico (SE San Luis Potosí to N Oaxaca) S & E to Yucatán, Belize and N Guatemala.
- A. p. warneri* Winker, 2000 - SE Mexico (Sierra de Los Tuxtlas, in S Veracruz).
- A. p. volcanius* Dickey & van Rossem, 1930 - E El Salvador (San Miguel Volcano slopes).
- A. p. virescens* Ridgway, 1912 - SE Mexico (Chiapas) to Honduras and Nicaragua.
- A. p. caeruleogularis* (Gould, 1854) - Costa Rican mountains to W Panama.
- A. p. cognatus* (Nelson, 1912) - C & E Panama S to W Colombia (Chocó).
- A. p. lautus* (Bangs, 1898) - NE Colombia (Santa Marta Mts).
- A. p. albivitta* (Boissoneau, 1840) - W Venezuelan Andes S to Colombia (E slope of C Andes, E Andes) and E Andean slopes of Ecuador.
- A. p. griseigularis* Chapman, 1915 - N part of W Andes and W slope of C Andes of Colombia.
- A. p. phaeolaemus* (Gould, 1874) - W slope of W Andes in W Colombia, N of Patia Canyon.
- A. p. cyanolaemus* (Gould, 1866) - E Andean slope of S Ecuador to N Peru (La Libertad, Amazonas).
- A. p. atrogularis* (Sturm, 1841) - E Andean slope from N Peru to C Bolivia (W Santa Cruz).
- A. p. dimidiatus* (Ridgway, 1886) - hills and lowlands from E Peru to W Brazil (Acre) and N Bolivia (Pando).

**Descriptive notes.** 30-37 cm; male 124-239 g, female 110-205 g (S races lighter, except *albivitta* and *phaeolaemus* as heavy as *N. prasinus*). Green toucanet with black and yellow bill, sometimes with some chestnut colour at base; basal line of bill large, white to gold; tail tipped chestnut, undertail-coverts chestnut. Male of nominate race has bronze-green crown, white throat, dark grey-brown to rufous orbital skin, yellow-white basal line of bill. Differs from *A. sulcatus* in chestnut colour of tail tips and undertail-coverts. Female like male, but shorter-billed. Races vary in throat colour, colour of basal line of bill, tone of green around

head and breast, and extent of black from bill base and tomlia to culmen and tip of maxilla: *wagleri* like nominate, but crown yellow, breast paler with blue tinge; *albivitta* also white-throated, with white basal bill line, and more blue around eye than previous race; *warneri* has yellow wash on throat and auriculars; *caeruleogularis* and *cognatus* have blue to violet throat; *cyanolaemus* has blue throat, and almost all-black bill; *phaeolaemus* has blue-grey throat; *griseigularis* has grey throat; *atrogularis* and *dimidiatus* black-throated, *dimidiatus* also smallest of all races. Voice. Song an often prolonged series of variable barking to growling notes, from loud, hoarse "egruk" to soft "ah" or "ek", c. 1-5 to 3 per second, notes shorter and tempo faster than in congeners; sexes at times sing together, male lower-pitched, and countersinging can result in song up to 3 or even 5 minutes long. Growl, rattled "eeaaah", other soft calls uttered singly; nestlings beg with single, later double, "cha" notes.

**Habitat.** Usually wet montane and submontane forest, cloudforest, edges, well-developed secondary forest, pasture with thickets, sometimes plantations and gardens, occasionally pine-oak woodland and alder woods. In Peruvian lowlands along rivers and lakes, in transitional forest, and floodplain-forest. In areas of overlap with other species of *Aulacorhynchus*, usually separated from them by altitude; locally occurs up to 3700 m, in Peru.

**Food and Feeding.** Fruits include lauraceous species (*Ocotea*, *Nectandra*, *Phoebe*) and solanaceous species (*Solanum*, *Cestrum*), also *Cecropia* and *Piper*; c. 120 species recorded eaten at one locality; also eats flowers or flower parts. Animal food includes beetles, grasshoppers, Homoptera, flies, caterpillars and Hymenoptera, also spiders, scorpions, bird eggs and young, lizards, snakes. Yellow plumage tints require carotenoids in diet. Regular visits to a feeding tree usually last 2-8 minutes, rarely up to 4 hours recorded; averages 26 g of fruit eaten per visit; digestion 24-70 minutes, so can consume more small fruits at once than larger ones. Sneaks through trees; enlarges cavity entrance to get at nest contents. Usually solitary when foraging, but sometimes in groups, occasionally quite large ones.

**Breeding.** Mar-Jul or later in Middle America, generally similar in NW South America, locally from Feb and to Nov; sometimes 2 broods. Displays with nodding, head-jerking, tail-cocking; courtship feeding may lead to copulation. Nest 2-27 m up, often at forest edge or on tree in pasture, even in utility pole, oval entrance higher than wide, to 57 cm deep; can excavate in very rotten wood, or usurps woodpecker nest if entrance in sufficiently decayed wood; much of excavating is by female, and some done as part of courtship; nest sometimes reused in subsequent years. Eggs 1-5; incubation period c. 16 days, female performing greater share; naked hatchlings brooded mostly by female, which feeds small fruits, male brings more arthropods, eggs, vertebrates; nest sanitation mainly

by female, which can raise young alone; nestling period 42-45 days. Preyed on by weasels, monkeys, falcons, hawks; usually 2 young fledge.

**Movements.** Some evidence of downslope movement in Middle America, mainly by groups of young birds.

**Status and Conservation.** Not globally threatened. Locally common in parts of range. Found in moderate numbers in El Triunfo Biosphere Reserve, Chiapas, Mexico. Present in several protected areas in Costa Rica, e.g. Tapantí and Birds of Volcán Poás National Parks, Guayabo National Monument and Monteverde Biological Reserve. Uncommon to fairly common locally in Ecuador. In Peru, fairly common, with c. 2 pairs/100 ha of transitional forest, fewer in more mature forest. May be threatened locally, perhaps in particular those races with restricted ranges, as forest is generally cleared from lower mountain slopes.

2. Groove-billed Toucanet

*Aulacorhynchus sulcatus*

**French:** Toucanet à bec sillonné      **German:** Blauzügelarassari      **Spanish:** Tucanete Picosurcado  
**Other common names:** Yellow-billed Toucanet (*calorhynchus*)

**Taxonomy.** *Pteroglossus sulcatus* Swainson, 1820, Venezuela.

Forms a superspecies with *A. derbianus*. Rather closely related also to *A. prasinus*, with which race *calorhynchus* overlaps somewhat. Race *calorhynchus* sometimes considered a separate species, but resembles other races vocally and intergrades with nominate. Three subspecies recognized.

**Subspecies and Distribution.**

- A. s. calorhynchus* (Gould, 1874) - NE Colombia (Santa Marta and Perijá Mts) E into W Venezuela (E to SW Lara).
- A. s. sulcatus* (Swainson, 1820) - N Venezuela (Falcón E to Miranda).
- A. s. erythronathus* (Gould, 1874) - NE Venezuelan mountains.

**Descriptive notes.** 33-37 cm; 150-200 g. Typical green toucanet, white-throated, with blue about rear of eye, undertail-coverts green-yellow, bill flat at base of culmen, grooved along culmen, mandible also grooved. Male nominate race with thin white basal line at bill, occasionally lacking; black from before eye diagonally across tomlia to gonys of mandible, rest of bill wine-red to brown-red. Female slightly smaller, with shorter bill. Immature with lax plumage, duller, rectrices more pointed, has paler orbital skin, bill lacks grooves and tomlial "teeth" and pattern obscured; shows evidence of spiky hypotarsal pad. Race *erythronathus* lacks basal line of bill, black of bill reduced to near centre of mandible and tomlial area, mandible orange-red near base, culmen more rounded, nostrils lower on maxilla, grooves shallower; *calorhynchus* very like nominate, including structure and pattern of bill, but white base line slightly broader and brown-red of nominate replaced by yellow distally, yellow-green near base of maxilla. Voice. Song of barking-growling notes or croaks, vary in quality, "wik-wik" to "waak-waak", c. 2-4 per second, in usually short series of up to c. 20 notes; sometimes notes are compounded in series. Also rattles bill.

**Habitat.** Humid montane forest, from upper tropical to edge of temperate forest, also second growth, forest edges, nearby isolated trees, even gardens. Does not cross sizeable open areas. Usually recorded at 900-2000 m, but up to 2440 m in Colombia; in N Venezuela, occurs on wet slopes down to 400 m or lower.

**Food and Feeding.** Fruits, insects, eggs and young of birds; few data, but reported as frequently raiding nests of birds, and as omnivorous. Forages from understorey to canopy, alone, in pairs, or in groups; in last case, birds move in single file from spot to spot.

**Breeding.** Specimens indicate breeding Mar-Jul, except May-Aug in NE Venezuela. Nest, eggs, and all other aspects of breeding undocumented.

**Movements.** None reported.

**Status and Conservation.** Not globally threatened. No detailed information available on numbers, but species appears to be common generally in suitable habitat, e.g. in Henri Pittier National Park, Venezuela. Also occurs in Cueva de los Guácharos National Park, Venezuela. Biological and further ecological data required in case any of the three subspecies should eventually need to be monitored.

**Bibliography.** Boesman (1998), Bond *et al.* (1989), Cory (1919), Fjeldså & Krabbe (1990), Haffer (1974), Hellmayr & Seilem (1912), Hilty & Brown (1986), Meyer de Schauensee (1949, 1964, 1966, 1982), Meyer de Schauensee & Phelps (1978), Olrog (1968), Phelps & Phelps (1958), Ridgway (1914), Rodner *et al.* (2000), Röhl (1935), Schäfer & Phelps (1954), Schwartz (1972), Stotz *et al.* (1996), Todd & Carriger (1922), Vereá & Solórzano (2001), Wetmore (1939).

3. Chestnut-tipped Toucanet

*Aulacorhynchus derbianus*

**French:** Toucanet de Derby      **German:** Derbyarassari      **Spanish:** Tucanete de Derby

**Taxonomy.** *Aulacorhynchus Derbianus* Gould, 1835, no locality = Huánuco, Peru.

Forms a superspecies with *A. sulcatus*. Also related, less closely, to *A. prasinus*. Form described from C Peru as *nigrirostris* now lumped within nominate *derbianus*. Four subspecies currently recognized.

**Subspecies and Distribution.**

*A. d. derbianus* Gould, 1835 - extreme S Colombia S along E slope of Andes to C Bolivia (Cochabamba).

*A. d. duidae* Chapman, 1929 - mountains of S Venezuela in Amazonas and W Bolívar, and adjacent N Brazil.

*A. d. whiteliani* (Salvin & Godman, 1882) - mountains of S Venezuela (SE Bolívar) and N Guyana.

*A. d. osgoodi* Blake, 1941 - S Guyana (Acarí Mts) and Surinam (Wilhelmina Mts).

**Descriptive notes.** 33-41 cm; 141-262 g (*derbianus*), 117-160 g (other races). Green toucanet with grooves on maxilla only, bill tip especially hooked, base line of bill narrowly but conspicuously white, equal in width on mandible and maxilla; throat white, rump green, undertail-coverts yellow-green. Both sexes of nominate race with deep red and black bill, some individuals fully black-billed; bluish on nape, tail feathers tipped chestnut; blue under and behind brown-red orbital area. Differs from similar *A. sulcatus* in chestnut tips of tail, deep red base of mandible, lack of mandibular groove. Race *duidae* smaller than

nominate, less blue on head and around eye, redder (less black) bill, smaller rusty tail tips; *whiteliani* smaller still, with smaller rusty tipping on tail; *osgoodi* smallest, lacks rusty tail tips. **VOICE.** Song often long series of "grrrrump" to "kwuk" notes, 1-2-1-55 per second, notes longer and more evenly pitched than in *A. sulcatus*; some versions probably sexual in nature, pair-members often sing simultaneously. Also "ggg-rgg", "ngg-ngg", and rattling "bbdt-bbdt" notes. Voices of 2 smallest races not recorded.

**Habitat.** Usually subtropical moist montane cloudforest, to tropical high-valley forest in Bolivia; forested slopes on tepuis in Venezuela, and hilly tropical forest in Guyana and Surinam. Generally at 600-2400 m, in Andes usually 800-1600 m, in the Guianas at c. 300-800 m. In Andes usually occurs below *A. coeruleicinctis* and *A. prasinus*, but above latter in S Peru and Bolivia.

**Food and Feeding.** Little known. Fruits and their seeds comprise much of diet, but insects, including ants and grasshoppers, also reported. Feeds largely in canopy, often in pairs, occasionally in groups of up to c. 10.

**Breeding.** Data from specimens suggest breeding in May-Oct in Andes, Feb-Jul in NE of range. No other information; nest and eggs unknown, even territoriality not firmly established.

**Movements.** Probably sedentary.

**Status and Conservation.** Not globally threatened. Little known. Still common in some Andean and Venezuelan localities. Occurs in Imataca Forest Reserve and El Dorado, Venezuela. In Ecuador, generally rare to uncommon; regularly recorded in small numbers in Podocarpus National Park. Rare in Peru. Information urgently needed on subspecies *osgoodi*, potentially threatened, in small Guyana-Surinam range.

**Bibliography.** Anon. (1995a), Blake (1941, 1950), Bond (1954), Bond & Meyer de Schauensee (1943), Chapman (1917, 1926, 1929, 1931), Chubb (1916), Cory (1919), Dickerman & Phelps (1982), Fjeldsá & Krabbe (1990), de Germigny (1930a), Greenway (1978), Haffer (1974), Haverschmidt & Mees (1994), Hilty & Brown (1986), Hornbuckle (1999), Mayr & Phelps (1967), Meyer de Schauensee (1949, 1964, 1966), Meyer de Schauensee & Phelps (1978), Morrone (2000), Parker & Bailey (1991), Parker *et al.* (1993), Phelps & Phelps (1958), Remsen (1984), Remsen *et al.* (1993), Ridgely & Greenfield (2001), Ridgway (1914), Robbins *et al.* (1987), Röhl (1935), Sick (1985, 1993), Snyder (1966), Stotz *et al.* (1996), Traylor (1951a), Willard *et al.* (1991), Zimmer (1930).

## 4. Crimson-rumped Toucanet

### *Aulacorhynchus haematopygus*

**French:** Toucanet à croupion rouge **German:** Blutbürzelarassari **Spanish:** Tucanete Culirrojo

**Taxonomy.** *Pteroglossus haematopygus* Gould, 1835, no locality = Concordia, Antioquia, Colombia. Forms a superspecies with *A. huallagae* and *A. coeruleicinctis*. Two subspecies recognized.

**Subspecies and Distribution.**

*A. h. haematopygus* (Gould, 1835) - Andean slopes from W Venezuela (Perijá Mts) and N & C Colombia S to SW Colombia; possibly also E slope in N Ecuador.

*A. h. sexnotatus* (Gould, 1868) - extreme SW Colombia and S in W Ecuador.

**Descriptive notes.** 40-45 cm; 200-232 g (*haematopygus*), 141-200 g (*sexnotatus*). Green toucanet with red rump, rather block-like brown-red and black bill flattened on culmen base, thus ridged on sides, white basal line broadening ventrally and widest at lower base of mandible. Male nominate race with bluish areas over eye, below eye, on sides of breast; throat green; central 2-3 pairs of rectrices chestnut-tipped; orbital skin orange-brown. Female shorter-billed. Immature has duller, lax plumage, with orangey rump; lacks bill "teeth", bill mainly reddish with pattern obscured, no basal bill line. Race *sexnotatus* smaller, with less blue in plumage

and more red on bill. **VOICE.** Series of variable, gruff, barking notes, "daakk" to "eggruk", to 2 minutes or longer, slower and lower-pitched than in *A. prasinus*; pair-members sing together, partly in duet, male with deeper, growl-like notes, female with clearer "drak". Also soft, long notes, rattle notes, interactive "snark" calls; loud wing sounds, especially during interactions.

**Habitat.** Lowland premontane to montane evergreen forest and second growth, edges, dense thickets nearby, also isolated fruit trees in pastures and gardens. Generally at 300-2200 m, occasionally to 2750 m.

**Food and Feeding.** Mainly fruits, such as those of *Cecropia* and lauraceous plants, palm nuts; probably also some insects and bird eggs; captives catch and eat small birds and insects inside aviaries, also dead mice when breeding. Feeds alone, in pairs or in small groups; skulks through understory to canopy, bounding upwards in trees. Slower, less laboured flight than *Pteroglossus*. Drinks from epiphytes that hold water.

**Breeding.** Jan-May, as early as Nov in Ecuador and S Colombia. Much singing, calling, chasing until pair established at start of breeding; both sexes courtship-feed, allopreen, male cocks tail, erects breast feathers; singing bird points bill below horizontal, twitches tail in time with notes; switches tail about, cocks tail, assumes compressed "thin" look, drops down in attacks. Probably in most cases nest in old woodpecker hole, with rotted wood excavated out. In captivity, up to 4 eggs; female does

much of the incubating, period c. 16-17 days; nestling naked, pink, fed on insects, fruits, young birds; nest kept clean by both parents; young develop slowly, feathering starts to appear before eyes open at c. 3 weeks, fully feathered except for flight-feathers at c. 6 weeks, fledging at c. 7 weeks; young probably return to roost with parents, may stay together until next breeding season.

**Movements.** None known.

**Status and Conservation.** Not globally threatened. Common in Colombia, where occurs in La Planada Nature Reserve and Río Nambí Natural Reserve. Fairly common in Ecuador, where present in Podocarpus National Park. Seems to be adaptable, using secondary forest even in patches. Breeds successfully in captivity.

**Bibliography.** Allen (1998), Best *et al.* (1993), Bloch *et al.* (1991), Boesman (1998), Chapman (1917, 1926), Cory (1919), Evans & Coles (1982), Fjeldsá & Krabbe (1990), de Germigny (1930a), Haffer (1974), Hilty (1997), Hilty & Brown (1986), Hughes (1988), Lantermann (1995), María & Olivares (1967), Meyer de Schauensee (1949, 1964, 1966), Meyer de Schauensee & Phelps (1978), Miller (1963), Parker & Carr (1992), Phelps & Phelps (1958), Remsen *et al.* (1993), Ridgely & Greenfield (2001), Ridgely *et al.* (1998), Rundel (1975), Salaman (1994), Salaman *et al.* (1999), Schlenker (2000), Schulenberg & Parker (1997), Stotz *et al.* (1996), Thompson (1980), Todd *et al.* (1973).

## 5. Yellow-browed Toucanet

### *Aulacorhynchus huallagae*

**French:** Toucanet à sourcils jaunes

**German:** Gelbbrauenarassari

**Spanish:** Tucanete del Huallaga

**Taxonomy.** *Aulacorhynchus huallagae* Carriker, 1933, Utcubamba, La Libertad, Peru.

Forms a superspecies with *A. haematopygus* and *A. coeruleicinctis*, and perhaps closer to latter. Monotypic.

**Distribution.** Locally in Peru (San Martín and La Libertad).

**Descriptive notes.** 38-44 cm; 150-278 g. Green toucanet with red rump, and black-based, ivory-tipped bill, base line of which is white, broader on mandible. Yellow superciliary mark, pale blue to yellow-white mark under eye, black orbital skin; white throat, pale blue across lower breast to sides, gold-yellow undertail-coverts; two central pairs of rectrices chestnut-tipped. Female has shorter bill. Differs from rather similar *A. coeruleicinctis* in white basal line of bill, and also distinct gold-yellow undertail patch. **VOICE.** Variable, usually growling "gggrrowk" notes, varying in length, c. 1-2-1-6 per second; occasionally a clearer, "peet-peet-".

**Habitat.** Montane wet cloudforest with mosses and epiphytes, at 2125-2510 m; usually at elevations above *A. prasinus* and below *Andigena hypoglaucha*.

**Food and Feeding.** Fruits and their seeds, some melostome fruits; probably also some insects and other animals. Probes into flower clusters of *Clusia*, a dominant tree in its habitat. Forages singly, in pairs or in small groups.

**Breeding.** Season includes Oct, probably early Oct, but uncertain. Adult approached playback of voice, shifted head and tail from side to side, synchronously, but in opposite directions. No other data available.

**Movements.** Presumably sedentary.

**Status and Conservation.** ENDANGERED. Restricted-range species: present in North-east Peruvian Cordilleras EBA. Until recently considered Near-threatened. Local and little-known species; in recent times, forest within its limited range has in places been taken over for growing coca, probably further reducing both range and numbers of present species. Where it does occur, it has sometimes been seen in fair numbers; new Río Abiseo National Park might hold sizeable population, although current information suggests species is very rare there; other areas where it occurs are largely unprotected. Range very small, for reasons unknown, perhaps connected to competition from other toucan species; does not appear to occupy all apparently suitable forest available within its overall range. Data on species' ecology and biology urgently needed in order to assist in plans for its monitoring.

**Bibliography.** Bond (1954), Carriker (1933), Clements & Shany (2001), Collar & Andrew (1988), Collar, Crosby & Stattersfield (1994), Collar, Gonzaga *et al.* (1992), Fjeldsá & Krabbe (1990), Haffer (1974), Leo *et al.* (1988), Meyer de Schauensee (1966, 1982), Olrog (1968), Parker (1990), Parker, Parker & Plenge (1982), Parker, Schulenberg *et al.* (1985), Remsen *et al.* (1993), Schulenberg & Parker (1997), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), Stotz *et al.* (1996), Wege & Long (1995).

## 6. Blue-banded Toucanet

### *Aulacorhynchus coeruleicinctis*

**French:** Toucanet à ceinture bleue

**German:** Grauschnabelarassari

**Spanish:** Tucanete Pechiazul

**Taxonomy.** *Aulacorhynchus coeruleicinctis* d'Orbigny, 1840, no locality = Yungas, Bolivia.

Forms a superspecies with *A. haematopygus* and *A. huallagae*, and possibly closer to latter. Putative race *borealis* of NC Peru (Junín) considered invalid, as appears to be based on individual, not geographical, variation. Species name often listed as *coeruleicinctus*, but original spelling, *coeruleicinctis*, must stand. Monotypic.

**Distribution.** C Peru (S Huánuco) on E Andean slope, including a few isolated montane areas to E, to S & SE Bolivia (Chuquisaca, Santa Cruz).

**Descriptive notes.** 40-44 cm; 173-257 g. Green toucanet with red rump, blue-horn bill lacking basal line. Blue and white superciliary and white throat; blue band across breast from sides, often somewhat diffuse; undertail-coverts greenish-yellow; tail with rusty chestnut tips on central feathers, rusty colour less extensive or absent on second rectrices; orbital skin dark greyish, but pale blue below eye; eyes white to yellow, sometimes brown or brown-red, no geographical pattern (e.g. brown or white in SC Peru). Differs from *A. huallagae* in having bill narrower at base, with no white line, more rigid laterally, and greener (not golden) undertail-coverts. Sexes alike. Immature duller, with lax plumage; lacks tomial serrations;

has rump and tail particularly dull. Voice. Song a series of barking, growling, variable notes, “kunnk” to “krakk”, 1-2.2 notes per second, lasting to over 1 minute; also various rattle calls, “kyak” yelps, a “kra-a-a” and “gek-ek-ek” compound notes. Functions of variants and calls unknown.

**Habitat.** Various forms of montane subtropical moist forest, cloudforest with dense undergrowth, reaching edge of subhumid tropical forest below and temperate forest above; recorded at 1470-3050 m, more usually 1600-2500 m.

**Food and Feeding.** Not known in detail. Fruits, also insects and other arthropods. Forages alone, in pairs or in small groups, from understorey to canopy.

**Breeding.** Data from specimens indicate season Jan-Apr, or later, in Peru, Aug-Jan in Bolivia. Nest, eggs, courtship and other aspects of breeding unknown.

**Movements.** No information.

**Status and Conservation.** Not globally threatened. No information on numbers; considered to be generally uncommon in Peru, though regularly noted near Manu Cloud Forest Lodge. Clearing of montane forest from lower levels could have adverse effect on this toucanet, although it should have noticeable impact on others such as *A. prasinus* and *A. derbianus* before this species. Studies required on its breeding biology and ecology.

**Bibliography.** Anon. (1995a), Bond (1954), Bond & Meyer de Schauensee (1943), Carriker (1933), Cassin (1867), Clements & Shany (2001), Fjeldså & Krabbe (1990), de Germiny (1930a), Haffer (1974), Meyer de Schauensee (1966, 1982), Olog (1968), Parker *et al.* (1982), Remsen (1985), Remsen & Traylor (1989), Remsen *et al.* (1993), Ridgway (1914), Schulenberg & Parker (1997), Stotz *et al.* (1996), Terborgh (1972).

## 7. Guianan Toucanet

*Selenidera culik*

French: Toucanet koulík

German: Pfefferfresser

Spanish: Tucanete Culik

**Taxonomy.** *Pteroglossus Culik* Wagler, 1827, Cayenne.

Distinct from all others of genus. Although not very closely related to *S. spectabilis*, both that and present species have sometimes been thought to belong to probable superspecies formed by *S. nattereri*, *S. reinwardtii*, *S. gouldii* and *S. maculirostris*, but they differ from those four in voice and displays. Monotypic.

**Distribution.** Extreme SE Venezuela, the Guianas and N Brazil N of Amazon (from lower R Negro E to E Amapá).

tle joined with squawk, rooster-like at times; rattles used alone aggressively, or introducing squawks; also long scream, like that of *Andigena*, perhaps an alarm call, but given in series with rattles as prelude; various soft rattles and other calls, some aggressive, others used in courtship feeding and at nest.

**Habitat.** Moist lowland to hill forest, and gallery forest in savannas; selectively cut forest used less than primary, undisturbed forest. Usually below 600 m; to 800-900 m in Venezuela and Surinam. Competes with woodpeckers for roosting and nesting holes.

**Food and Feeding.** Peppers, *Cecropia* and other fruits, including figs and palm fruits; also insects at times. Evidence for co-evolution with palm *Oenocarpus bacaba*, allowing toucanets few fruits at a time. In captivity, does well on grapes, melons, peppers, cooked beets and carrots. Feeds mainly in canopy, in pairs or small groups.

**Breeding.** Mar-May, or Apr-Jul in Brazil. Male courtship-feeds female, allopreens; raises head when calling or singing, sometimes directs song to sides with head up (shows sexual colours). Takes over woodpecker hole for nesting; a nest 9 m up palm tree in casava field, with 2 nestlings and 3 adults present, hence may nest socially. Eggs 2-3; no details on incubation and nestling periods, or on other aspects.

**Movements.** Probably sedentary.

**Status and Conservation.** Not globally threatened. Often common. Possible that relatively small size and formidable bill may enable this species to acquire suitable nesting cavities more readily than its larger relatives.

**Bibliography.** Beebe *et al.* (1917), Blake (1950, 1963), Bühler (1993, 1995b), Chubb (1916), Cohn-Haft *et al.* (1997), Cory (1919), Haffer (1974, 1978, 1987, 1991), Haverschmidt & Mees (1994), Jennings, J. (1993b, 1995b), Karr *et al.* (1990), Meyer de Schauensee (1966), Meyer de Schauensee & Phelps (1978), Morrone (2000), O'Brien (1979), Parker *et al.* (1993), Phelps & Phelps (1958), Remsen *et al.* (1993), Rodner *et al.* (2000), Sick (1985, 1993), Snyder (1966), Stotz & Bierregaard (1989), Stotz *et al.* (1996), Thiollay (1992), Tostain *et al.* (1992).

## 8. Tawny-tufted Toucanet

*Selenidera nattereri*

French: Toucanet de Natterer

German: Nattererarassari

Spanish: Tucanete de Natterer

**Taxonomy.** *Pteroglossus Nattereri* Gould, 1836, Brazil.

Probably forms a superspecies with *S. reinwardtii*, *S. gouldii* and *S. maculirostris*; *S. culik* and *S. spectabilis* have sometimes been included too, but these two appear to differ from others in voice and display behaviour. Monotypic.

**Distribution.** Patchily distributed along rivers, from extreme E Colombia (R Vaupés region) and S Venezuela to NW Brazil (R Solimões from Tonantins to Codajás, and N to upper R Negro); reports from Guyana and French Guiana require confirmation, as there is no evidence of occurrence in intervening areas.

bill has very different appearance). Female differs in chestnut crown to upper mantle, rusty chin to belly, paler tawny ear-tuft and yellow back band, green-muted flank patch, orbital-facial skin less bright. VOICE. Growl-like, croaking "ggruukk" notes, c. 83-86 per minute, recorded calls mainly 10-

**Descriptive notes.** 33-35 cm; 129-165 g. Long bill red and black, upperparts green, tail green above with chestnut tips usually on all pairs of rectrices, red undertail-coverts. Male with black forehead to nape, throat and most of underparts, gold "collar" across upper mantle; large blue facial-orbital area, gold or yellow ear-tuft, black cap. Female with chestnut nape to upper back, muted yellow "collar", grey to green-grey underparts with belly green-yellow, paler blue orbital skin, shorter bill. Immature with lax plumage, duller, black areas sootier; bill less patterned, black mixed with brown. VOICE. Large repertoire, basic call rattle

15 seconds in duration; also more rattling version, "dddkk-"; other rattle calls show tendency towards those of *S. culik*.

**Habitat.** Forested lowlands, frequently on sandy soil, usually near streams; also low open forest.

**Food and Feeding.** Only fruits and fruit seeds found in stomachs; no other data.

**Breeding.** Almost unknown. Season suggested as Mar-May in all areas, mostly Apr-Nov. Displays, eggs, nest and all other details undocumented.

**Movements.** Probably sedentary.

**Status and Conservation.** Not globally threatened. Range is not small, but apparent patchiness of this species' occurrence gives cause for concern; reasons for presence in some areas and absence in many others uncertain. Data urgently needed on its habitat and feeding requirements, as well as on its breeding biology and behaviour.

**Bibliography.** Chubb (1916), Cory (1919), Friedmann (1948), Gyldenstolpe (1945a), Haffer (1974, 1978, 1991, 1997b), Hilty & Brown (1986), Maria & Olivares (1967), Meyer de Schauensee (1949, 1964, 1966), Meyer de Schauensee & Phelps (1978), Morrone (2000), Olivares (1964a), Parker *et al.* (1993), Pelzelin (1867-1871), Phelps & Phelps (1958), Pinto (1938a), Remsen *et al.* (1993), Rodner *et al.* (2000), Schomburgk (1848), Sick (1985, 1993), Snyder (1966), Stotz *et al.* (1996), Todd (1943b), Tostain *et al.* (1992), Willard *et al.* (1991), Zimmer & Hilty (1997).

## 9. Gold-collared Toucanet

*Selenidera reinwardtii*

French: Toucanet de Reinwardt

German: Reinwardtarassari

Spanish: Tucanete de Reinwardt

**Other common names:** Golden-collared Toucanet; Langsdorff's Toucanet (*langsdorffii*)**Taxonomy.** *Pteroglossus Reinwardtii* Wagler, 1827, Brazil.

Probably forms a superspecies with *S. nattereri*, *S. gouldii* and *S. maculirostris*; *S. culik* and *S. spectabilis* have sometimes been included too, but these two appear to differ from others in voice and display behaviour. Race *langsdorffii* has sometimes been considered a separate species, but interbreeds with nominate race in N Peru (upper R Ucayali and R Huallaga), where intergrades occur. Two subspecies recognized.

**Subspecies and Distribution.**

*S. r. reinwardtii* (Wagler, 1827) - EC & SE Colombia (along Brazil border) S to E Ecuador and CN & NE Peru.

*S. r. langsdorffii* (Wagler, 1827) - NC & E Peru, and W Brazil (E, S of R Solimões, to R Purus and probably upper R Madeira), S to NW Bolivia (W of R Beni).

**Descriptive notes.** 33-35 cm; 129-178 g (*reinwardtii*), 134-200 g (*langsdorffii*). Male nominate race with black head to mantle, gold-yellow ear-tuft, and yellow band separating black from green back and tail; black below, with gold or orange-gold flank patch, red-undertail-coverts; central 2-3 pairs of rectrices tipped chestnut; bill with black basal line, black culmen expanding to all-black distal maxilla and mandible, tomial teeth black to ivory, rest of bill dull red; pale eye with darkened iris before and behind pupil, pupil appearing slit-like; orbital skin variably green, blue or yellow. Female chestnut where male black, duller ear-tuft blends with chestnut background, flank patch less gold, yellow band on upper back narrower, bill shorter. Immature with blotchy bill, no basal line, no tomial "teeth", keel at base of culmen, duller throughout, lax-plumaged, rusty-orange undertail; sexual features appear early. Race *langsdorffii* has orbital area greener, flank patch more orange, but differs mainly in bill colours: maxilla mainly black, mandible distally black, rest of sides green to grey-green, "teeth" creamy to whitish, or bill can be nearly all black, or sometimes with 2-4 vertical or angled black lines above maxillary tomentum, latter suggesting pattern of *S. maculirostris*. VOICE. Song of both races a series of c. 4-14 "ggraaawk" notes at 60-85 per minute, notes longer than in *S. gouldii* and *S. maculirostris*, tempo much as in *S. maculirostris*; sexes seem to sing solo, not duetting; countersinging occurs; calls include "eh", "uh", "kik" and other softer sounds; also loud bill-wiping in aggression, loud wing sounds in interactions.

**Habitat.** Lowland and lower hill and mountain-slope forest, also floodplain-forest and occasionally várzea, but more common in dry upper areas of forest and on ridges; uses forest edges, but not secondary forest. Occurs generally up to c. 1000 m, in Ecuador sparsely up to 1200 m, in Peru reaching 1500 m rarely, and to 1300 m in NW Bolivia.

**Food and Feeding.** Diverse fruits, including figs, *Cecropia* fruits and many others; also some insects, and in captivity can be maintained on all-insect diet; has been captured while seeking to attack small birds in mist-nets. Forages from understorey to canopy, singly, in pairs, or in groups of up to 4 birds. Forages over bark and foliage, fly-catches inexpertly but successfully, also probes for termites. Joins mixed-species foraging flocks.

**Breeding.** Mar-Jul in N, Jun-Dec in Peru, Bolivia and W Brazil. Apparently territorial, mainly or entirely in pairs. Male courtship-feeds female, sometimes several fruits in succession, laying fruit across into her open bill; singer lowers tail as bows head deeply, then cocks it as head and bill lifted high, and red undertail-covert feathers erected, roughly 2-3 notes per full bow and rise. Nest in tree cavity, but unknown to what extent excavated, and nest details undescribed; used cavities seen at 2.4-4 m. Clutch size and other breeding data unreported.

**Movements.** Probably sedentary, and territorial throughout year.

**Status and Conservation.** Not globally threatened. Generally uncommon in Colombia. Uncommon to fairly common in Ecuador. Reported to be fairly common locally in Peru, but recorded density of only c. 1 pair/100 ha of forest, of which c. 35% is utilized. Occurs in Cuyabeno Reserve, Ecuador, and in Tambopata Reserve, Peru. Additional information needed regarding species' requirements for breeding. This genus is an appropriate one for designating indicator species, as the *Selenidera* toucanets are more strictly forest species than are other toucans.

**Bibliography.** Anon. (1995a), Bond (1954), Chapman (1917, 1921b, 1926), Clements & Shany (2001), Cory (1919), Cracraft & Prum (1988), Foster *et al.* (1994), Gyldenstolpe (1945a, 1951), Haffer (1974, 1978, 1991, 1993a, 1997b), Hilty & Brown (1986), Hornbuckle (1999), Karr *et al.* (1990), Maria & Olivares (1967), Meyer de Schauensee (1949, 1964, 1966), Morrone (2000), Novas (1957), Parker & Bailey (1991), Parker & Remsen (1987), Parker *et al.* (1991), Remsen & Traylor (1989), Remsen *et al.* (1993), Ridgely & Greenfield (2001), Robinson & Terborgh (1997), Salaman *et al.* (1999), Sick (1985, 1993), Stotz *et al.* (1996), Terborgh *et al.* (1990), Traylor (1958), Zimmer (1930).

## 10. Gould's Toucanet

*Selenidera gouldii*

French: Toucanet de Gould

German: Gouldarassari

Spanish: Tucanete de Gould

**Taxonomy.** *Pteroglossus Gouldii* Natterer, 1837, Pará, Brazil.

Probably forms a superspecies with *S. nattereri*, *S. reinwardtii* and *S. maculirostris*; *S. culik* and *S. spectabilis* have sometimes been included too, but these two appear to differ from others in voice and display behaviour. Closely related to *S. maculirostris*, and may be conspecific, as sometimes treated. Populations named as races *hellmayri* (NC Brazil) and *baturitensis* (NE Brazil) appear to represent clinal variation of trivial nature, size decreasing eastwards; either or both of these sometimes placed in *S. maculirostris*. Monotypic.

**Distribution.** C & E Brazil, S of Amazon (from R Madeira E to Maranhão and N Ceará), S to E Bolivia (R Mamoré, E Beni and NE Santa Cruz) and C Mato Grosso, there reaching tributaries of upper R Paraguay.

**Descriptive notes.** c. 33 cm; 131-209 g. Male with black head to mantle, gold-yellow ear-tuft, yellow band on upper back, green back and tail; black below, with golden flank patch, red-undertail-coverts; central 1-3 pairs of rectrices tipped chestnut; maxilla with narrow ivory base behind black patch, latter often with 3-5 vertical black lines beneath, mandible with ivory base to over half-way along and much smaller black patch below or ahead of front end of maxillary patch, one-third or more of bill tip orange-yellow, tomlia ivory; yellow eye slit-like owing to darkened iris before and behind pupil; facial-orbital area green-yellow to

blue. Distinguished from almost identical *S. reinwardtii* and *S. maculirostris* in bill colours. Female chestnut where male black, ear-tuft duller, flank patch more yellow, yellow band on upper back narrower, bill shorter. Immature duller, virtually lacking yellow band on back, plumage lax, bright areas of adults duller; bill lacks "teeth" and fine basal line, pattern obscure, blotchy, pale areas horn-coloured. Voice. Series of "ggrawnk" to "ggrraaw" notes, very like those of *S. reinwardtii* and *S. maculirostris*, but at slower tempo of 60-75 per minute; other calls probably also similar.

**Habitat.** Moist to wet tropical lowland forest, and gallery forest, especially in *N cerrado*; also palm forest, deciduous forest, some secondary forest, and thickets near forest; at times *várzea* flooded forest. Occurs on some slopes to 700 m, e.g. in Serra de Baturitá (Ceará, in NE Brazil), and to 725 m in Bolivia.

**Food and Feeding.** Very little known. Fruits, e.g. of the palm *Euterpe*; also, "meat" in one stomach. Forages from undergrowth to canopy, usually in pairs or in groups of up to 4.

**Breeding.** Season suggested as May-Sept; probably from Jun-Jul in W Brazil (Amazonas, Rondônia) and in Bolivia. No information available on nest, eggs and all other aspects; probably much as for *S. maculirostris*.

**Movements.** Presumably sedentary.

**Status and Conservation.** Not globally threatened. No information available on numbers. This species' ability to use second growth should favour it. Details of breeding and ecology are needed for possible monitoring.

**Bibliography.** Anon. (1995a), Bates *et al.* (1989), Beebe (1916), Cory (1919), Dubs (1992), Griscom & Greenway (1937), Gyldenstolpe (1945a), Haffer (1974, 1978, 1991, 1993a, 1997b), Hellmayr (1910), Novaes (1976), Novaes & Lima (1991), Oren & Parker (1997), Parker *et al.* (1991), Pinto & Camargo (1961), Remsen & Traylor (1989), Sick (1985, 1993), da Silva (1996), Stotz, Fitzpatrick *et al.* (1996), Stotz, Lanyon *et al.* (1997), Todd (1943b), Willis (1976), Willis & Oniki (1990), Zimmer *et al.* (1997).

## 11. Spot-billed Toucanet

*Selenidera maculirostris*

French: Toucanet à bec tacheté

German: Fleckenarassari

Spanish: Tucanete Piquimaculado

**Taxonomy.** *Pteroglossus maculirostris* M. H. K. Lichtenstein, 1823, Brazil.

Probably forms a superspecies with *S. nattereri*, *S. reinwardtii* and *S. gouldii*; *S. culik* and *S. spectabilis* have sometimes been included too, but these two appear to differ from others in voice and display behaviour. Closely related to *S. gouldii*, and possibly conspecific, as sometimes treated. Forms described as *hellmayri* (NC Brazil) and *baturitensis* (NE Brazil), apparently result only of clinal variation, usually treated as part of *S. gouldii*, but sometimes included in present species. Monotypic.

**Distribution.** Atlantic forest of SE Brazil (S Bahia and E Minas Gerais S to Paraná and Santa Catarina, possibly to Rio Grande do Sul), also adjacent E Paraguay and NE Argentina (Misiones).

**Descriptive notes.** 33-37 cm; 137-193 g. Male with black head and underparts, green upperparts and tail, with gold-yellow ear-tuft, yellow hindcollar, yellow-gold flank mark, rusty thighs, red undertail-coverts, chestnut tips of central 3 pairs of rectrices; bill with fine black basal line, mainly greenish-yellow to ivory, brighter at tip, central culmen black, maxilla with 3-5 vertical black stripes (rear 1 or 2 can be isolated or dull), mandible with small anterior black mark level with or sometimes slightly forward of front maxillary stripe; eye yellow, black pupil appearing slit-like; orbital skin blue to green and yellow. Distinguished from

*S. gouldii* and others of superspecies by bill pattern and colours. Female chestnut on head, more cinnamon-rufous underparts, cinnamon front of ear-tuft and flanks, bill shorter. Immature laxy-plumaged, dull, without collar, bill muted in colour, without tomlia "teeth"; shows black vertical maxillary marks at c. 8-9 weeks of age. Voice. Gruff, growing "ggroaw" to "kkrowk" notes in series lasting to c. 15 seconds, at tempo of 75-90 per minute; sexes usually sing one at a time, sometimes together but usually not very close; somewhat similar notes during interactions, also low "tut" notes, rattling notes, purring low notes, bill-snapping sounds.

**Habitat.** Subtropical moist primary forest, selectively cut forest, nearby secondary patches, palm groves of *Euterpe edulis*; gallery forest at SE edge of the *cerrado*; also remnant patches of forest in Paraguay. Occurs to over 1000 m on mountain slopes that have forest remaining.

**Food and Feeding.** Fruits of *Euterpe*, *Cecropia* and others; insects and vertebrates probably also taken; in captivity eats many cultivated fruits, also captures insects in aviaries, and feeds dead young mice to nestlings. Forages in middle storey and undergrowth, even down to ground at times. Feeds singly, in pairs, or in small groups, but at one tree 19 seen with 5 *Baillonius bailloni* and other birds. Drinks from tree crevices. Often perches for extended periods; infrequently flies to isolated fruit trees in open, used by other toucans.

**Breeding.** Dec-Jun in N, Oct-Jan in S part of range. Most data from aviary birds. Nests in pairs, territorial. Male courtship-feeds, sometimes repeatedly, with regurgitated fruits, may give female a piece and keep rest, and pair allopreens; singer bows low, more or less in time with notes, raising head high, ear-covert tuft flared, flank patch out, undertail-coverts fluffed, tail twitched upward and sideways, to cocked position, then down, head may be held up or down for 2 notes, tail may move twice with 1 note, entire display like that of *Andigena* species. Nest probably excavated in old woodpecker hole; in captivity, both sexes excavate in rotted log with an essential chamber cut out for them. Eggs 2-3; for captives, incubation c. 15 days, both sexes in nest at night, male rattles softly when entering; nestlings fed fruits and dead mice, develop slowly, can be sexed by plumage at c. 25 days, reach 120 g at 31 days, fledging at 6-7 weeks, fed by adults until c. 55 days. One aviary pair, after its fledged young had been removed, adopted two 2-day-old *Pteroglossus viridis* and successfully raised them.

**Movements.** Unknown.

**Status and Conservation.** Not globally threatened. CITES II. Sizeable populations exist in some protected areas in Brazil, such as around Iguaçu, but locally threatened in other parts, where loss of forest has impact on species. Elsewhere in Brazil, occurs in Nova Lombardia Biological Reserve and Sooretama Biological Reserve. Present in Iguazú National Park, Argentina. Small Paraguayan populations much separated, and inbreeding probably occurs; present in that country in Estancia San Antonio Private Nature Reserve, Reserva Natural del Bosque Mbaracayú, La Golondrina Private Nature Reserve and Estancia Itabó Private Nature Reserve. Information needed on breeding biology of wild birds.

**Bibliography.** Belton (1984, 1994), Brooks *et al.* (1993), Buzzetti (2000), Canevari *et al.* (1991), Capper *et al.* (2000), Chebez (1994), Cory (1919), Cracraft & Prum (1988), Galetti *et al.* (1998), Guix (1995), Guix & Jover (2001), Guix *et al.* (2000), Haffer (1974, 1978, 1991, 1997b), Hayes (1995), Jennings, J. (1985b, 1995a, 1995b), Lüdcke (1960), McConnell (1991), Meyer de Schauensee (1966), Narosky & Yzurieta (1993), Parker & Goerck (1997), de la Peña (1994), Pinto (1935), do Rosário (1996), Saibene *et al.* (1996), Sick (1985, 1993), da Silva (1996), Stotz *et al.* (1996).

## 12. Yellow-eared Toucanet

*Selenidera spectabilis*

French: Toucanet à oreilles d'or

German: Gelbohrarassari

Spanish: Tucanete Orejigualdo

**Taxonomy.** *Selenidera spectabilis* Cassin, 1857, Cucuyos de Veragua, Panama.

Distinct within genus. Although not very closely related to *S. culik*, both that and present species have sometimes been thought to be part of probable superspecies formed by *S. nattereri*, *S. reinwardtii*, *S. gouldii* and *S. maculirostris*, but they differ from those four in voice and displays. Monotypic.

**Distribution.** N Honduras S, locally, to NW & CW Colombia and extreme NW Ecuador (Esmeraldas); apparently absent from SW Colombia.

**Descriptive notes.** 36-38 cm; 175-245 g. Largest, most distinctive of its genus. Male with black cap to hindneck, with yellow ear-tuft, green back and uppertail-coverts, and blackish tail; below, black chin and malar to belly, yellow flank patch, chestnut thighs, red undertail-coverts; long bill with grey or black basal line, yellow (sometimes with admixed green) maxilla with olive-brown from base diminishing distally, mandible dark olive to brownish-black, tomlia tips horn-coloured, mouth-lining orange-red; orbital skin blue to green and yellow. Distinguished from other *Selenidera* by larger size, bill pattern, lack of

yellow collar, no chestnut tips of rectrices. Female differs from male in chestnut forehead to hindneck, no yellow ear-tuft (but black ear-coverts sometimes with yellow flecks), shorter bill. Immature duller, plumage lax, bill pattern vague and no tomlia teeth; plumage shows sexual features, but black of adult male is sooty and chestnut of adult female brownish. Voice. Song a short to long series normally of double notes, "tik-et", often with associated rattles or snapping of bill, at 1-1-1-8 notes per second; pair-members sometimes sing simultaneously; also rattling notes, both long and short, as calls, rattle possibly made by tongue inside closed bill.

**Habitat.** Wet forested slopes and ridges in lowlands; also forest edges, adjacent secondary forest, and fruit trees close to forest. Generally at 300-1100 m, extremes sea-level to c. 1500 m; in Honduras below 500 m.

**Food and Feeding.** Few observations. Diet of fruits, many arillate, such as those of *Dendropanax*, *Guateria*, *Hampea* and *Protium*; also insects, spiders, lizards. Inconspicuous; feeds in pairs or small groups, from middle storey to canopy, lower at times.

**Breeding.** Apr-Aug generally; perhaps earlier in Honduras, as early as Feb in Colombia, possibly earlier still in Ecuador. Singing bird bows and tosses head upwards, bill sometimes open, showing red-orange mouth, and tail fits up to one side and then other, often flipped twice with each double note. Other data essentially lacking; condition of female specimens indicates clutch size probably 2-4 eggs.

**Movements.** Downslope post-breeding movement into lowlands known to occur in Costa Rica and Panama, sometimes preceded by individuals gathering in groups larger than family; it is uncertain whether such movements involve most of population, or predominantly younger birds. Rare occurrence in NW Ecuador has been suggested to coincide only with very wet El Niño years; further investigation required.

**Status and Conservation.** Not globally threatened. Uncommon to locally fairly common in N of range. Appears to have decreased in Costa Rica, where habitat continuity possibly essential for it to thrive; occurs in that country in Braulio Carrillo National Park. Generally uncommon to rare, and local, in NW South America; rare and local in NW Ecuador, where may only occur sporadically. Should be considered for monitoring, but basic information needed regarding its biology. Not known to be kept in captivity.

**Bibliography.** Anon. (1998b), Best *et al.* (1997), Blake (2001), Blake & Loiselle (2000), Bond & Meyer de Schauensee (1944), Chapman (1917), Cory (1919), Gillespie (2001), Haffer (1974, 1975, 1997b), Hilty & Brown (1986), Karr *et al.* (1990), Meyer de Schauensee (1949, 1964, 1966), Monroe (1968), Norton *et al.* (1972), Remsen *et al.* (1993), Ridgely & Greenfield (2001), Ridgely & Gwynne (1989), Ridgely *et al.* (1998), Ridgway (1914), Robbins *et al.* (1985), Rodner *et al.* (2000), Slud (1964), Stiles (1983), Stiles & Levey (1994), Stiles & Skutch (1989), Stotz *et al.* (1996), West (1976), Wetmore (1968a).

PLATE 18

inches 5  
cm 13

Genus *ANDIGENA* Gould, 1851

13. Grey-breasted Mountain-toucan

*Andigena hypoglauca*

French: Toucan bleu German: Blautukan Spanish: Tucán Pechigris

**Taxonomy.** *Pteroglossus hypoglaucus* Gould, 1833; no locality = Colombia. Forms a superspecies with *A. cucullata* and *A. laminirostris*. Races poorly differentiated, intergrading in Ecuador. Two subspecies recognized.  
**Subspecies and Distribution.**  
*A. h. hypoglauca* (Gould, 1833) - mountains of C & S Colombia to E Ecuador.  
*A. h. lateralis* Chapman, 1923 - Andes of E Ecuador and Peru.

**Descriptive notes.** 46-48 cm; 244-370 g. Large toucan with black cap and face, grey-blue hindneck, green-tinged brown back, grey-blue to grey underparts. Male nominate race with bright yellow rump, blackish to brown-black tail with 2-3 central pairs of feathers tipped chestnut; sides and flanks somewhat pale grey-blue, thighs chestnut, undertail-coverts red; bill yellow to greenish basally, with black band near base, separated from red-orange culmen by thin oblique black line, mandible yellow with distal half black; facial skin mostly blue, with some black around brown eye. Female as male, but bill shorter. Immature duller, bright colours

muted, bill brown to blackish and horn-coloured with no marks at base and without "teeth". Race *lateralis* has paler yellow rump, variable pale yellow flank patch, yellow to green eye with bluer outer ring. Voice. Song of low "gweeeeeeet", at 1-75 to over 2 seconds the longest known piciform note, slowly repeated at 24-36 per minute, with occasional bill-whacking sounds; notes vary considerably: "wek", singly or in irregular series, aggressive and alarm notes, with or without added bill-snaps.

**Habitat.** Wet temperate montane forest, often in cloudforest, stunted trees at tree-line, edges and second growth. Reaches higher elevations than other toucans; at 2200-3650 m generally, occasionally lower, to 1800 m in parts of Peru and under 1700 m in Ecuador. Although locally sympatric with *A. nigrirostris*, apparently never found in same site, being replaced by that species at c. 2300-2500 m and below, but at times can probably hear each other.

**Food and Feeding.** Various fruits and berries, including species of *Rubus*, *Cecropia* and others; presumably animal foods fed to young, but unknown. Forages singly or in groups of up to 6, from canopy to near ground, usually quiet and not conspicuous. Can hang upside-down when feeding. May join mixed-species foraging flocks of tanagers (Thraupidae), thrushes (*Turdus*) and New World blackbirds (Icteridae).

**Breeding.** Dec-Feb in Colombia, Jun/Jul-Nov in Ecuador and Peru. No information on breeding behaviour, nest or eggs; possibly occupies large home range or territory.

**Movements.** None known.

**Status and Conservation.** Not globally threatened. Currently considered Near-threatened. Occurs in several protected areas, including Las Cajas National Recreation Area and Podocarpus National Park, in Ecuador. Within its range, some areas of high-altitude forest are certainly being cleared, though most of the clearance going on is at lower elevations than those occupied by this species; nonetheless, forest loss occurs throughout species' range, in some areas to severe degree, especially in Colombia; clearance in different areas for commercial and subsistence agriculture, grazing, mining activities, fuel, etc.; best preserved forest appears to be in SE Peru. Population fragmentation and inbreeding are possible problems; further information is needed on all aspects of its biology.  
**Bibliography.** Baez *et al.* (1997), Best *et al.* (1997), Bloch *et al.* (1991), Bond (1954), Butler (1979), Chapman (1917, 1926), Clements & Shany (2001), Cory (1919), Cresswell, Hughes *et al.* (1999), Davies *et al.* (1994, 1997), Fjeldså (1987), Fjeldså & Krabbe (1990), Greenway (1978), Haffer (1974), Hilty (1985), Hilty & Brown (1986), Hornbuckle (1999), Jacobs & Walker (1999), Krabbe (1991), López *et al.* (2000), Meyer de Schauensee (1949, 1964, 1966, 1982), Olrog (1968), Ortiz & Carrión (1991), Parker, Parker & Plenge (1982), Parker, Schulenberg *et al.* (1985), Rensen (1984), Rensen *et al.* (1993), Renjifo *et al.* (1997), Ridgely & Greenfield (2001), Stattersfield & Capper (2000), Stotz *et al.* (1996), Williams & Tobias (1994).

14. Hooded Mountain-toucan

*Andigena cucullata*

French: Toucan à capuchon German: Schwarzkopftukan Spanish: Tucán Encapuchado

**Taxonomy.** *Pteroglossus cucullatus* Gould, 1846, Cocapata, Cochabamba, Bolivia. Forms a superspecies with *A. hypoglauca* and *A. laminirostris*. Monotypic.  
**Distribution.** Andes in SE Peru (Puno) and W & C Bolivia (La Paz to Cochabamba).

**Descriptive notes.** 48-50 cm; 222-380 g. Brown-backed, green-winged, blackish-tailed toucan with grey-blue collar across hindneck, black head including ear-coverts and throat; sooty-blue to blue-grey below, with rusty thighs and red undertail-coverts; facial skin shades of pale blue; bill yellow-green with black tip, mandible yellow for basal two-thirds with black spot near base. Differs from *A. hypoglauca* and *A. laminirostris* in mainly green-yellow bill, lack of yellow rump patch, no chestnut tips of tail feathers, more black on head. Female like male, but shorter bill. Immature duller, lax plumage sootier on head, greyer below, bright

colours muted, rectrices more pointed; bill dull, with dark culmen and tip, mandible shows spot at base but lacks yellow behind it, no tomial "teeth". Voice. Song a slow series of "peeeeah" notes c. 1-5 seconds long, in regular to irregular series at intervals of 1-5 seconds; also series of "ik" or "tik" notes at c. 2 per second; bill-clapping with either of these calls.

**Habitat.** Wet temperate and uppermost subtropical forest, usually above range of most other toucans, c. 2400-3300 m, at times wandering to 2000 m, where it could meet *Aulacorhynchus coeruleicinctis*.

**Food and Feeding.** Fruits, species of which undetermined, but various colours of seeds and skins of different sizes in stomachs. Forages singly or in groups of up to 4, probably family parties, from canopy to understorey. Little known.

**Breeding.** Season estimated from Feb-Jun, perhaps earlier, to Nov. Displays, nest, eggs, and all other aspects of cycle unreported; generally calls or sings from treetops, often in morning and evening.

**Movements.** Possible movement down to below usual altitude, perhaps by foraging independent subadults.

**Status and Conservation.** Not globally threatened. Restricted-range species: present in Bolivian and Peruvian Upper Yungas EBA. Until recently considered Near-threatened. Found to be surprisingly common in late 1990's in humid montane forest near Cochabamba, in C Bolivia, where at least 10 individuals in study area of 2 km<sup>2</sup>. Uncommon in Peru. Has small range in which pairs or groups occupy large areas, so populations may be small generally, and somewhat fragmented. Data on nesting and foraging are needed in order to provide bases for monitoring.

**Bibliography.** Anon. (1995a), Bond & Meyer de Schauensee (1943), Cassin (1867), Clements & Shany (2001), Collar, Crosby & Stattersfield (1994), Collar, Gonzaga *et al.* (1992), Cory (1919), Fjeldså & Krabbe (1990), de Germigny (1930a), Haffer (1974), Herzog *et al.* (1999), Meyer de Schauensee (1966, 1982), Olrog (1968), Parker *et al.* (1982), Rensen (1984, 1985), Rensen & Traylor (1989), Rensen *et al.* (1993), Stattersfield *et al.* (1998), Stotz *et al.* (1996).

15. Plate-billed Mountain-toucan

*Andigena laminirostris*

French: Toucan montagnard German: Leistenschnabeltukan Spanish: Tucán Piquiplano  
Other common names: Plain-billed/Laminated Mountain-toucan/Hill-toucan

**Taxonomy.** *Andigena laminirostris* Gould, 1851, Quito, Ecuador. Forms a superspecies with *A. hypoglauca* and *A. cucullata*. Monotypic.  
**Distribution.** W Andes from SW Colombia (Patia Canyon, in Nariño) S to S Ecuador (S possibly as far as R Chanchan).

**Descriptive notes.** 46-51 cm; 275-355 g. Large, with black forehead to hindneck, rest of upperparts brown and green, except for pale yellow rump; tail blackish, central 2-3 pairs of rectrices tipped chestnut; blue-grey sides of neck; blue-grey chin to belly, with yellow patch on sides and flanks, chestnut thighs, red undertail-coverts; bill black, with reddish base narrow on maxilla, nearly half-way along on mandible, sides of maxilla near base covered by raised, square creamy or buffy yellow "plate"; facial skin blue above, yellow below; eye brown-red. Differs from both *A. hypoglauca* and *A. cucullata* in pattern of bill, lack

of blue hindcollar. Female slightly smaller than male, differs mainly in shorter bill. Immature greyer below, browner above, grey-black bill with "plate" only hinted at by yellow area, no tomial "teeth". Voice. Song a series of loud, braying "kyeeowp" to "kyewp", 35-42 per minute, initiated by rattles, vocal or made by tongue against inside of bill, that gradually take on "eeeeowp" sound and lose rattle element; rattles variable, up to 3 per second (usually 1-2), and some bill-snapping, but bill nearly to fully closed during many rattles; female at higher pitch; also squeak notes, "ddrak" possibly as contact call, "ek-ek" calls when pair-members close together; several begging calls; loud wing-flapping during interactions.

**Habitat.** Moist montane forest with epiphytes, mosses, bromeliads; also enters nearby secondary forest, and occurs where forest has been selectively logged. Mainly at 1300-2500 m; found occasionally down to 300 m, and rarely up to 3200 m.

**Food and Feeding.** Mainly fruits, in Colombia of 49 plants in 22 families; especially important are species of *Cecropia*, arecaceous palms, *Ocotea*, *Beilschmiedia*, myrtaceous trees, *Clusia*, *Ficus*, *Miconia* and *Blakea*, the first 5 of which are important in nestling diet. Although up to 98% frugivorous, c. 16% of food provided to young is animal, e.g. beetles and other insects, snails, birds and eggs, and rodents; will tear open birds' nests to get at chicks; captives prey on eggs and young of any birds caged with them. Largest fruits broken up by holding with foot and tearing with bill, others swallowed whole; most seeds pass through gut, but largest, such as avocado seed, regurgitated. Feeds in groups at height of 2-30 m, in one study mean height 15-2 m. Aggressive towards hole-nesters, especially Toucan-barbets (*Semnorhis ramphastinus*), *Aulacorhynchus haematopygus* and woodpeckers.

**Breeding.** Mar-Oct in Colombia, Jun-Sept in Ecuador. Sometimes 2 broods, but may not breed yearly. Groups with home range break up prior to breeding, non-breeders keeping away from nest area. Often pair-members bound about, undertail-coverts erected, flank patches spread, male cocking tail; sings with bowing and bobbing of head and bill, tail flicked and cocked and lowered, undertail-coverts fluffed, very much as in species of *Selenidera*; male courtship-feeds female, latter stays close to nest, may solicit food from male, copulation 15-20 seconds in duration. Nest 6-30 m up in dead tree, stump, utility pole, often usurped from Toucan-barbet; some excavating occurs, and continues during nesting; captives excavate soft palm logs; nest entrance round to oval, c. 8 cm in diameter, depth c. 2 m. Eggs 2-3, laid c. 2 weeks after nest ready; both sexes incubate, female sits at night, incubation period c. 16-17 days; both also feed young, female tends to feed more often, feeding rate 1-2 times per hour, small items fed first, later larger fruits, male may feed more insects; most nest sanitation by female; nestlings open eyes at c. 4 weeks, fledging at 46-60 days, mainly 49-51 days; fledglings do not return to nest, fed by parents for 2-3 weeks, are chased from territory if second brood attempted. Nest predation often severe, usually only 1 or 2 young fledge.

**Movements.** Downslope and other movements noted in Colombia, with groups of up to 25 moving to lower levels in Aug; this probably due to reduced fruit availability, as groups sometimes leave home range in poor fruiting seasons, joining other groups and wandering extensively.

**Status and Conservation.** Not globally threatened. Restricted-range species; present in Chocó EBA. Currently considered Near-threatened. Home range of 1 group 8-34 ha. Fairly common in La Planada Nature Reserve, Colombia. Common locally where forest remains more or less intact, but lives at altitudes at which clearing of forest is rampant; main causes of clearance include logging, cattle grazing, mining and agriculture. Also, illegally taken for captive-bird trade. Protective measures, and tighter enforcement of these by authorities, needed in all parts of range.

**Bibliography.** Allen (1998), Beltrán (1994), Best *et al.* (1997), Bloch *et al.* (1991), Butler (1979), Chapman (1926), Cory (1919), Fjeldså & Krabbe (1990), Hilty & Brown (1986), Meyer de Schauensee (1949, 1964, 1966, 1982), Olrog (1968), Remsen *et al.* (1993), Renjifo *et al.* (1997), Restrepo (1990), Restrepo & Mondragón (1998), Ridgely & Greenfield (2001), Ridgely *et al.* (1998), Rodner *et al.* (2000), Rundel (1975), Salaman (1994), Schlenker (2000), Shannon (1991), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), Stotz *et al.* (1996), Suárez & García (1986), Terborgh & Winter (1983), Tobin & Rundel (1975).

## 16. Black-billed Mountain-toucan

### *Andigena nigrirostris*

**French:** Toucan à bec noir **German:** Schwarzschnabeltukan **Spanish:** Tucán Piquinegro

**Taxonomy.** *Pteroglossus nigrirostris* Waterhouse, 1839, no locality = Subia, near La Mesa, Cundinamarca, Colombia.

Rather distinct from other *Andigena* species. Races intergrade where they meet. Three subspecies recognized.

#### Subspecies and Distribution.

*A. n. nigrirostris* (Waterhouse, 1839) - Andes of W Venezuela and E Andean slopes in Colombia.

*A. n. occidentalis* Chapman, 1915 - W Andes of Colombia.

*A. n. spiliorhynchus* Gould, 1858 - C Andes and W slope of E Andes in S Colombia, and E slope in Ecuador; recently collected in extreme N Peru (Cerro Chinguela).

**Descriptive notes.** 48-51 cm; 335-367 g, 450 g (1 subadult). Black-capped mountain-toucan with bronzy upperparts, pale yellow rump, dark slate tail with chestnut tips of central 2-3 rectrices; white face and throat, grading into blue on breast, chestnut thighs, red undertail-coverts. Male nominate race with bill all black, moderately broad-based; facial skin pale blue before eye, yellow or orange behind; eye brown-red. Distinguished from *A. hypoglaucha* by all-dark bill, white throat. Female shorter-billed than male. Immature duller. Races differ mainly in bill coloration: *spiliorhynchus* with bill broader-based, with dark red over small area at

base and along sides of maxilla; *occidentalis* has bill similarly broader, with thick red base which on culmen extends distally more than half-way along, also darker chestnut thighs. **Voice.** Commonly rattling or bill-clacking sounds, rattles varying in length, at c. 25 per minute; also series of c. 3-15 nasal "gwaak" notes, with overtones, at tempo of 25-45 per minute; variable, notes can be drawn out, or yelp-like, or mixed with rattling; also loud wing sounds during interactions.

**Habitat.** Moist to wet cloudforest, subtropical to temperate montane forest, thickets, bogs, cultivated areas beside forest, open areas with scattered fruiting trees. At c. 1700-2700 m; rarely down to 1200 m, and to 3245 m. Where sympatric with *A. hypoglaucha*, apparently never found in same site, being replaced by that species at c. 2300-2500 m and higher; probably within hearing distance of each other at times.

**Food and Feeding.** Little known. Diet mainly fruits and their seeds, but also some insects, e.g. beetles; 1 stomach with beetles and no fruit remains. Feeds in pairs or family groups, mainly in canopy, which often not very high.

**Breeding.** Aug-Nov in W Venezuela, Mar-Aug in Colombia and probably similar or later in Ecuador. Details all but unknown, and nest and eggs unreported; supposed nest in tree cavity at c. 20 m, but no details given.

**Movements.** None, so far as is known.

**Status and Conservation.** Not globally threatened. Until recently, species was considered Near-threatened; not now listed as such, but probably still hovers around borderline. Local in much of range. Occurs in Puracé National Park, Colombia. Because it occurs below *A. hypoglaucha*, and clearing of forest proceeds from lower to higher elevations, may actually be more likely to come under threat than that species; populations in Ecuador considered to be smaller than those of *A. hypoglaucha*. Lack of biological information impedes monitoring of present species.

**Bibliography.** Best *et al.* (1997), Butler (1979), Chapman (1917, 1926), Clements & Shany (2001), Cory (1919), Fjeldså & Krabbe (1990), Greenway (1978), Haffer (1974), Hilty (1985), Hilty & Brown (1986), Krabbe (1991), López *et al.* (2000), Meyer de Schauensee (1949, 1964, 1966, 1982), Meyer de Schauensee & Phelps (1978), Olivares (1963), Olrog (1968), Phelps & Phelps (1958), Rasmussen *et al.* (1996), Renjifo *et al.* (1997), Ridgely & Gaulin (1980), Ridgely & Greenfield (2001), Ridgely *et al.* (1998), Rodner *et al.* (2000), Salaman *et al.* (2000), Stotz *et al.* (1996), Vélez & Velázquez (1998).

## Genus *BAILLONIUS* Cassin, 1868

### 17. Saffron Toucanet

#### *Bailloni bailloni*

**French:** Toucan de Baillon **German:** Goldtukan **Spanish:** Arasarí Banana  
**Other common name:** Baillon's/Banana Toucan/Toucanet

**Taxonomy.** *Ramphastos Bailloni* Vieillot, 1819, no locality = Brazil. Has been allied with *Andigena*, and even placed within that genus, but probably more closely related to *Pteroglossus*, though even this relationship appears to be distant. Probably a relict species, purportedly the sister taxon of *Pteroglossus*. Monotypic.

**Distribution.** E Brazil (Pernambuco; Bahía, Espírito Santo and adjacent Minas Gerais S to W & NE Santa Catarina and far N Rio Grande do Sul) to EC Paraguay and NE Argentina (N Misiones).

**Descriptive notes.** 35-39 cm; female c. 156-169 g. Highly distinctive. Male saffron-yellow, gold and olive, with rump red; culmen and most of bill horn with obvious greenish-yellow tones, red area around base narrowing to a point around middle of maxilla, with diffuse greenish to grey-blue margins; facial skin red; eye pale yellow. Female more olive, less gold and yellow, with shorter bill. Immature with lax plumage more olive and grey, rump pinkish-red, blotchy bill without basal line and tomial "teeth", rectrices more pointed, tarsi with remnant hypotarsal scutes, eye brown. **Voice.** Extensive repertoire: song

a series of 12-15 loud "teeee-up" notes, c. 1-75 per second; also "yeeep" or "yi" notes in series, may be rattle-like, some rattles wavering and to 35 seconds or more; purring, soft "uh" or "perp" notes, low "eeeeee" notes, soft rattles or tapping at nest, rattles also in courtship feeding and aggression.

**Habitat.** Moist subtropical forest, generally on slopes and beside streams; also edges, and in secondary and selectively logged forest. From sea-level to 1550 m, in S usually at c. 400-600 m.

**Food and Feeding.** Mainly fruits, such as those of *Cecropia*, *Ficus*, *Euterpe*, *Sloanea* and *Nectandra*. Possibly eats young birds; once seen to enter woodpecker nest containing young after throwing out female woodpecker, was still in nest after 3 hours. Feeds in pairs or small groups, skulking and inconspicuous; 5 fed with 19 *Selenidera maculirostris* in fruiting palmito (*Euterpe edulis*), with other birds such as trogons (Trogonidae). Also seen with rails (Rallidae) and doves (Columbidae) on ground in ploughed field.

**Breeding.** Jun-Jul in far N, Dec-Apr in most of range. Details little known. Probably nests in pairs, excavating out old woodpecker hole. Male sings, also courtship-feeds female, both tap at nest entrance, allopreen; male may attempt copulation after softly allopreening facial area of female. Captive pair laid 2-3 eggs, both male and female incubated, period c. 16 days. No other information. Longevity in captivity up to 13 years and 3 months.

**Movements.** Probably moves to fruiting trees outside home range; possibly also some downslope movement after breeding.

**Status and Conservation.** Not globally threatened. CITES II. Currently considered Near-threatened. Nowhere common, but is quite inconspicuous, and numbers possibly underestimated. In hills of mainly lowland SE São Paulo, c. 5 birds/km<sup>2</sup> at altitude of 400-600 m; another study in the same area found a density of c. 12 birds/km<sup>2</sup>. Main threats are cage-bird trade, hunting, and habitat loss; montane forest generally suffering less intensive destruction than lowland forests, but isolated patches of forest in N are increasingly suffering inroads from agriculture and pastoral farming. Species occurs in several protected areas in all three countries of its range: known to occur in Itatiaia and Foz do Iguaçu National Parks, in Brazil; in Estancia San Antonio Private Nature Reserve, in Reserva Natural del Bosque Mbaracayú, in La Golondrina Private Nature Reserve, and in Estancia Itabó Private Nature Reserve, all in Paraguay; and in Iguazú National Park, Argentina. Still hunted in parts of Paraguay, where often occurs in fragmented forest patches. More information required on pair and group relations, as well as data on breeding in the wild.

**Bibliography.** Aleixo & Galetti (1997), Belton (1984, 1994), Brooks *et al.* (1993), Canevari *et al.* (1991), Chebez (1994), Eckelberry (1964), Galetti *et al.* (1998), Giraudo & Sironi (1992), Guix (1995), Guix & Jover (2001), Guix, Mañosa *et al.* (1997), Guix, Martín *et al.* (2000), Hackett & Lehn (1997), Haffer (1974), Hayes (1995), Holt (1928), Jennings, J. (1995b), Lowen *et al.* (1996), Madroño & Esquivel (1995), Madroño, Clay *et al.* (1997), Meyer de Schauensee (1966, 1982), Narosky & Yzurieta (1993), Navas & Bó (1988), Olrog (1968), Parker & Goerck (1997), de la Peña (1994), do Rosário (1996), Saibene *et al.* (1996), Scherer-Neto (1985), Schifter (1998), Sick (1979, 1985, 1993), Stattersfield & Capper (2000), Storer (1989), Stotz *et al.* (1996), Sztoleman (1926), Tobias *et al.* (1993).

## Genus *PTEROGLOSSUS* Illiger, 1811

### 18. Green Araçari

#### *Pteroglossus viridis*

**French:** Araçari vert **German:** Grünarassari **Spanish:** Arasarí verde

**Taxonomy.** *Ramphastos viridis* Linnaeus, 1766, Cayenne.

May form a superspecies with *P. inscriptus*. Less closely related to *P. bitorquatus*. Race *humboldti* of *P. inscriptus* treated by some authors as belonging within present species, but appears much closer to *P. inscriptus*. Monotypic.

**Distribution.** E Venezuela (Delta Amacuro S to E Amazonas) E through the Guianas, and S to N Brazil (S to Amazon, W to E Roraima and R Negro).

**Descriptive notes.** 30-39 cm; 110-162 g. Distinctive, small toucan, green above and yellow below, with red rump. Male with black head; bill yellow above, black below, with orange to red in between and at base of mandible. "teeth" ivory to white; facial skin violet-blue to greenish-yellow, with scarlet patch over and behind eye. Female shorter-billed, with chestnut to rusty head, cinnamon often showing on underparts. Immature duller, bill horn-coloured with few signs of patterning, no "teeth", more keeled; shows sexual colours early, but more cinnamon below. **Voice.** Rattling "briddididit", 1-6 per second, some more

rattling as "ddddd", others as "up-up-up" resembling slow motorbike; also soft chattering, purring and whining notes; calls more "voiced", less mechanical, than those of *P. inscriptus*.

**Habitat.** Lowland forest including sand-ridge forest, riverine forest in savanna country, tall second-growth forest, also some tree plantations, and fruiting trees isolated from but near forest; from sea-level to c. 800 m.

**Food and Feeding.** Mainly fruits, such as figs, and fruits of *Cecropia*, palm (*Oenocarpus*) and others, dispersing their seeds widely; captives eat mealworms, various fruits such as berries, bananas, apples, grapes, papayas, peaches, pears, maize, also carrots and peas. Forages mainly in pairs and small groups, from canopy to lower levels of understory. Clings to hanging palm fruits; may reach fruits from upside-down position. Sometimes follows Red-throated Caracara (*Daptrius americanus*) groups through forest.

**Breeding.** Generally Feb-Jun; Oct-Apr near Amazon mouth. Breeds in pairs. Male courtship-feeds female, calls with tail cocked, often switching it up and down, and sideways; may feed her inside nest-cavity. Nest up to 20 m or higher, an old cavity of woodpeckers, which it excavates further; in captivity, both sexes perform some excavation. Most data from captive birds: eggs 2-4; incubation by both sexes, period c. 17 days; both adults feed young; nestling period 43-45 days; young probably remain with parents for 6 or more months. In captivity, easily disturbed by human activity, may eat or abandon young; 2 chicks 2 days old adopted and successfully reared by pair of *Selenidera maculirostris*, after latter's fledged young had been removed.

**Movements.** Presumed to be sedentary.

**Status and Conservation.** Not globally threatened. CITES II. Species' small size and its ability to use secondary forest should be positive factors in its conservation. Occurs in Imataca Forest Reserve and El Dorado, Venezuela. Almost no information on breeding biology of wild populations; study needed.

**Bibliography.** Beebe *et al.* (1917), Blake (1950, 1963), Bühler (1993, 1995b, 1996), Cherrie (1916), Chubb (1916), Cohn-Haft *et al.* (1997), Friedmann (1948), Haffer (1974, 1978), Haverschmidt & Mees (1994), Jennings (1993a), Karr *et al.* (1990), McConnell (1991), Meyer de Schauensee (1966), Meyer de Schauensee & Phelps (1978), Page (1988), Phelps & Phelps (1958), Remsen *et al.* (1993), Rodner *et al.* (2000), Sick (1985, 1993), Snyder (1966), Stotz & Bierregaard (1989), Stotz *et al.* (1996), Thiollay (1992), Thiollay & Jullien (1998), Tostain *et al.* (1992), Vince (1998), Zimmer & Hilty (1997).

**19. Lettered Araçari**  
*Pteroglossus inscriptus*

**French:** Araçari de Humboldt      **German:** Schriftarassari      **Spanish:** Arasarí Marcado

**Taxonomy.** *Pteroglossus inscriptus* Swainson, 1822, Guyana; error = Pará, Brazil. May form a superspecies with *P. viridis*. Less closely related to *P. bitorquatus* and *P. azara*. Race *humboldti* sometimes considered a separate species, but interbreeds sporadically with nominate race in R Madeira region; *humboldti* placed within *P. viridis* by some authors, but appears more appropriately treated with present species. Form from upper Amazonia, described as race *didymus*, now considered a synonym of *humboldti*; form described from R Juruá as "*olallae*", and initially thought to be full species, found to be hybrid between *humboldti* and *P. azara mariae*. Two subspecies recognized.

**Subspecies and Distribution.**  
*P. i. humboldti* Wagler, 1827 - SE Colombia and W Brazil (E narrowly along Amazon to R Negro mouth in N, broadly E, S of Amazon, to R Madeira, crossing it occasionally in N and, more often, in S), S in lowlands E of Andes to NC Bolivia.  
*P. i. inscriptus* Swainson, 1822 - NC Brazil S of Amazon (from R Madeira E to Maranhão, NW Piauí), S to E Bolivia, SW Mato Grosso (in upper R Paraguay drainage) and upper R Tocantins; also E Brazil in Pernambuco and E Alagoas.

**Descriptive notes.** 33-40 cm; 95-140 g (*inscriptus*), 111-185 g (*humboldti*). Green and yellow, with red rump, unusual bill marks. Male nominate race with black head; bill with yellow basal line, oval yellow patch with black script-like marks on maxilla and mandible, with black beyond it and be-

hind it, black mouth-lining; facial skin blue to nearly violet, with red area below and behind eye. Female shorter billed, with chestnut on face, sides of neck, malar area and throat to chin. Immature duller, bill pattern much subdued. Race *humboldti* much larger; bill with black on culmen and tip, basal line and pale area of maxilla more orange (latter still "inscripted"), mandible entirely black apart from orange-yellow base, mouth-lining red, thighs more rusty, more buff to rusty tinge at belly-breast border; in female, chestnut extends onto crown and nape. Voice. Less vocal than other, larger araçaris. Common call a fast series of "kik" or "kek" notes, c. 3 per second, mainly to c. 5 but sometimes to 50 seconds, often variable within series, usually with 1 accented "kek-ek" per series; also rattles, "bddd", in short bursts, mechanical elements rapid at over 30 per second; and single "rak" notes.

**Habitat.** Primary lowland forest, including seasonally flooded várzea, forested islands, nearby secondary forest, riverine forest as at edges of Brazilian cerrado, dense "zabolo" cane and bamboo along streams, also palm woods, dense cerrado woodland; may be forced into some habitats by competition from larger, sympatric araçaris. Occasionally reaches montane subtropical forest along Andes, to 1000 m, even 1200 m.

**Food and Feeding.** Fruits such as those of *Ficus*, *Cecropia* and *Ocotea*; probably insects as well; also, groups prey on nestlings of some pigeons (Columbidae), finches (Fringillidae) and swallows (Hirundinidae), and perhaps also those of Yellow-rumped Cacique (*Cacicus cela*), nests of which it sometimes tears apart. Feeds mainly in groups or pairs, from canopy to subcanopy; sometimes descends to ground when following ant swarms. When *P. azara* or other araçaris arrive in groups, present species retreats from fruiting tree in fast, direct flight, each bird grasping 1 fruit on departure.

**Breeding.** Data from specimens indicate Dec-Jul in W of range, Aug-Mar in E. Displays, nest, eggs and other aspects all undescribed in detail. Known to enter tree cavities, 1 pair reportedly nested in lone dead *Cedrela odorata* tree standing in lakebed; a group of 4 apparently had nest usurped by 5 *P. castanotis*. Young stay with parents for extended period, perhaps beyond 1 year in some cases, if nesting in group.

**Movements.** Apparently sedentary.

**Status and Conservation.** Not globally threatened. Density in SE Peru up to 1 territory/100 ha in mixed habitat of *Ficus-Cedrela*, transitional forest and mature floodplain-forest. Fairly common in Ecuador. Occurs in Amacayacu National Park, Colombia, and in Cuyabeno Reserve, Ecuador. This species' diverse use of habitats suggests adaptability. Possibly some threats locally, as in case of isolated NE Brazilian population of Pernambuco and Alagoas. Hunted by humans, and sometimes entire group may be killed one by one. Lack of knowledge of its breeding biology would hamper any conservation efforts, if and when needed.

## 20. Red-necked Araçari

### *Pteroglossus bitorquatus*

**French:** Araçari à double collier **German:** Rotnackenaarassari **Spanish:** Arasari Cuellirrojo  
**Other common names:** Double-collared Araçari

**Taxonomy.** *Pteroglossus bitorquatus* Vigors, 1826, no locality = north-eastern Brazil. Probably related more closely to *P. inscriptus* and *P. viridis* than to *P. azara*. Races *sturmii* and *reichenowi* considered by some authors to constitute two further distinct species, but they clearly share major features with nominate race, and differences between the various populations seem significant enough only for subspecific treatment; also, *sturmii* and *reichenowi* appear to hybridize, e.g. in SW Pará (Cururu Valley of upper R Tapajós) and N Mato Grosso. Three subspecies currently recognized.

#### Subspecies and Distribution.

*P. b. sturmii* Natterer, 1842 - NC Brazil S of Amazon, between R Madeira and R Tapajós, S to Rondônia, Bolivia (E Beni, NE Santa Cruz), thence E to C Mato Grosso (R Paraguay drainage, and E almost to R Xingu).

*P. b. reichenowi* Sneath, 1907 - S of Amazon, between R Tapajós and R Tocantins, S to N Mato Grosso.

*P. b. bitorquatus* Vigors, 1826 - NE Brazil S of Amazon: Marajó I and E of R Tocantins to Maranhão.

**Descriptive notes.** c. 36 cm; 112-117 g. Green and yellow with red rump, red nape and upper back, broad red breast patch. Male nominate race with blackish crown, dark brown ear-coverts and face to chin and throat, lower throat bordered by narrow black and yellow bands; bill with yellow, green-yellow or green-white maxilla with white and black tomial "teeth", mandible black with this colour angling upwards towards rear, setting off large white base; orbital skin blue to greenish-grey, facial skin red; eye yellow to reddish with brown marks before and behind pupil, latter thus looking slit-like. Female differs in browner crown, less black on lower throat, narrower yellow band in front of red breast, shorter bill. Immature duller, browner, more orange where adults red, plumage lax, bill lacking "teeth" and basal line and obscurely patterned horn and brown. Races differ mainly in bill coloration, and a few other traits: *reichenowi* with no yellow or only as traces in front of red breast, red of sides not reaching flanks, bill somewhat similar to nominate but black of mandible meets white base and breaks into 2-5 black spots along tomtia; *sturmii* largest, has broader yellow band on breast before the red compared with nominate, maxilla with less black on tomial "teeth", mandible almost all black beyond orange-yellow basal line, tip yellow-white, eye brown. Voice. Series of "tik" or "tek" notes, tempo c. 13 per second, usually grouped in sets of c. 6 but only brief pauses between sets; may have cadence like "revving-up" motorbike; also "ttak" or "tyat", more varied, less mechanical in clusters; also grating notes, single "ik" notes, a "tweah", and growl-like, chattering "dcheeah" calls.

**Habitat.** Inhabits lowland and hilly moist tropical forest, well-drained forest, and gallery forest where its range reaches *cerrado*; also found in dense bamboo and tree growth alongside streams and tall secondary forest. Recorded from sea-level up to c. 550 m, reaching its highest levels in Bolivia.

**Food and Feeding.** Very poorly known. Eats fruits of various species of fig, cinnamon and Cecropia; probably also takes some insects and vertebrates, such as nesting birds, eggs and lizards. Observed attacking a vine snake, though it is not known whether this was predation or mobbing; the snake escaped. Forages in middle storey and canopy, in pairs or groups of up to 5-6 birds.

**Breeding.** Virtually unknown. Specimen data suggest season Feb-Aug in much of range, later, Apr-Sep, in upper R Tapajós region, even later, Jul-Dec, in Bolivia and Mato Grosso. Nest and eggs undescribed, and no details available on behaviour; seen entering and leaving possible nesting cavity in NE Brazil (near Belem, NE Pará), in Nov.

**Movements.** Probably resident, with only local movements.

**Status and Conservation.** Not globally threatened. No details available on population numbers. Occurs in Noel Kempff Mercado National Park, Bolivia. Habitat probably being fragmented in some areas by road-building and clearance of forest. Data on breeding biology required for any conservation efforts.

**Bibliography.** Anon. (1995a), Bates *et al.* (1989), Beebe (1916), Cabot *et al.* (1988), Cory (1919), Cracraft & Prun (1988), Griscom & Greenway (1941), Gyldestolpe (1941b, 1945a, 1951), Hackett & Lehn (1997), Haffer (1969, 1974, 1978, 1993a, 1993b, 1997c), Hellmayr (1910, 1929), Meyer de Schauensee (1966), Morrone (2000), Naumburg (1930), Novas (1976), Oniki & Willis (1983), Oren & Parker (1997), Remsen *et al.* (1993), Sick (1985, 1993), da Silva (1996), Stotz, Fitzpatrick *et al.* (1996), Stotz, Lanyon *et al.* (1997), Whittaker (1996), Willis (1976), Willis & Oniki (1990), Zimmer, J.T. & Mayr (1943), Zimmer, K.J. *et al.* (1997).

## 21. Ivory-billed Araçari

### *Pteroglossus azara*

**French:** Araçari d'Azara **German:** Rotkropfarassari **Spanish:** Arasari de Azara  
**Other common names:** Azara Araçari/Toucan; Yellow-billed Araçari (*flaviostris*); Brown-mandibled/Maria's Araçari (*mariae*)

**Taxonomy.** *Ramphastos Azara* Vieillot, 1819, Brazil.

Related to *P. bitorquatus* and *P. inscriptus*. Thought unlikely to be related directly to any of the "*P. torquatus* group". Races *flaviostris* and *mariae* sometimes considered to constitute two separate species, but both of these and nominate race interbreed wherever they meet: *mariae* with nominate and *flaviostris* along Amazon, and with *flaviostris* also in N Peru; *flaviostris* also interbreeds with nominate race on upper R Negro. Race *mariae* has hybridized with race *humboldtii* of *P. inscriptus* in W Brazil (R Jurua), and hybrid was originally thought to be a distinct species under the name "*P. allalae*". Present species, as constituted herein, has sometimes erroneously been named *P. flaviostris*, apparently due to confusion over priority. Three subspecies currently recognized.

#### Subspecies and Distribution.

*P. a. flaviostris* Fraser, 1841 - SE Colombia, S Venezuela and NW Brazil (W of upper R Negro, S to N bank of R Solimões) to E Ecuador and NE Peru.

*P. a. azara* (Vieillot, 1819) - Brazil in Amazonas, between W bank of R Negro and N bank of R Solimões-Amazon.

*P. a. mariae* Gould, 1854 - S of Amazon, from E Peru and W Brazil (E to R Madeira), S to NC Bolivia.

**Descriptive notes.** 36-45 cm; 100-200 g, mainly 120-160 g. Typical banded araçari, small and with long, mostly yellow or cream bill. Male nominate race has black cap, rest of head and throat chestnut, black band across lower throat, almost entirely maroon-red upper back to nape, red rump; broad red upper breastband, broad black lower breastband, yellow belly, thighs largely green; yellow bill with deep red to brown line on side of maxilla, broad at base, tapering to black tip, tomial "teeth" red, black and ivory; orbital area black to grey, generally surrounded by maroon to red facial skin. Female shorter-billed, with cap

dark brown, narrower line of black at lower throat. Immature duller, lax-plumaged, black areas browner, reds more orangey, yellow paler, mottled, bill vaguely marked without tomial "teeth" or basal line. Races differ almost solely in bill colour: *flaviostris* has yellow to greenish-cream or ivory maxilla with orange spot below nostril, black and white "teeth", mandible yellow or ivory with tiny to long and narrow orange-brown line at centre beside tomtia; *mariae* with maxilla yellow to ivory with black and white "teeth", black sometimes forming tomial line distally, mandible mainly orange-brown, tip yellow or ivory, base beyond yellow basal line sometimes with small buff area behind brown, also orbital area perhaps more narrowly slaty-grey, so red facial area larger. VOICE. Possible song a series of 2-6 wailing "twaaa-a-a" or "tweee-ee" or "traaa-at" notes, each 0.2-0.5 seconds long, up to c. 1 per second, slowing in tempo over series, sometimes with initial more squawking "tree-awk" note; series of "ttaaaw" given at times; also voiced rattles, grunt-like contact notes, nasal "nyek", purr-like notes, "kyeek" alarm, pure rattles "bddd", loud wing noises during interactions.

**Habitat.** Inhabits seasonally flooded as well as *terra firme* wet forest, in lowlands and up to lower slopes of mountains, at times reaching cloudforest; also occurs in bamboo and other riverine vegetation, gallery forest, woodland and forest along streams in savanna, secondary forest, plantations of trees, and edges. Numbers tend to be greatest in early and middle successional stages along lakes and streams, with fewer individuals in later successional stages, and fewest in latest transitional stages and in *terra firme* forest; occupation of islands and shifting rivers perhaps responsible for some apparently cross-river interbreeding of races across the Amazon-Solimões system. Mainly found below 600 m, but reaches 900 m and locally as high as 1400 m along E Andes between Ecuador and Bolivia.

**Food and Feeding.** Feeds on fruits of *Ficus*, *Cecropia*, *Ocotea*, *Pagainea* and others; has also been observed flycatching, and arthropod remains were found in one stomach; overall, however, few details available. Usually forages in pairs and in groups of 3-5 individuals, in upper levels and canopy, but also caught in mist-nets in understorey. Flees from fruiting trees on approach of calling group of larger *P. beauharnesii*.

**Breeding.** Data from specimens indicate breeding season of Dec-May in NE of range, Feb-Aug in W & SW. Courtship feeding observed in the wild; no displays otherwise reported. Nest undescribed, probably uses old woodpecker hole; seen entering a cavity 18 m up a tree. Eggs 2-3 or 4; no further information available.

**Movements.** Probably resident.

**Status and Conservation.** Not globally threatened. Fairly common in Colombia and Peru, but uncommon in Ecuador. Recorded density c. 2 pairs/100 ha in optimum habitats. Occurs in Cuyabeno Reserve, Ecuador, and in Tambopata Reserve, Peru. Varied habitats utilized and changing nature of its successional habitats suggest that species is not likely to become threatened in near future. Lack of knowledge of its breeding could hinder any conservation action, should that become necessary.

**Bibliography.** Anon. (1995a), Beebe *et al.* (1917), Berlepsch (1889), Bond (1954), Chapman (1926), Cherie (1916), Clements & Shany (2001), Cory (1919), Foster *et al.* (1994), Friedmann (1948), de Gerniny (1930a), Gyldestolpe (1941b, 1945a, 1951), Hackett & Lehn (1997), Haffer (1969, 1974, 1978, 1985, 1987, 1993a), Hellmayr (1907a, 1910), Hilty & Brown (1986), Ihering (1900), Karr *et al.* (1990), Maria & Olivares (1967), Meyer de Schauensee (1949, 1964, 1966), Meyer de Schauensee & Phelps (1978), Moskovits *et al.* (1985), Olivares (1964a), Parker & Bailey (1991), Phelps & Phelps (1958), Remsen *et al.* (1993), Ridgely & Greenfield (2001), Robinson & Terborgh (1997), Schönewetter (1967), Sick (1985, 1993), Stotz *et al.* (1996), Terborgh *et al.* (1990), Todd (1943b), Willard *et al.* (1991), Zimmer & Hilty (1997).

## 22. Black-necked Araçari

### *Pteroglossus aracari*

**French:** Araçari grigri **German:** Schwarzkehlarassari **Spanish:** Arasari Cuellinegro  
**Other common names:** Maximilian's/Wied's Araçari

**Taxonomy.** *Ramphastos Aracari* Linnaeus, 1758, Brazil.

Forms a superspecies with *P. castanotis*. Both belong to the "*P. torquatus* group", which also includes *P. pluricinctus*, *P. torquatus* and *P. frontii*, all being closely related. Contrary to some views, probably not closely related to *P. azara*. Race *atricollis* has hybridized with *P. pluricinctus* in SE Venezuela (Carapo, R Paragua). Other described forms now considered unacceptable are *roraimae* (E Venezuela and the Guianas), synonymized with *atricollis*; *amazonicus* (NC & EC Brazil), now lumped into nominate; and *wiedii* and *formosus* (S & E Brazil), synonymized with *vergens*. Three subspecies currently recognized.

#### Subspecies and Distribution.

*P. a. atricollis* (P. L. S. Müller, 1776) - E Venezuela and the Guianas, and N Brazil S to R Amazon (W to R Negro).

*P. a. aracari* (Linnaeus, 1758) - disjunct populations in NC, E & SE Brazil: S of Amazon, W to R Madeira, E to Maranhão and S to NE Mato Grosso and Goiás; E Pernambuco and E Alagoas; and also Minas Gerais and Espírito Santo.

*P. a. vergens* Griscom & Greenway, 1937 - S Goiás, S Minas Gerais and Espírito Santo S to E Paraná and E Santa Catarina.

**Descriptive notes.** 43-46 cm; 177-325 g. Male nominate race with black head, chestnut-black ear-coverts, green above with red rump; yellow below, with broad red band across lower breast, thighs greenish; bill ivory with black culmen and mandible; facial-orbital skin blue-grey to black, eye brown. Differs from *P. castanotis* in almost entirely black head to upper breast and upper back; also, whiter, less orange-yellow, bill, less black maxilla. Female like male, but bill shorter. Immature with lax plumage, black and green areas sootier, browner, red and yellow colours paler, bill browner, duller, paler.

tern less clear, no tomial "teeth", no ivory basal line. Race *atricollis* differs from nominate in generally broader culmen stripe, more red-brown in ear-coverts, more cinnamon-rusty thighs; *vergens* with culmen stripe only slightly broader than in nominate, black of ear-coverts and of chin and throat (except lower throat) replaced by chestnut, thus more closely resembling *P. castanotis*. Voice. Common call "tsee-eet" to "sneet", in irregular series, or regular at c. 2 per second; also used singly, sometimes as longer "tseeeee-eet"; also rattled "bdd-dddit", produced vocally or by bill-snapping.

**Habitat.** Occurs in lowland wet forest, sand-ridge forest, secondary forest, some woodlands, *cerrado*, gallery forest of savannas, edges and clearings, also fruit-tree plantations (e.g. papayas), and single fruiting trees near forest. Generally found in lowlands below 500-600 m; at higher elevations in S Venezuela, it is replaced by *P. pluricinctus*; occasionally recorded up to 1000 m in SE of range.

**Food and Feeding.** Diverse fruits of species of *Ficus*, *Viola*, other genera of Sapotaceae, various palms including *Oenocarpus*, and others; also takes insects; captives eat a range of fruits, dog meal, chopped cabbage and lettuce, grated carrots, and mice, crickets and roaches. Feeds in groups of up to 6, occasionally more, in canopy and subcanopy; clings, turns, hangs to reach food. Captives feed also on ground, turning bill and head sideways to pick up bits of food. Avoids large *Ramphastos* toucans, watches them closely. Is an important seed-disperser of fruiting trees.

**Breeding.** Season Nov-Aug in most of range, but Sept-Feb in S. Breed in pairs; captive pairs coming into breeding condition kill other "group"-members caged with them. Displays include rump-fluffing, head-tossing, bowing, tail-cocking; courtship feeding occurs, male may feed incubating female. Nest situated in old woodpecker hole, with some excavating probably occurring; captives given pulpy palm log with only entrance cut out readily excavate cavity, to 10 cm by 80 cm. Eggs 2-4; incubation by both parents, 16-17 days; hatchling naked, grey, sits on hypotarsal pads and cloacae; young fed by both parents, which sometimes regurgitate items as they approach nest; fledging at c. 40 days, and family group moves away from nest; no data on subsequent parent-young relationships, observed groups are presumed to constitute single family, or extended family with previous year's young joining parents and fledged young for much of year.

**Movements.** Mainly resident, so far as is known.

**Status and Conservation.** Not globally threatened. CITES II. Widespread, and still relatively common in many areas. SE race *vergens*, living near heavily populated cities and farming areas, possibly suffering drastic fragmentation of its population. Species is hunted in places; once 150 individuals killed by 1 person in single day. Present in several protected areas, e.g. Imataca Forest Reserve and El Dorado (Venezuela), and Rio Doce State Park, Sooretama Biological Reserve and Parque Estadual da Pedra Talhada (Brazil).

**Bibliography.** Beebe *et al.* (1917), Blake (1950, 1963), Brabourne & Chubb (1912b), Bühler (1993, 1995b, 1996), Cherrie (1916), Chubb (1916), Cory (1919), Friedmann & Smith (1950), Fry (1970b), Griscom & Greenway (1937, 1941), Hackett & Lehn (1997), Haffer (1969, 1974, 1978, 1985, 1987, 1993a, 1997c), Haverschmidt & Mees (1994), Hellmayr (1910, 1929), Meyer de Schauensee (1966), Meyer de Schauensee & Phelps (1978), Moskovits *et al.* (1985), Novaes & Lima (1992a), Oniki & Willis (1983), Parker & Goerck (1997), Pernaletti (1989), Phelps & Phelps (1958), Pinto (1935), Remsen *et al.* (1993), do Rosário (1996), Schomburgk (1848), Sick (1985, 1993), Snyder (1966), Stotz *et al.* (1996), Thiollay (1992), Tostain *et al.* (1992).

## 23. Chestnut-eared Araçari

### *Pteroglossus castanotis*

French: Araçari à oreillons roux German: Braunohrassari Spanish: Arasarí Caripardo

**Taxonomy.** *Pteroglossus castanotis* Gould, 1834, River Solimões, Brazil.

Forms a superspecies with *P. aracari*. Both belong to the "*P. torquatus* group", which also includes *P. pluricinctus*, *P. torquatus* and *P. frantzii*, all being closely related. Contrary to some views, probably not closely related to *P. azara*. Nominant intergrades with race *australis* in S & E of its range. Two subspecies recognized.

#### Subspecies and Distribution.

*P. c. castanotis* Gould, 1834 - S & E Colombia and W Brazil (along N bank of R Solimões-Amaزون to lower R Negro), S to SE Peru and, in Brazil, to Acre and S Amazonas (extending E to R Madeira).

*P. c. australis* Cassin, 1867 - NC Brazil S of Amazon, E to Parintins, and S to NE & E Bolivia, E Paraguay, NE Argentina (Misiones), and SE Brazil (E to W Minas Gerais and W São Paulo, and Paraná to N Rio Grande do Sul).

**Descriptive notes.** 43-47 cm; 220-310 g (slightly lighter to S). Male nominate race with black crown to nape, brown to chestnut sides of head, lower nape and upper throat, lower throat black; dark green above with red rump; underparts yellow, with red or red and chestnut-black band on lower breast-belly, often some red also on upper breast, thighs cinnamon to chestnut-black; broad-based bill with orange to yellow basal line, mandible mainly black, maxilla with broad triangular black culmen stripe and orange-yellow sides, latter narrowing from tip backwards over long black triangle pointing from base towards tip.

large tomial "teeth" black and ivory; facial skin mainly blue. Female browner from crown to

nape and upper throat, narrower black area of lower throat, bill shorter. Immature duller, bill pattern muted, no basal line or tomial "teeth". Race *australis* paler, rusty on nuchal area to upper throat, thighs green and rusty, red band below with rufous (not chestnut-black) admixed, base of bill with red mark ahead of orange basal band, latter more pronounced than in nominate race. Voice. Major call "sneep" to longer "psheee-eeep", in irregular series at c. 2 per second, piercing and high-pitched; also single "tekk" call, low "eeeee-eee", call with 4 whistled "weet" notes and a "pyeeee-tyee-tyee-tyee-tyet."

**Habitat.** Shows predilection for wet forest about lakes and rivers, *várzea* flooded forest, forest islands in rivers, swampy and old stream-channel forest, gallery forest, also old secondary forest, edges, clearings, and disturbed areas; in addition, found in dense bamboo and canebrake "zabolo", *cerrado*, plantations and farms in forest, coffee plantations, and even woodland patches in *cerrado* and Pantanal. In SE Peru, tends to be commonest in middle stages of succession along rivers and lakes, being less common than either *P. inscriptus* or *P. azara* in earlier successional stages, and decidedly uncommon in primary forest. Is the only toucan species on some Amazon islands; probably under pressure of competition from congeners. Occurs mainly below 600 m, but up to 1200-1300 m in places along Andes, and up to 1000 m or more in WC & SE Brazil (Minas Gerais and Goiás).

**Food and Feeding.** Feeds on fruits such as those of *Cecropia*, *Coussapoa*, *Ficus*, *Ocotea* and others; at times, takes flowers and nectar, and also insects. Also hunts nestling birds and searches for eggs; in one study, species was successful in 24% of its attempts in obtaining young Yellow-rumped Caciques (*Cacicus cela*) from their colonies; also known to prey on nests of swallows (*Hirundinidae*), finches (*Fringillidae*), doves (*Columbidae*). Attacks and drives some *Campephilus* woodpeckers from their cavities. Forages in lower canopy down to understorey, in vines and shrubs, as well as in trees; takes fruits by reaching, even hanging upside-down. Investigates, probes crevices and tree cavities.

**Breeding.** Season Feb-Sept in N & W, Jun-Jan in Bolivia; Sept-Feb in SE Brazil, NE Argentina and E Paraguay. More than pair may be involved in some nestings, as very frequent in groups, uncommonly seen alone or in pairs. Rump often erected in display. Nest in old woodpecker hole, probably clears hole by excavating; in Peru, 2 nests in dead *Cedrela odorata* trees standing in lakebed; 5 birds of present species seen to drive 4 *P. inscriptus* from tree cavity, later nested in it. Eggs 2, probably up to 4; incubation and nestling periods unknown. Longevity in captivity 17 years and 9 months.

**Movements.** Crosses rivers, occasionally large ones; in SE, numbers gather in loose flocks, which move into fruit and other plantations as austral winter begins.

**Status and Conservation.** Not globally threatened, CITES II. Considered common in Colombia and Peru, uncommon to fairly common in Ecuador; probably relatively common throughout much of rest of range. Occurs in a number of protected areas, such as Iguazú National Park, Argentina, and, in Paraguay, in Estancia San Antonio Private Nature Reserve, Reserva Natural del Bosque Mbaracayú, La Golondrina Private Nature Reserve and Estancia Itabó Private Nature Reserve; also in Tambopata Reserve, Peru. Rather catholic in its use of habitats; probably more tolerant of changes, and more adaptable, than are its more forest-restricted relatives. Is still hunted by humans in parts of its range.

**Bibliography.** Anon. (1995a), Bates *et al.* (1989), Belton (1984, 1994), Berlepsch (1889), Bond (1954), Bond & Meyer de Schauensee (1943), Brooks *et al.* (1993), Canavari *et al.* (1991), Cavalcanti & Marini (1993), Chapman (1917, 1921b, 1926), Cory (1919), Foster *et al.* (1994), Fry (1970b), Giraudo & Sironi (1992), Griscom & Greenway (1937), Gyldestolpe (1945a, 1951), Hackett & Lehn (1997), Haffer (1974, 1985, 1987, 1993a), Hayes (1995), Hellmayr (1910), Hilty & Brown (1986), Hornbuckle (1999), Karr *et al.* (1990), Krabbe (1991), María & Olivares (1967), Meyer de Schauensee (1949, 1964, 1966), Morales (1988), Narosky & Yzurieta (1993), Naumburg (1930), Novaes (1957), O'Brien (1979), Parker & Bailey (1991), Parker & Goerck (1997), Pearman (1993b), de la Peña (1994), Pinto (1932, 1948), Remsen & Parker (1983), Remsen *et al.* (1993), Ridgely & Greenfield (2001), Robinson (1985, 1997), Robinson & Terborgh (1997), do Rosário (1996), Schifter (1998), Short (1975), Sick (1985, 1993), Stager (1961a), Stotz *et al.* (1996), Terborgh *et al.* (1990), Traylor (1952), Willis (1976), Willis & Oniki (1990).

## 24. Many-banded Araçari

### *Pteroglossus pluricinctus*

French: Araçari multibande German: Doppelbindenarassari Spanish: Arasarí Fajado

**Taxonomy.** *Pteroglossus pluricinctus* Gould, 1836, River Solimões, Brazil.

Belongs to the "*P. torquatus* group", which also includes *P. aracari*, *P. castanotis*, *P. torquatus* and *P. frantzii*; within this group possibly closest to *P. castanotis* and *P. aracari*. Female hybrid between present species and *P. aracari atricollis* known from SE Venezuela (Carapao, R Paragua), Monotypic.

**Distribution.** NE Colombia and NW & SE Venezuela S in lowlands to NE Peru (S to R Ucayali, but mostly N of R Marañón) and NW Brazil (N of R Solimões, E to N Roraima, middle R Negro and upper R Japurá).

**Descriptive notes.** 43-46 cm; 215-302 g. Large, notably short-winged araçari with distinctively banded underparts. Male with head and throat black except for small chestnut area behind eye; dark green above, with red rump; yellow below, upper breast marked with red, and with black anterior band and black and red posterior one; thighs chestnut, green and yellow; bill with orange-yellow basal line, mandible black, maxilla orange-yellow with broad black culmen and black at base; orbital and facial skin blue-green to various shades of green; eye yellow. Differs from all other toucans in pattern of underparts. Female differs from male in shorter bill; shows less or no chestnut behind eye, and on average has broader black breastband. Immature lax-plumaged, duller overall than adults, especially yellow areas, and has green thighs; bill grey, brown, horn and black, with only a suggestion of the adult pattern, and no tomial "teeth" or basal line. Voice. Gives "seent", "seet" or "see-yeet" notes, often paired in loose series to fast bursts, functions unclear, but serve as contact, aggressive and alarm notes; terminal notes may be rough "bbbrt", resembling some calls of unbanded araçaris and *P. bitorquatus*.

**Habitat.** Mainly inhabits low, wet but not flooded primary forest, generally occurring in smaller numbers in *várzea* and gallery forest. Ranges up into wet upper tropical forest, at 500-750 m, along Andes; in S Venezuela, at higher elevations in upper valleys, replaces *P. aracari*; recorded up to 900 m.

**Food and Feeding.** Little known. Various fruits and some arthropod remains found in stomachs. Forages in pairs, in small groups or singly, in forest canopy.

**Breeding.** Estimated season Nov-Mar in Colombia and Ecuador, and Mar-Oct in Brazil, Venezuela and, probably, Peru. No information available on nest, clutch size, parental duties or any other aspects of breeding.

**Movements.** Probably resident.

**Status and Conservation.** Not globally threatened. Relatively poorly known: apparently uncommon to fairly common in Colombia and Ecuador, and fairly common in Peru; no other information available. Occurs in several protected areas, including Amacayacu National Park, Colombia, and Cuyabeno Reserve, Ecuador. Range not precisely known in some areas, e.g. in NW Brazil. Lack of information on its biology and population ecology would be serious handicaps if species comes to need any protective action.

**Bibliography.** Berlepsch & Hartert (1902), Blake (1961), Boesman (1998), Bond (1954), Chapman (1917, 1926), Cherrie (1916), Clements & Shany (2001), Cory (1919), Friedmann (1948), Hackett & Lehn (1997), Haffer (1967b, 1974, 1978, 1985, 1987, 1993a, 1997c), Hilty & Brown (1986), María & Olivares (1967), Meyer de Schauensee (1949, 1964, 1966), Meyer de Schauensee & Phelps (1978), Moskovits *et al.* (1985), Olivares (1962, 1964a), Phelps & Phelps (1958), Remsen *et al.* (1993), Ridgely & Greenfield (2001), Ridgely *et al.* (1998), Salaman *et al.* (1999), Sick (1985, 1993), Stotz *et al.* (1996), Zimmer & Hilty (1997).

25. Collared Araçari  
*Pteroglossus torquatus*

**French:** Araçari à collier      **German:** Halsbandarassari      **Spanish:** Arasarí Acollarado  
**Other common names:** Spot-breasted/Banded/Ringed/Red-rumped/Red-backed/Spot-chested Araçari; Stripe-billed Araçari (*sanguineus*); Pale-mandibled Araçari (*erythropygius*)

**Taxonomy.** *Ramphastos torquatus* J. F. Gmelin, 1788, Veracruz, Mexico. Forms a superspecies with *P. frantzii*; although not in full contact, these two have hybridized, and they may be conspecific. Both belong to the “*P. torquatus* group”, which also includes *P. aracari*, *P. castanotis* and *P. pluricinctus*, all these species being closely related. Southern races *sanguineus* and *erythropygius* sometimes considered to represent one or two additional species, but they interbreed to a significant extent with each other in SW Colombia and NW Ecuador, as also does *sanguineus* with nominate *torquatus* in E Panama and NW Colombia, so they are better treated as races of present species; in addition, race *nuchalis* intergrades with *sanguineus*. Birds from SE Mexico (Chiapas), described as *esperanzae*, now lumped within nominate *torquatus*; those from NW Venezuela, named as race *pectoralis*, now included in *nuchalis*. Five subspecies currently recognized.

**Subspecies and Distribution.**  
*P. t. torquatus* (J. F. Gmelin, 1788) - EC Mexico S to NW corner of Colombia.  
*P. t. erythrozonus* Ridgway, 1912 - Yucatán Peninsula, S to Belize and NE Guatemala.  
*P. t. nuchalis* Cabanis, 1862 - NE Colombia (area of Santa Marta Mts) and mountains of N Venezuela.  
*P. t. sanguineus* Gould, 1854 - E Panama and N & NW Colombia S to NW Ecuador.  
*P. t. erythropygius* Gould, 1843 - W Ecuador; recently recorded in extreme N Peru (Tumbes).

**Descriptive notes.** 43-48 cm; 147-198 g (*erythrozonus*), 240-310 g (*erythropygius*). Male nominate race with black head and throat, maroon-chestnut nuchal collar, dark green upperparts, red rump; yellow below, breast with red patch and black spot, belly with black and red band, flanks red, thighs rufous; bill with white basal line, black mandible, yellow-ivory maxilla black-tipped with black culmen line, orange-red area near base, and coarse, large tomial “teeth”; facial-orbital skin red and blue to slaty; eye cream or yellow. Female with nuchal collar darker than in male, with bill shorter. Immature duller than

adults, with dark areas sootier, cinnamon in green areas on upperparts, reds and yellows generally paler, and breast mark larger; blotchy bill lacks tomial “teeth” and basal line, facial skin yellow-orange, eyes blue to brown or white. Race *erythrozonus* similar to nominate but much smaller, with breast spot smaller or absent; *nuchalis* with breast mark on average larger, thighs paler and cinnamon, “teeth” finer; *sanguineus* lacks chestnut nuchal mark, and has bill broader with ridges beside nostrils, tip orange-yellow, long black line on each side along tomia, “teeth” fine and inconspicuous; *erythropygius* larger but shorter-tailed, also lacks nuchal mark, bill without culmen stripe, almost entirely pale ivory-yellow, with black tip to mandible, black line along maxilla above tomia, and rather fine tomial “teeth”. Voice. Major call “tseep”, high-pitched and variable, 1-3 per second in series, notes often doubled as “tis-seek”; present species reacts strongly to playback of this call, but equally to calls of *P. castanotis* and *P. aracari*; also produces rattle notes, or rattle-“tseep” calls, soft rattles “bddd” at nest (captive); grating “ddddd”, purring calls, “pee-yew” notes; alarm squeak or loud “pit” notes; aggressive “arghrr”; chatters, and other calls; makes loud wing sounds in interactions; hits nest entrance with bill, and can sound like woodpecker drum.

**Habitat.** Inhabits wet or moist primary forest in lowlands, in some places occurring up into sub-tropical cloudforest; also uses secondary forest, forest patches, gallery forest in woodland, edges, clearings, plantations of fruits, cacao and coffee, forest swamps, and mixed forest and cultivation. Generally found below 1000 m, but recorded up to 1300 m in Mexico, and up to 1500 m in W Ecuador (W Pichincha).

**Food and Feeding.** Feeds on fruits of species of *Caesaria*, *Ehretia*, *Ficus*, *Metopium*, *Myrica*, *Neea*, *Protium*, *Talisia*, *Trophis*, *Virola*, various palms, guavas and papayas; often regurgitates fruits and then swallows them again. Also takes eggs and young of birds, lizards, and insects; feeds insects to hatchlings. Forages in pairs, and in groups of up to five individuals, sometimes up to 15, rarely 20, mostly in canopy, but lower down in plantations. Jumps, clings, leans and hangs in order to get fruits; probes into epiphytes. Tears apart bird nests it encounters, whether occupied or not. Sometimes associates with *Ramphastos* toucans; a group was seen to attack and chase a lone *R. brevis*.

**Breeding.** Jan-Aug throughout range, but breeds in most months in Colombia. May nest in groups, but only 1 adult incubates and roosts in nest. Displays with swinging, bowing, jerking head about, calling, pair-members sometimes side by side, rump feathers erected; often cocks and shakes tail interactively. Nest in old woodpecker hole, especially of large *Campophilus* woodpecker, 6-30 m up, entrance to 7 cm, nest c. 16 cm deep, 12 cm wide, with thick layer of regurgitated seeds and fruit stones at bottom; nest reused if breeding successful. Eggs 2-5, commonly 3; incubation c. 16 days; after hatching, any helpers return to feed young, roost in nest; newly hatched young 8-9 g, captives

double weight every 4 days, are brooded by parents and helpers, which feed insects to them for c. 1 month; nest kept clean by adults, removing faecal material; young come to entrance at c. 35 days, fledge at c. 44 days; may return to nest to roost, or family roosts in other hole. Nest predators probably include *Ramphastos ambiguus*; among other predators are raptors such as Collared Forest-falcon (*Micrastur semitorquatus*), Ornate Hawk-eagle (*Spizaetus ornatus*) and White Hawk (*Leucopternis albicollis*); dispersing araçaris may face attacks that bloody them in attempting to join new group. Has lived 12 years and 8 months in captivity.

**Movements.** Largely sedentary so far as known, with only local movements.

**Status and Conservation.** Not globally threatened. Considered to be common to fairly common in Mexico; common, even locally abundant, in Central America; common in Colombia; locally common in Ecuador, although race *erythropygius* has declined markedly as a result of extensive deforestation. In Panama, density c. 1 pair or group/5-6 ha. Could become threatened locally, and perhaps generally, with continued clearing of forest and fragmenting of distribution, but seems adaptable, using diverse habitats; becomes tame when not molested. Hunted by humans in some places. Present in several protected areas, e.g. Guayabo National Monument, Santa Rosa and Braulio Carrillo National Parks (Costa Rica), Los Katíos National Park and Río Nambí Natural Reserve (Colombia), and Río Palenque Science Centre (Ecuador).

**Bibliography.** Álvarez del Toro (1980), Best *et al.* (1993), Binford (1989), Blake (2001), Bloch *et al.* (1991), Brodkorb (1939a, 1943), Brydon (1995), Chapman (1917, 1926), Dickey & van Rossem (1938), Gómez de Silva (1998), Hackett & Lehn (1997), Haffer (1967a, 1967b, 1974, 1975, 1985, 1987), Hellmayr (1911), Hilty (1997), Hilty & Brown (1986), Howe (1977, 1981), Howell, S.N.G. & Webb (1995), Howell, T.R. 26. Fiery-billed Araçari  
*Pteroglossus frantzii*

**French:** Araçari de Frantzius      **German:** Feuerschnabelarassari      **Spanish:** Arasarí Piquinaranja

**Taxonomy.** *Pteroglossus Frantzii* Cabanis, 1861, Aguacate, Costa Rica. Forms a superspecies with *P. torquatus*; although not in full contact, these two have hybridized, and they may be conspecific. Both belong to the “*P. torquatus* group”, which also includes *P. aracari*, *P. castanotis* and *P. pluricinctus*, all these species being closely related. Monotypic.

**Distribution.** From W Costa Rica (Gulf of Nicoya) S into Panama (W Chiriquí; formerly occurring E to Veraguas).

**Descriptive notes.** c. 45 cm; 225-280 g. Male with black head and throat, chestnut nuchal collar, blue green upperparts with red rump; yellow mixed with red below, black spot on breast, red breast-belly bar with little black; bill with ivory basal line, black mandible, mainly red maxilla with tip yellow and base greenish, black culmen, fine tomial “teeth” not conspicuous; red orbital-facial skin with black loreal area. Distinguished from very similar *P. torquatus* by red maxilla with pale tip, less conspicuous “teeth”, and redder band below. Female like male, but darker nuchal collar, shorter bill. Immature duller, bill pattern obscure.

**Voice.** Calls “pseep” to “tis-sik” in series, high-pitched, probably indistinguishable from those of *P. torquatus* and essentially as in other species of the “*P. torquatus* group”; also a croaking call, and soft rattle.

**Habitat.** Inhabits wet lowland forest, edges, cleared areas in forest, and secondary forest; less numerous in forest of foothills and lower mountains, occurring up to 1200 m, occasionally to 1500 m or even 1800 m.

**Food and Feeding.** Feeds on fruits, such as those of *Cecropia*, *Dipterodendron*, *Ficus*, *Lacistema* and *Protium*, also vines such as *Sourouba*; in addition, captures insects, especially during nesting period. Takes eggs and young of such birds as doves (Columbidae) and woodpeckers; Lineated Woodpeckers (*Dryocopus lineatus*) guard nests to prevent predation and usurpation by this araçari species. Feeds in pairs or in groups of up to 10 individuals, mostly in or near canopy, but comes to low berry-bearing bushes. Holds larger fruits and pods by foot as it breaks them or eats them piecemeal.

**Breeding.** Season Jan-Apr, perhaps later in Panama. Mostly in pairs, occasionally in trios, thus subadults make up most groups. “Duelling” occurs, hitting bills together and holding bills; pair-members courtship-feed berries and pieces of large fruits. Uses old woodpecker nest or ejects woodpecker from newly excavated one. Eggs 2, possibly more; incubation, for unknown period, by parents and any helpers, for short to long periods, mostly shorter, average 15-27 minutes in several cases, eggs covered c. 65% of daytime; chicks are fed insects at first, then mainly fruits; nestling period unknown, two young fledged 3 days apart; newly fledged young led back to nest to roost, but may not reach nest for 1-2 nights. Nests that are situated in old cavities of trees isolated in pastures suffer high predation, or may be cut down. Probably does not breed until 2 years old or more.

**Movements.** Considered resident.

**Status and Conservation.** Not globally threatened. Restricted-range species: present in South Central American Pacific Slope EBA. Occurs in Caracara Biological Reserve and Corcovado National Park, in Costa Rica. Reasonably common in some areas, but small range, together with range contraction that has been taking place in Panama, suggest that monitoring may be needed; formerly occurred E in Panama to Veraguas and islands such as Brava, Cebaco and Gobernador Is. Studies needed of breeding within forest, of group formation, and of dispersal and movements of groups.

**Bibliography.** Angehr (1995), Anon. (1998b), Aparicio (1996), Blake (1958), Cory (1919), Delgado (1985), Hackett & Lehn (1997), Haffer (1974), Nadkarni & Matelson (1989), Olrog (1968), Remsen *et al.* (1993), Ridgely & Gwynne (1989), Ridgway (1914), Skutch (1969a, 1983, 1989, 1999), Slud (1964), Stattersfield *et al.* (1998), Stiles & Skutch (1989), Stotz *et al.* (1996), Wetmore (1968a).

## 27. Curl-crested Araçari

### *Pteroglossus beauharnaesii*

**French:** Araçari de Beauharnais    **German:** Krauskopfarassari    **Spanish:** Arasarí Crespo

**Taxonomy.** *Pteroglossus Beauharnaesii* Wagler, 1832, Pará; error = eastern Peru.

Distinct from congeners, and in past occasionally isolated in monotypic genus or subgenus *Beauharnaisius*. Probably related to ancestor of the "*P. torquatus* group", which comprises *P. aracari*, *P. castanotis*, *P. pluricinctus*, *P. torquatus* and *P. frantzii*; recent work suggests it is unlikely to be related to *P. inscriptus* and *P. bitorquatus*. Monotypic.

**Distribution.** SW Amazonia S of Amazon, from N Peru (S of R Marañón) and W Brazil (E to mouth of R Madeira and, farther S, to upper R Xingu), S to N & C Bolivia (Pando, Cochabamba) and N Mato Grosso.

**Descriptive notes.** 42-46 cm; 164-280 g. Unmistakable, with relatively short bill, very long tail. Both sexes have curled, modified, shiny black feathers, like pieces of enamel, on top of head; red upper back and rump, rest of upperparts dark green; pale throat, the yellow-white feathers with shiny black spots at tips, sometimes persisting on to yellow breast, band across lower breast red with some black, belly yellow, undertail-coverts yellow but can show red; bill with basal line brown-orange, mandible ivory-coloured, becoming orange towards tip, orangey culmen expanding distally, then yellow at tip, maxilla with maroon stripe narrowing distally on sides and with green or bluish above it, tomial "teeth" ivory-white; blue facial-orbital skin, ruby-red over and behind eye, often hidden in feathers; iris red. Female shorter-billed

than male. Immature duller. **VOICE.** Very variable, deep "rrek" notes, soft "rrr" to hard, even grunting "grenk" notes, in series, faster or slower, some accented with bill-snapping; softer "et-et" by group before roosting; occasional piping "eet" notes; variation likely related to individual interactions in group.

**Habitat.** Occurs in lowland wet forest, both well-drained and swampy, forest edges and clearings, also lower hill forest; usually found below 500 m, but occasionally recorded up to c. 900 m near Andes.

**Food and Feeding.** Diet poorly known, mainly fruits such as figs and those of *Ocotea*; also eggs and young birds at times, perhaps when it is nesting and needs protein for young. Forages almost entirely in groups of 3-12, mainly in canopy, but to 1-2 m in bushes of clearings. Vigorously attacks and tears apart nests of Yellow-rumped Cacique (*Cacicus cela*) at times. Captives reportedly not so aggressive and predatory as are other araçaris.

**Breeding.** Data from specimens indicate season May-Aug, occasionally to Nov or even Feb. Probably nests in groups. Displays include deep bowing and calling, with chase-bounding. Nest and eggs, hence all associated behaviour, unknown.

**Movements.** Some aggregations reported along Amazon when many trees in fruit, as in Jul; presumably local or short-distance movements involved.

**Status and Conservation.** Not globally threatened. Relatively widespread, but not well known. Generally occupies forest at density of c. 1 bird/10-12 ha, or c. 8 birds/100 ha, but fewer occur in successional stages beside rivers and lakes in Peru. More data on this species' biology are essential, in case it becomes necessary to protect it; observations of interactions with *P. aracari* and *P. castanotis* could provide useful information. Vulnerable to human hunting activities: when one member of group is taken by hunter or predator, rest of group do not flee but all remain nearby, calling loudly. Known to occur in Tambopata Reserve (Peru).

**Bibliography.** Allen (1995), Anon. (1995a, 1997), Bond (1954), Brush (1967), Clements & Shany (2001), Cory (1919), Gyldestolpe (1945a, 1951), Hackett & Lehn (1997), Haffer (1974, 1978, 1985, 1993a, 1993b, 1997c), Hellmayr (1910), Hilty & Brown (1986), Karr *et al.* (1990), Kavkova & Kralickova (1997), Meyer de Schauensee (1966), Parker & Bailey (1991), Remsen, Hyde & Chapman (1993), Remsen, Traylor & Parkes (1986), Robinson (1985), Robinson & Terborgh (1997), Rundel (1975), Sick (1985, 1993), Stotz *et al.* (1996), Terborgh *et al.* (1990), Zimmer *et al.* (1997).

## 28. Red-breasted Toucan

### *Ramphastos dicolorus*

**French:** Toucan à ventre rouge **German:** Bunttukan **Spanish:** Tucán Bicolor  
**Other common names:** Green-billed/Keel-billed(!) Toucan

**Taxonomy.** *Ramphastos dicolorus* Linnaeus, 1766, Cayenne; error = south-eastern Brazil. No very close relatives. One of the so-called "croaking group" of *Ramphastos* species, along with *R. sulfuratus*, *R. brevis*, *R. vitellinus* and *R. toco*; possibly closest to *R. sulfuratus*. Has hybridized with *R. vitellinus*. Monotypic.  
**Distribution.** SC, CE & SE Brazil (S Tocantins, C Minas Gerais and W Espírito Santo to NC Rio Grande do Sul) to E Paraguay and N Argentina (E Chaco, Corrientes).

**Descriptive notes.** 42-48 cm; 265-400 g (averages larger towards S). Both sexes are glossy black from forehead to tail, except red uppertail-coverts; sides of face, most of bib yellow-white with central orange area; broad red area on lower breast, belly and undertail-coverts, vent and flanks black; bill with broad black basal line that projects forwards at tomtia, is mainly green to green-yellow, tip yellow, tomtial "teeth" ivory with red line through and above them on maxilla, some green striations from tomtia upwards on maxilla; red facial skin, blue to yellow-green around eye; iris green-blue to green-yellow. Female shorter-billed

than male. Immature with lax plumage, duller, especially paler in red areas, also orange and yellow paler, iris brown at first; bill with nostrils on top of base, no tomtial "teeth", largely pale yellow, no red or green. **Voice.** Sometimes long series of noisy honking "grekk" notes, higher-pitched than similar grunting croak of *R. toco*, noisier than in *R. vitellinus*, tempo variable, often c. 31 per minute, occasionally at 2 per second; also low "ek", "zneep", growl-like begging, bill-tapping at nest, and tongue-rattling with bill closed in aggression.

**Habitat.** Inhabits subtropical and tropical montane and submontane forest, also some second-growth scrub, trees in Pantanal savanna, and lowland forest at times; extends into plantations after breeding. Mainly found at 100-1500 m, but rarely up to 2070 m; may breed at higher elevations where *R. vitellinus* occurs.

**Food and Feeding.** Feeds on fruits, such as those of introduced *Ardiontophenix*, *Cabralea*, *Didymopanax*, the palm *Euterpes edulis*, *Guarea*, *Morus*, *Myrciaria*, and *Syagrus*; also takes green coffee fruits and other orchard fruits; captives fed on apples, bananas, cherries, grapes, peas, raspberries, zucchini, and others. Also takes insects at times, and preys on small birds; in cages, hunts down House Sparrows (*Passer domesticus*) that have come in to eat its food. Usually in pairs or groups, occasionally gathering in parties of up to 20 individuals or more. Forages mostly in canopy, but readily drops to ground to pick up fallen fruits. Aggressive towards *Bailloni* *bailloni* and *Pteroglossus castanotis*, and captives are aggressive towards other birds such as woodpeckers and parrots (Psittacidae).

**Breeding.** Season Oct-Feb in S, Jan-Jun farther N; has been recorded laying 3 clutches in 5 months in captivity. Often in territories, usually in pairs; aggressive to conspecifics, at times to mate in captivity. Sings usually with head thrown up to one side, then other, sometimes cocks tail, does not bow; male allopreens, courtship-feeds female, tongue-rattles in crouch after her, may attempt to copulate. Excavates to enlarge hole opening, and to clear and enlarge cavity; 1 nest partly excavated in exotic plane (*Platanus*) tree; another 6 m above ground, with entrance 6.5 cm, cavity only 15 cm deep, 13 cm wide at bottom. Eggs 2-4; both adults incubate, female sometimes more, period c. 16 days; young fed insects at first, then fruits, larger ones of which are broken up by parent; in captivity, parents fed 2 dead mice or sparrows per day to nestlings, and roost with young; nesting period c. 40 days, 2 definite instances of 42 days; post-fledging behaviour in wild unknown. Known-age female bred at 21 months, male at 34 months. Longevity in captivity up to 16 years and 8 months.

**Movements.** Downslope movements occur, especially in S, in Jun-Jul, birds moving into plantations of fruiting trees.

**Status and Conservation.** Not globally threatened. Probably reasonably common in general. Occurs in various protected areas, e.g. Itatiaia National Park (Brazil), Estancia San Antonio, La Golondrina and Estancia Itabó Private Nature Reserves, and Reserva Natural del Bosque Mbaracayú (Paraguay), and Iguazú National Park (Argentina). Is still persecuted in some places as a predator of small birds and because it eats fruits in plantations; is hunted for food in other places. Should probably be monitored, as its habitat around increasingly urbanized centres is disappearing.

**Bibliography.** Belton (1984, 1994), Brehm (1969), Brooks *et al.* (1993), Bühl (1982), Canevari *et al.* (1991), Cory (1919), Eckelberry (1964), Galetti *et al.* (1998), Guix (1995), Guix & Jover (2001), Guix & Ruiz (1995), Haffer (1974, 1985, 1991, 1997b), Hayes (1995), Hayes *et al.* (1990), Höfling & Camargo (1993), Höfling *et al.* (1986), Holt (1928), Iwinski & Iwinski (1984), Lange (1967), Martín (2000), Mauricio & Dias (1998), Meyer de Schauensee (1966), Narosky & Yzurrieta (1993), Novaes (1949), de Oliveira (1985), Parker & Goerck (1997), de la Peña (1994), Remsen *et al.* (1993), do Rosário (1996), Schiffer (1998), Schönwetter (1967), Short (1975), Sick (1985, 1993), da Silva (1996), Stotz *et al.* (1996), Thirkhill (1987).

## 29. Rainbow-billed Toucan

### *Ramphastos sulfuratus*

**French:** Toucan à carène **German:** Fischertukan **Spanish:** Tucán Piquiverde  
**Other common names:** Keel-billed(!)/Sulphur-breasted Toucan

**Taxonomy.** *Ramphastos sulfuratus* Lesson, 1830, Mexico. Distinctive within the so-called "croaking group", which also includes *R. dicolorus*, *R. brevis*, *R. vitellinus* and *R. toco*. Not especially closely related to any other species, with nearest relatives probably *R. dicolorus* and *R. brevis*. Races weakly defined, intergrading where they meet. Two subspecies recognized.

#### Subspecies and Distribution.

*R. s. sulfuratus* Lesson, 1830 - SE Mexico (from Veracruz) S through Belize and Guatemala to Honduras.

*R. s. brevicarinatus* Gould, 1854 - Guatemala, Belize and Honduras S to N Colombia (R Atrato, lower R Cauca and lower R Magdalena) and extreme NW Venezuela.

**Descriptive notes.** 46-51 cm; 275-550 g, male 20-50 g heavier than female. Large black, white, yellow and red toucan. Both sexes of nominate race with maroon tinge to black of head and upper back; throat to breast yellow, with narrow, often inconspicuous red band beneath; bill orange, blue and green, with red tip; facial skin yellow-green, sometimes with blue, even orange, in it; iris green to brown or yellow. Distinguished from all other toucans by bill colours. Female smaller and shorter-billed than male. Immature with duller, softer plumage, tips of rectrices more pointed, bill colours muted, bill more keeled, nostrils on top of bill, no "teeth". Race *brevicarinatus* generally smaller, with broader, but still narrow, red band behind yellow on breast. **Voice.** Series of variable notes, "bbrik" to more grunting "ggrrr", grating elements slower than in other "croaking" toucans, higher-pitched than *R. toco*, female higher-pitched than male; pair may "sing" simultaneously, countering with other pairs; also "bbbbb" rattle that is vocal or made by tongue in bill, soft "nip" notes, and buzzing, squeaky, whining and wailing calls of young.

**Habitat.** Usually occurs in wet lowland forest, occasionally lower montane subtropical forest, extending into dry areas in forest along streams; often at edges, in old secondary forest, in larger forest patches, overgrown plantations, as of coffee; less often penetrates mangrove forest and dry deciduous forest. Visits fruiting trees in open pastures. Generally found below 800 m, in places higher; locally up to 1600 m in Colombia, 1400 m in Mexico, and 900-1300 m in other parts of Central America.

**Food and Feeding.** Fruits of various trees, lianas and others: e.g. of *Alchornea*, *Aristolochia*, the palm *Astrocaryum*, *Cecropia*, *Ehretia*, *Exothea*, *Ficus*, *Iriarteia*, *Mulnea*, *Metapodium*, *Nectandra*, *Neea*, *Ocotea*, *Phoebe*, *Poulsenia*, *Protium*, *Prunus*, *Rapanea*, *Symplocos*, *Trichilia*, *Trophis*, *Viola*, and others, including fruits over 30 mm long, swallowed whole. Also eats various beetles, cicadas, grasshoppers, ants, spiders, some lizards and snakes, and probably bird eggs. De-husks some fruits with bill; holds larger insects and vertebrates in foot, breaks them up with bill. Usually in pairs or families, sometimes in gatherings of up to 22. Forages from canopy to middle levels; comes to ground rarely, e.g. for discarded bananas. Tears open some bird nests. At times follows army-ant swarms seeking food.

**Breeding.** Mainly Jan-Jul. Jerks head and tail when singing; male courtship-feeds female. Nest in natural cavity 3-27 m above ground, entrance hole often very small, difficult for male to enter, cavity to c. 45 cm, at times to 2 m deep; cavity cleaned out up to 6 weeks before laying, may place green leaves into nest and remove them later; nesting trees include species of *Cupania*, *Hura* and *Inga*; nest reused in following year if breeding successful. Eggs 1-4, laid on consecutive days; incubation by both parents, for 4-86 minutes at a time, period uncertain; naked hatchling sits on abdomen and spiky hypotalar protuberances; both parents feed young insects and fruits, also some vertebrates, and remove faecal debris; young fully feathered at c. 37 days, fledge at 42-47 days; family leaves nest area after fledging. Predation by hawk-eagles (*Spizetus*) and Collared Forest-falcons (*Micrastur semitorquatus*) possibly significant; 1 of last species, over 10-week period, delivered 27 individuals of this toucan to nest as food for its young. Lives to at least 15 years and 7 months in captivity.

**Movements.** Apparently only local movements.

**Status and Conservation.** Not globally threatened. CITES II. Considered to be fairly common to common in Mexico; common in parts of Costa Rica and Panama, mainly on Caribbean slope; common in Colombia. Recorded density of up to 4 pairs nesting in 16 ha of forest in Panama. Survival in forest patches of different sizes requires study. Relatively tame in protected areas. Possibly under some degree of threat locally. Likely disturbance factors, including taking of young as pets in some areas, are important when considering its conservation. This species is hunted by humans in parts of its range. Present in several protected areas, e.g. Santa Rosa National Park and Guayabo National Monument (Costa Rica), and Los Katíos and Tayrona National Parks (Colombia).

## 30. Choco Toucan

### *Ramphastos brevis*

**French:** Toucan du Choco **German:** Küstentukan **Spanish:** Tucán del Chocó

**Taxonomy.** *Ramphastos ambiguus brevis* Meyer de Schauensee, 1945, River Mechengue, Cauca, Colombia.

A distinctive species within the so-called "croaking group" of *Ramphastos* species, which also includes *R. dicolorus*, *R. sulfuratus*, *R. vitellinus* and *R. toco*. Probably most closely related to *R. sulfuratus*; sibling species of *R. ambiguus*, though not very closely related to it. Was long considered to be a race of *R. ambiguus*, but differs significantly in several aspects, notably voice. Monotypic.

**Distribution.** NW Colombia (N Chocó) S, W of Andes, to SW Ecuador (S to Manta Real).

**Descriptive notes.** 46-48.5 cm; 365-482 g. Both sexes with maroon tinge in black from forehead to upper back; black above, uppertail-coverts white; yellow throat and breast, narrow red band below yellow, black belly, red undertail-coverts; bill yellow above, with green on culmen and central sides meeting black of maxillary base, with grey marks above 3-5 maxillary tomtial "teeth", mandible

black, tip sometimes yellow; facial-orbital skin yellow-green to olive-green, shows bluish in some; iris green with yellow to grey tinge. Distinguished from very similar *R. ambiguus swainsonii* by smaller size, and voice. Female with shorter, more blocky-looking bill than male. Immature soft-plumaged, colours duller, red orange, bill more keeled, basal line and "teeth" absent, nostrils visible on top, which is browner. Voice. A series of croaks, "tree-aak" to "tyook" or "tyeerp", 40-55 (sometimes to 100) per minute, notes growl-like and longer at start of series, which may go on for some minutes; male deeper, more growly notes; variations include more honking version, and soft notes audible only at close range; also clacks bill, and makes grating, clapping sounds with bill closed.

**Habitat.** Generally inhabits lowland forest and also forest on lower Andean slopes, as well as adjacent pastures with fruiting trees or plantations. Groups or pairs wander widely, moving upslope to c. 1550 m.

**Food and Feeding.** Diet little known; mainly undetermined fruits in stomachs; probably takes some insects and small vertebrates. Feeds in canopy, often with *Pteroglossus torquatus*, with which it interacts, but rarely with larger *R. ambiguus*. Can turn head upside-down in feeding. Noted following raiding army ants, presumably for animal prey they disturb. Drinks from water in bromeliads.

**Breeding.** Poorly known. Thought to breed in Jun-Aug, probably earlier, to Jan, in W Colombia. "Singing" bird swings head upwards to one side, and across and up in an arc to other, with almost no downward or bowing motion; in conflicts, holds head low, plumage sleeked except for erected rump and undertail-covert feathers. No information available on nest, eggs, incubation or other details.

**Movements.** None known other than upslope, foraging movements in pairs or in groups of up to 6, rarely 14.

**Status and Conservation.** Not globally threatened. Restricted-range species; present in Chocó EBA. No information available on numbers. Judged to be uncommon to locally common in Ecuador, where has declined markedly due to extensive deforestation; large populations apparently persist in Esmeraldas, where much of forest remains largely intact. Occurs in Río Nambí Nature Reserve, Colombia, and in Río Palenque Science Centre, Ecuador. May possibly become threatened by further fragmentation of habitat; patchy habitat likely to render foraging for food for young difficult; also, nest-sites may be limited, as species probably requires large, secure natural cavities. Hunted for food, and its bill is used in traditional medicinal remedies. Requires study in order to determine its requirements, and to ascertain whether its present conservation status needs to be reassessed.

**Bibliography.** Allen (1998), Best *et al.* (1997), Butler (1979), Chapman (1917, 1926), Cory (1919), Haffer (1967a, 1974, 1975, 1985, 1987, 1991), Hilty & Brown (1986), Maria & Olivares (1967), Meyer de Schauensee (1945, 1949, 1964, 1966, 1982), Parker & Carr (1992), Remsen *et al.* (1993), Ridgely & Greenfield (2001), Ridgely *et al.* (1998), Rodner *et al.* (2000), Salaman (1994), Stattersfield *et al.* (1998), Stotz *et al.* (1996), Todd (1943b), Willis (1983).

## 31. Channel-billed Toucan

### *Ramphastos vitellinus*

**French:** Toucan ariel **German:** Dottertukan **Spanish:** Tucán Picoacanalado  
**Other common names:** Osculated/Sulphur-and-white-breasted Toucan; Citron-throated/Orange-billed Toucan (*citreolaemus*); Yellow-ridged Toucan (*culminatus*); Ariel Toucan (*ariel*)

**Taxonomy.** *Ramphastos vitellinus* M. H. K. Lichtenstein, 1823, Cayenne.

One of the so-called "croaking group" of toucans, along with *R. dicolorus*, *R. sulfuratus*, *R. brevis* and *R. toco*. No very close relatives. Has hybridized with *R. dicolorus*. All four races well marked, and sometimes considered four distinct species: all four, however, interbreed to massive extent wherever they meet, forming huge hybrid populations, e.g. *culminatus* interbreeds with *citreolaemus* in NW Venezuela, with nominate *vitellinus* in S Venezuela and Brazil N of Amazon, and widely with *ariel* S of Amazon (in Amazonas, W Pará, Rondônia, Tocantins, Goiás, Piauí, NW São Paulo, and Mato Grosso); hybrids probably outnumber genetically "pure" individuals of all forms, and it proves impossible to draw strict boundaries separating races geographically. Several previously described forms now known to represent hybrids: "berliozii" (R Negro, N Brazil) is cross between nominate *vitellinus* and *culminatus*; and "osculans" (upper R Negro), "theresae" (NE Brazil) and "pinto" (SE Brazil) are all hybrids of *culminatus* with *ariel*. Four subspecies currently recognized.

#### **Subspecies and Distribution.**

*R. v. citreolaemus* Gould, 1844 - CN & NE Colombia into NW Venezuela.

*R. v. culminatus* Gould, 1833 - NW & SW Venezuela, and Colombia E of Andes, E to C & E Brazil (W Pará, Piauí), and S to C Bolivia, Mato Grosso and SE Brazil (NW São Paulo).

*R. v. vitellinus* Lichtenstein, 1823 - Trinidad, and E Venezuela, the Guianas, and NE Brazil N of Amazon.

*R. v. ariel* Vigors, 1826 - Brazil S of Amazon, E from R Tapajós in Pará, Maranhão and Piauí, and disjunctly from E Pernambuco S to Santa Catarina.

**Descriptive notes.** 46-56 cm; 285-455 g, female averages 10-25 g less than male. Black above and on belly, with pale throat and breast, brightly coloured uppertail-coverts, red undertail-coverts; laterally channelled bill mostly black with black basal line. Both sexes of nominate race with red uppertail-coverts, white-sided orange-centred bib, broad red breastband; bill all black but for blue patch towards base; facial skin blue, iris brown. Immature duller, lax plumage with muted reds, orange and yellow, rectrices more pointed, face paler, eyes dark, bill more keeled with diffuse patterning, nostrils atop bill, no basal line; pattern of bill, bare parts, underparts: *ariel* similar to nominate, but gold around base of bill and blue basal culmen spot, facial skin red, iris pale blue, bib has orange to its edge, where yellower, and red breastband very broad and extending to abdomen; *citreolaemus* has deeper bill with green-yellow culmen and orange, yellow and blue around its base, face blue, iris dark blue, bib mainly yellow-white, red breastband narrow, also pale yellow

spiky tarsal "heel". Races differ mainly in colours of bill, bare parts, underparts: *ariel* similar to nominate, but gold around base of bill and blue basal culmen spot, facial skin red, iris pale blue, bib has orange to its edge, where yellower, and red breastband very broad and extending to abdomen; *citreolaemus* has deeper bill with green-yellow culmen and orange, yellow and blue around its base, face blue, iris dark blue, bib mainly yellow-white, red breastband narrow, also pale yellow

uppertail-coverts; *culminatus* generally heaviest race, has shallower bill with yellower culmen and yellow and blue base without orange, iris brown, bib almost purely white, red breastband very narrow, also gold-yellow uppertail-coverts; hybrids varyingly intermediate, with some semi-stabilization of populations of *culminatus* × *ariel* in EC Brazil. Voice. All races have note, disyllabic, of noisy and clear elements mixed variously, "kee-ark" to "kerrrk" to "keee", singly or in series, c. 30-50 per minute; sexes sing simultaneously, female generally slower, at higher pitch than male, countering singing common; grunting to whistle-like notes less harsh than in *R. sulfuratus*, *R. toco* and *R. dicolorus*, but lacking yelping, whistled, clear quality of *R. tucanus* and *R. ambiguus*; also pure grunts, peeping calls of young; clacks bill aggressively, taps softly to loudly at nest, producing woodpecker-like drumming.

**Habitat.** Forested lowlands, most commonly near water, forest edge, also swamp-forest, forest clearings, riverine forest and forest patches in savannas and llanos, *cerrado* river forest, and up into wet upper tropical and at times subtropical forest to c. 1700 m; much less common in secondary, selectively cut forest, even a decade or more after cutting. Occurs below *R. dicolorus* in SE Brazil.

**Food and Feeding.** Palm "nuts", figs, other fruits; also insects, spiders, other arthropods, lizards and other small vertebrates, probably frogs, toads, and roosting bats; takes eggs and young of birds; and nectar or flowers of *Coumbrum* and *Quararibea*. In captivity, kills and eats other birds in aviary; thrives on meat such as mice, and cooked carrots, potatoes and spinach, eggs, dog food, apples, pears, bananas, papayas, grapes. Feeds in canopy to middle storey, descends to ground for fallen fruits or to prey on animals. Stalks lizards, insects; takes termites in air; tears apart bird nests for eggs and young. Joins other birds following army ants, seizing small animals disturbed by the ants. Drinks from bromeliads, holds bill open in rain. Submissive to *R. tucanus*, also less actively dominant than that species in latter's absence, often allowing other toucans to feed in same tree. Sometimes follows noisy groups of social Red-throated Caracaras (*Daptrius americanus*), as anti-predator strategy.

**Breeding.** Almost all populations breeding to some extent in Feb-Jul; Aug-Mar in W Brazil, Oct-Apr in SC Brazil and Nov-Jul in Venezuela; extends into Aug-Sept, even to Nov, in the Guianas, NE Brazil and Ecuador. Male courtship-feeds female; singing in canopy, rarely from open perch as does *R. tucanus*, arc-swinging of head without deep bowing, may swing tail rapidly or jerk head in all directions; in captivity, breeding male and female kill any others caged with them. Nest in natural cavity, at any height, but sites limited so can be as low as 3-5 m; small entrance preferred, once 6.5 × 5.7 cm, but diameter to 10 cm; paired birds spend much time at cavity before laying, return to previously used hole if breeding there successful; territory c. 40 ha. Eggs 2-4 (2-5 in captivity); both sexes incubate, female perhaps more than male, which may feed her in nest, incubation period 16-18 days; hatchlings fed by both parents, probably with animal food at first; 3 chicks of captive pair were fed 10 mice and c. 80 small to large arthropods daily, and sought large insects entering cage; feeding rate very variable, e.g. once in 9 hours, and 29 feeds in 1 day; nest kept clean, faecal material removed; eyes of chicks open about as feathers start to appear, at 2-3 weeks, well feathered at 7 weeks, fledge at 37-46 days, young may fledge over several days; little information on post-fledging period, but captives feed themselves by c. 60 days. Normally 2 or 3 young fledge; preyed upon by hawk-eagles (*Spizaetus*) and Great Horned Owls (*Bubo virginianus*); captive pair laid 14 clutches in 14 consecutive years. Breeding possible at 2 years, more likely successful at 3-4 years of age.

**Movements.** Some movement suggested, not well known; rarely erupts in large numbers.

**Status and Conservation.** Not globally threatened. CITES II. Appears to be reasonably common, at least locally, throughout its range; uncommon to locally common in Ecuador. In lakeside Peruvian forest 2 pairs/100 ha, but 1-5 pairs/100 ha in mature forest away from water. Occurs in several protected areas, including Asa Wright Nature Centre, in Trinidad, Imataca Forest Reserve and El Dorado, in Venezuela, Chapada dos Guimarães National Park, Rio Doce State Park and Nova Lombardia Biological Reserve, in Brazil, Tambopata Reserve, in Peru, and Noel Kempff Mercado National Park, in Bolivia. Nesting-site requirements likely to be critical. Hybrid populations may prove genetically important in its conservation, as forest habitat becomes more fragmented. Is hunted by humans for food, also for use in medicine; formerly hunted for its feathers, which were used in official robes of Brazilian emperors.

(1995a), Bates *et al.* (1989), Beebe *et al.* (1917), Berlepsch (1889), Berlepsch & Hartert (1902), Blake (1950, 1961, 1963), Bloch *et al.* (1991), Bond (1954), Bond & Meyer de Schauensee (1943), Bourne (1974), Camargo (1967), Chapman (1917, 1926), Cherrie (1916), Chubb (1916), Cory (1919), ffrrench (1991), Friedmann (1948), Fry (1970b), Galetti *et al.* (1998), de Gerniny (1937a, 1937b), Gibbons (1992), Griscom & Greenway (1941), Guix (1995), Guix & Jover (2001), Guix & Ruiz (1995), Gyldenstolpe (1945a, 1951), Haffer (1967a, 1969, 1974, 1975, 1978, 1985, 1991, 1997a, 1997b, 1997c), Haverschmidt & Mees (1994), Hellmayr (1910, 1929, 1933), Hilty & Brown (1986), Höfling & Camargo (1993), Ihering (1900), Jennings (1979, 1993c), Karr *et al.* (1990), Krabbe (1991), Lill (1970), Maria & Olivares (1967), Messias *et al.* (1990), Meyer de Schauensee (1949, 1964, 1966), Meyer de Schauensee & Phelps (1978), Moskovits *et al.* (1985), Novaes (1949, 1960, 1976), Novaes & Lima (1992a), Olivares (1962), Oniki & Willis (1983), Oren & Parker (1997), Parker & Goerck (1997), Perry *et al.* (1997), Phelps & Phelps (1958), Pinto (1932, 1935, 1938a, 1948), Reiser (1950), Remsen *et al.* (1993), Ridgely & Greenfield (2001), Robbins *et al.* (1987), Robertshaw (1987), Robinson (1997), Robinson & Terborgh (1997), do Rosário (1996), Scherer-Neto & Straube (1995), Schönwetter (1967), Sick (1985, 1993), Snyder (1966), Stager (1961a), Stotz, Fitzpatrick *et al.* (1996), Stotz, Lanyon *et al.* (1997), Terborgh *et al.* (1990), Thiollay (1992), Thiollay & Julien (1998), Todd (1943b), Tostain *et al.* (1992), de Wald (1988), Wilkinson & McLeod (1991), Willard *et al.* (1991), Willis (1983), Willis & Oniki (1990), Zimmer, J.T. (1930), Zimmer, K.J. & Hilty (1997).

## 32. Toco Toucan

### *Ramphastos toco*

**French:** Toucan toco **German:** Riesentukan **Spanish:** Tucán Toco  
**Other common names:** Giant Toucan

**Taxonomy.** *Ramphastos toco* P. L. S. Müller, 1776, Cayenne.

Distinctive, with no very close relatives. Belongs to the so-called "croaking group" of *Ramphastos* species, which also includes *R. dicolorus*, *R. sulfuratus*, *R. brevis* and *R. vitellinus*. Race *albugularis* poorly differentiated. Two subspecies tentatively recognized.

#### **Subspecies and Distribution.**

*R. t. toco* P. L. S. Müller, 1776 - the Guianas and NE Brazil, S coastally to Pará, up Amazon W to Manaus, including large lower tributaries; SE Peru.

*R. t. albugularis* Cabanis, 1862 - Bolivia and C Brazil (Mato Grosso and Piauí) S to Argentina (Tucumán, Santa Fe) and SE Brazil (SE Rio Grande do Sul).

**Descriptive notes.** 55-61 cm; 500-860 g. Marginally the largest toucan, mostly black, with white bib and uppertail-coverts, red undertail-coverts. Both sexes of nominate race with fine red band behind white of throat, throat washed yellow; high-keeled bill red-orange, redder along ridge of culmen, black basal band and large black "spot" on tip of maxilla; facial skin orange, orbital skin violet, iris brown. Female almost size of male, including bill. Immature sooty-black, red and yellow colours pale, whitish orbital skin, spiky hypotarsal "heels", bill more keeled with irregular

brownish markings, no tomial "teeth" or basal band; bill features develop slowly, can take nearly 1 year to acquire basal line, "teeth" and black spot. Race *albugularis* tends to have shorter bill, less yellow wash on throat, thinner red breastband, but much variation in both races. VOICE. Series of deep, grunting "groomkk" notes, singly or at c. 50 per minute; also grating call and soft notes, and loud rattling or clacking, sometimes of bill, but may use tongue inside closed bill; bangs bill against branch; much noise from wings, especially in interactions; young give "ehh-ehh-" calls.

**Habitat.** The only non-forest toucan. Inhabits patches of forest and palm groves in savannas, wooded islands, streambeds in Chaco and *cerrado*, scrub, plantations, orchards; occasionally suburban gardens, rarely in cities. Reaches upland Bolivian valleys, to 1750 m.

**Food and Feeding.** Fruits such as figs, those of *Coccos*, *Capsicum*, *Psidium*, *Steiculia*, oranges and others; regularly takes insects such as caterpillars, termites, and preys on nestling birds and eggs; captives prefer meat, regularly hunt down any small birds entering their cages. Usually forages in small groups, moving in single file, with heavy beats and glides, from site to site; perches conspicuously. Feeds in canopy, but descends to ground at times, hops c. 70 cm per bound. Agile; twists, pulls with bill and head, shaking head, can hang and turn about adeptly upside-down.

**Breeding.** Sept-Feb in most areas, Dec-Jun in Bolivia to W Argentina, May-Jun in NE Brazil (Piau). Little known in wild. Mated birds tap bills frequently, allopreen, male at times spreading red undertail-coverts, cocking tail; aggression with loud rattling or bill-clapping, face-on to antagonist, approach, and attack. Some excavating of nest possibly essential; can nest in certain hollow palms, also in banks of streams and in terrestrial termite nests opened by Campo Flicker (*Colaptes campestris*); in captivity, hollow log readily used if outer hard area opened by humans. Eggs 2-4; incubation by both parents, period 17-18 days, captive male aggressive to mate at times; hatchling fed insects at first, with more and more fruits added, in captivity fed insects, mice, dog food; female may feed more than male as young develop; nest kept sanitary in early stages, later may become dirty; fledging at 43-52 days; young soon feed themselves in aviaries. Pairs can raise several broods per year in captivity. First breeding probably not until 2 or 3 years of age. Captives live to at least 15 years and 9 months.

**Movements.** Family groups and pairs range widely, cross large rivers and open areas; eruptions known, at least formerly, along Amazon during Jun.

**Status and Conservation.** Not globally threatened. CITES II. No data available on numbers; considered to be rare in Peru. Occupies large range and, since it does not require forested habitat, it may potentially spread into cleared forest areas. Occurs in various protected areas throughout its range. This species is hunted, however, and its young are taken as pets, so that it possibly needs to be monitored. Present in numerous protected areas, e.g. Serra da Canastra, Brasília and Das Emas National Parks (Brazil), Noel Kempff Mercado National Park (Bolivia), Reserva Natural del Bosque Mbaracayú, Estancia San Antonio and La Golondrina Private Nature Reserves (Paraguay), and El Rey, Calilegua and Iguazú National Parks (Argentina).

**Bibliography.** de Andrade (1992), Anon. (1995a), Belfort *et al.* (2000), Belton (1984, 1994), Bond & Meyer de Schauensee (1943), Brooks *et al.* (1993), Canevari *et al.* (1991), Chubb (1916), Contreras *et al.* (1990), Cory (1919), Dye & Morris (1984), Foster *et al.* (1994), Fry (1970b), Fukaya (1985), Graham *et al.* (1980), Griscom & Greenway (1941), Guix (1995), Haffer (1974), Haverschmidt & Mees (1994), Hayes (1995), Hoy (1968), Marini (2001), Meyer de Schauensee (1966), Mikich (1991), Narosky & Yzurieta (1993), Naumburg (1930), Novaes (1949), Parker & Bailey (1991), Paterson (1997), de la Peña (1994), Pinto (1948), Remsen *et al.* (1993), Rodrigues *et al.* (2000), do Rosário (1996), de Ruiter (1999), Rundel (1975), Scherer-Neto & Straube (1995), Schiffer (1998), Schomburgk (1848), Schönwetter (1967), Schürer (1983), Schütter (2000), Seibels (1979), Short (1975), Sick (1985, 1993), da Silva *et al.* (1997), Snyder (1966), Stager (1961a), Stotz *et al.* (1996), Svoboda (1988), Szolcman (1926), Tagaki & Sasaki (1980), Thiollay (1988), Todd (1943b), Tostain *et al.* (1992), Wetmore (1926), Willis & Oniki (1990).

### 33. White-throated Toucan

#### *Ramphastos tucanus*

**French:** Toucan à bec rouge      **German:** Weißbrustukan      **Spanish:** Tucán Pechiblanco  
**Other common names:** White-breasted Toucan; Cuvier's Toucan (*cuvieri*); Red-billed/Orange-billed Toucan (*tucanus*); Inca Toucan (*inca*)

**Taxonomy.** *Ramphastos Tucanus* Linnaeus, 1758, Surinam.

No very close relatives. Fairly close to *R. ambiguus*, but probably not forming a superspecies; together they constitute the so-called "yelping group" of toucans. Race *cuvieri* considered a separate species by some, but interbreeds with nominate over vast area; variably intermediate populations occur in large area in Brazil from R Solimões and Rondônia E to Pará, and from S Venezuela to Mato Grosso and Goiás. Race *inca* sometimes merged with *cuvieri*, with which intergrades, and *inca* appears to represent semi-stabilized hybrid population; in past, alternatively at times considered a distinct species. Forms named as "*aurantiostriis*", "*erythrorhynchus*" and "*haematorhynchus*" are merely red-billed or orange-billed varieties of nominate race; other described forms are *montilis* from Guyana and *oblitus* from R Tapajós, Brazil, both now included within nominate. Three subspecies recognized.

**Subspecies and Distribution.**

*R. t. cuvieri* Wagler, 1827 - S & SW Venezuela, also SE Colombia and W Amazonian Brazil S to E Peru and N Bolivia.

*R. t. tucanus* Linnaeus, 1758 - E Venezuela, the Guianas, and NE Brazil E of R Negro and, S of Amazon, E of lower R Xingu in N Pará and N Maranhão.

*R. t. inca* Gould, 1846 - N & C Bolivia.

**Descriptive notes.** 53-58 cm; 515-700 g (*tucanus*), 560-830 g (*cuvieri*), 540-780 g (hybrid *tucanus* x *cuvieri*). Mainly black, large toucan with very long bill, white bib bordered by red band at rear, red undertail-coverts. Both sexes of nominate race with yellow-white uppertail-coverts; bill dark red to orangey with green-yellow culmen stripe, basal area yellow above, blue below, with narrow black basal band; red mouth-lining; facial area green-blue or blue; orbital darker, to violet; iris brown. Female shorter-billed. Immature with spiky "heel" scutes, plumage sooty rather than black, bib yellowish-white, undertail-coverts pink or orange, bill brown, culmen pattern obscure, no basal line or "teeth", facial-orbital skin grey-blue, iris blue; bill not fully adult until c. 1 year. Race *cuvieri* somewhat larger than nominate, uppertail-coverts more golden, tips sometimes orange or red, has dark area of bill blacker (but even some W birds often show red-brown near bill base); *inca* like *cuvieri*, but redder tips of uppertail-coverts, and regularly shows variably sized red-brown patch on base of dark bill, even on mandible; *inca* less variable in these traits than are highly

against branches, soft "tuk" and "took" notes, "te-te-tut-tut-" calls; from begging nestlings buzzy squeaks, later wails.

**Habitat.** Mainly lowland tropical forest, especially old riverbeds, late stages of successional forest and mature forest near water; forages also in earlier successional stages of streamside forest with *Cecropia* and *Ficus*; also secondary forest, forest edges and clearings, patches of forest where being cleared, dead trees in lakes, forest patches in savannas, pasture trees, plantations, gardens, mangroves, *cerrado* river forest, and occasionally city trees. Usually below 900 m, higher in parts of Andean slopes; to 1440 m in Guyana.

**Food and Feeding.** Diverse fruits, including those of *Astrocaryum*, *Cecropia*, *Coussapoa*, *Didymopanax*, *Ficus*, *Ocotea*, *Phytolacca*, *Protium*, *Psidium*, *Tapinia*, *Tratinickia*, *Quyziyum*, *Virola*, and palms (*Euterpe*, *Oenocarpus*); also flowers and nectar of *Combretum* and *Quararibea*; also beetles, caterpillars, cicadas, termites, lizards, bird eggs and birds. Captives can prefer meat to fruits, eat various fruits, carrots, corn and peas, dogfood, myna pellets, mealworms, other insects, birds and mice; 1 survived well on bread, eggs, meat and a small bird daily. Forages in canopy, singly, in pairs, or in groups of up to 7, rarely 20. Bounds, twists, reaches, holds larger fruits in foot. Dominant over all birds at fruiting trees. Mobbed as nest predator; once took eggs of flycatcher (Tyrannidae) despite mobbing efforts of 12 flycatchers of 3 species; success rate of attacks on nests of flycatchers, doves (Columbidae) and Yellow-rumped Caciques (*Cacicus cela*) varies from 20% to 100%.

**Breeding.** Jan-Jul in the Guianas, Colombia, Ecuador and most of Venezuela; Feb-Sept/Oct in Bolivia and N Brazil; May-Aug in Peru and NE Venezuela; and Apr-Dec in SC Brazil. Pair leaves group, breeds in small part of group home range. Much play in groups, including bill-fencing, or "tag", supplanting one another; sings from conspicuous perch, raising bill high, gradually lowering to bow, then raising again, tail flicking up as bill raised; paired birds allopreen, especially face and orbit, may courtship-feed all year. Nest in natural cavity, at 3-20 m or more in tree such as *Caryocar*, *Eschweilera*, *Inga* or *Mora*, cavity cleared of debris some time before laying; nest entrance 6-15 cm x 12-17 cm, cavity to 1-2 m or more deep, lined with wood bits and fruit seeds; same nest used yearly if breeding successful. Eggs 2-3; incubation by both parents, either may perform most at night, diurnal shifts in one study 18-49 min, incubation period 15-16 days; hatchlings brooded often for 2 weeks, while naked, by both parents; both feed, perhaps female more than male, c. 2-7 times per hour; chick's eyes open as feathers break out, at c. 29 days; faecal material removed at intervals; young can reach entrance at c. 39 days, fledge at 48-49 days, after which family leaves nest for good; post-fledging behaviour little known. Eggs and young preyed on by white-throated capuchin monkey (*Cebus capucinus*). Probably does not breed until 2 years old or more.

**Movements.** Size of group's home range is large, but imprecisely known, and birds may move long distance at times, perhaps owing to failure of fruits, especially along Amazon and R Oyapuk in N Brazil; at Belém, as many as 1000 individuals recorded moving from S to N in Jun, with smaller numbers of *R. toco*.

**Status and Conservation.** Not globally threatened. CITES II. Common in many areas, e.g. in Peru; uncommon to locally common in Ecuador. Present in several protected areas, including Imataca Forest Reserve and El Dorado, Venezuela, and Tambopata Reserve, Peru. Because of its large size, its dependence on forest, and its importance in tree-seed dispersal, this species is a good "indicator" or "flagship" species. Availability of nesting cavities and forest clearance present conservation problems as habitats are fragmented. This toucan is also hunted by native peoples; when it holds back from attempting to cross large rivers in savanna, it is chased from one tree patch to another until unable to fly, and thus easily caught.

### 34. Yellow-throated Toucan

#### *Ramphastos ambiguus*

**French:** Toucan tocard      **German:** Goldkehltukan      **Spanish:** Tucán Pechigualdo  
**Other common names:** Black-mandibled/Yellow-breasted Toucan; Chestnut-mandibled/Swainson's Toucan (*swainsonii*)

**Taxonomy.** *Ramphastos ambiguus* Swainson, 1823, no locality = Buenavista, Colombia.

No close relatives. Fairly close to *R. tucanus*, but probably not forming a superspecies; these two constitute the so-called "yelping group" of toucans. Long considered to include *R. brevis* as race, but they are now generally accepted as distinct species, with different vocalizations. Race *swainsonii* often treated as a distinct species, but resembles nominate in behaviour, voice and morphology, and they apparently interbred in former contact zone in Colombia (lower Cauca Valley); species treatment of *swainsonii* presumably based largely on its sympathy with *R. brevis*, when this form was thought to belong within present species. Other described forms include *innotatus* from Colombia, a synonym of nominate *ambiguus*, and *tocard* and *tocardus*, which are synonyms of *swainsonii*. Three subspecies recognized.

**Subspecies and Distribution.**

*R. a. swainsonii* Gould, 1833 - SE Honduras, Nicaragua and Costa Rica S to W Colombia (E to Cauca Valley, formerly middle Magdalena Valley) and S along W Andes to SW Ecuador (El Oro). *R. a. abbreviatus* Cabanis, 1862 - NE Colombia, and NW & N Venezuela (E in mountains to Miranda). *R. a. ambiguus* Swainson, 1823 - SW Colombia (from upper R Magdalena) S along E Andean slopes to SC Peru (Junín).

**Descriptive notes.** 53-56 cm; 599-746 g. Large, mainly black toucan with maroon tips of crown to upper back feathers, less so on wings and below; creamy uppertail-coverts, red undertail-coverts; yellow-gold bib ending in red breast. Both sexes of nominate race with large bill having black line around base, green-yellow on culmen broadening distally, blackish triangle on rest of maxilla and on mandible, but sometimes some chestnut near base; facial skin blue or pale green or yellow-green; iris normally grey-brown, green-brown or blue-brown, but vary to yellow or grey. Female has shorter, more block-shaped bill. Immature with

sharp, pointed scutes of "heels", soft-plumaged, black sootier, less maroon tipping, yellow and red colours muted, tail feathers pointed, bill with more of keel, obscurely patterned, no "teeth" or basal band, nostrils open on top. Races vary mainly in colours of bill, facial skin and eyes, but considerable overlap: *swainsonii* with dark area of bill more red to brown, though often tending to black at edges and fore area, facial skin yellow-green or green-yellow, iris usually yellow-green to brown (variable, sometimes white, or partly pure green, or partly yellow); *abbreviatus* smaller, bill like nominate, facial skin like *swainsonii*. Voice. Yelping phrases, repeated at length, first note longer and double, others shorter, often transcribed as "Dios, te-de, te-de", loud, double-noted character different from mainly single-noted *R. tucanus*; initial "kee-yow" usually followed by 2 shorter notes, in some phrases by 1, 3 or 4; male and female may sing together, countering with others; also rattle sounds in aggression, ■ grunt, a croak; loud wing-flapping sounds.

**Habitat.** Forest in lowlands and lower mountain slopes, cloudforest, forest patches, edges, old secondary forest, forest clearings and swamps, riverine forest, nearby plantations, gardens with trees, golf courses. Locally to 1850 m in Middle America; *swainsonii* to 2286 m in Ecuador, other races 700-2670 m and usually above 1000 m, down to 400 m in Venezuela.

**Food and Feeding.** Mainly fruits, such as species of *Beilschmiedia*, *Caesarea*, *Cecropia*, *Didymopanax*, *Faramaea*, *Hampea*, *Protium*, *Sorocea*, *Tetragastris*, *Trophis* and *Virola*, and palms of genus *Socratea*;

flower parts of *Cecropia*; also fallen bananas in plantations; also takes various insects, including cicadas and stick-insects, hunts snakes, lizards, small birds and mammals, takes eggs and nestlings. Major disperser of some seeds, can take 45% of fruit crop at single tree. Favours canopy, but does come lower at times. Sometimes feeds in small groups, rarely gatherings of up to 20. Dominant over other frugivorous birds; 1 bird may defend whole fruiting tree against others, including mate. Audacious, sometimes hunts co-operatively; 1 took over chase of lizard from smaller *R. sulfuratus*, caught and ate lizard; another drove Double-toothed Kite (*Harpagus bidentatus*) from nest, took egg; 2 veered over squirrel monkeys (*Saimiri oerstedii*), each plucking baby from back of a monkey.

**Breeding.** Dec-Jul in all areas. Sings from conspicuous perch, all year, singer raises head high, gradually lowers head and bill with notes, in high-low bow, sometimes alternating rise from one side to other; male allopreens female about head, may courtship-feed her, regurgitating several fruits, female may pass food back and be fed again, or may allopreen mate. Nest in natural cavity at 5-15 m, entrance often small; occasionally nests close to *R. sulfuratus*, within 17 m. Probably 2-3 eggs; both parents incubate, feed young, defend nest from predators; no other details available. Longevity in captivity to at least 13 years and 5 months.

**Movements.** Moves up and down slopes in search of fruiting trees, possibly moves extensively into adjacent habitats at times.

**Status and Conservation.** Not globally threatened. Generally fairly common, locally common to very common. Uncommon in Peru. Uncommon to locally common in W Ecuador (*swainsonii*), where has declined markedly due to extensive deforestation, although sizeable population apparently persists in Esmeraldas, where much of forest remains largely intact; uncommon to rare and apparently very local in E Ecuador (*ambiguus*). Data on densities lacking, but in Panama 2 pairs nested in 16 ha. Does, however, require large forest tracts to sustain populations, and forest clearance and fragmentation have reduced it to point of near-extinction in some places. Occurs in Corcovado National Park and Braulio Carrillo National Park, in Costa Rica. Hunted in places, and is easily attracted by mimicked whistle of song; 57 taken by hunters of 1 village over two-week period. The fact that little is known of this species' breeding biology is a handicap to any conservation effort that might be needed.

## Class AVES

## Order PICIFORMES

## Family INDICATORIDAE (HONEYGUIDES)

- Medium-small, rather nondescript arboreal birds with small head, short bill, nostrils often raised, and generally rather drab plumage with white outer-tail markings.
- 10-20 cm.

- Sub-Saharan Africa and southern Asia.
- Forest and woodland, including streamside trees in near-desert; from lowlands to near tree-line in mountains.
- 4 genera, 17 species, 33 taxa.
- No species threatened; none extinct since 1600.

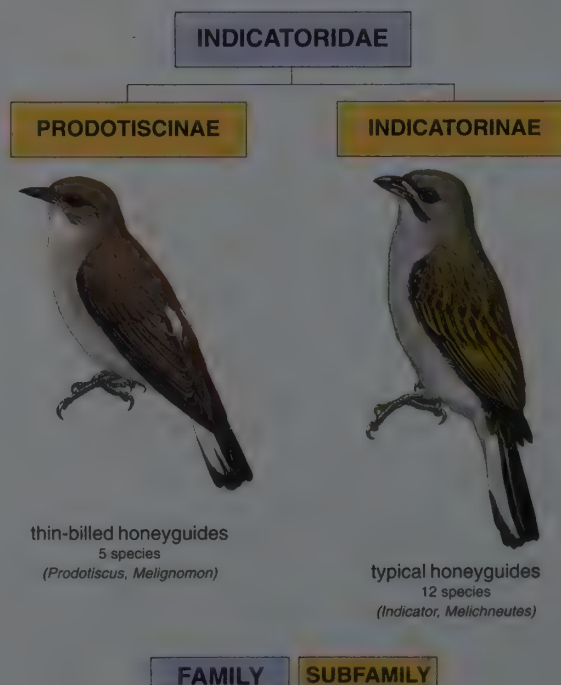

## Systematics

Despite their superficially passerine-like appearance, the 17 mainly green or olive honeyguides of the family Indicatoridae are members of the order Piciformes, allied with the other, more typical-looking piciform birds, the barbets (Capitonidae), the toucans (Ramphastidae) and the woodpeckers (Picidae). Their relationships with other groups within the Piciformes are, however, unclear. Various anatomical aspects (see Morphological Aspects) have led some authors to place the honeyguides near the barbets, whereas others have suggested that they are more closely related to the woodpeckers. P. J. K. Burton, for instance, found their structural bases for feeding to be similar to those of barbets. Through DNA-DNA hybridization studies, however, C. G. Sibley and J. E. Ahlquist concluded that the honeyguides are closer to the woodpeckers than they are to other piciforms. Nevertheless, their displays, including aerial displays, along with other aspects of their behaviour, and their vocalizations seem more like those of barbets than those of woodpeckers.

Perhaps the major point is that the Indicatoridae are distinctive, and not particularly close to one or another of the piciform families. Many of the species are poorly known, inconspicuous birds of tropical forest. The Dwarf Honeyguide (*Indicator pumilio*) was described in 1958, and the Yellow-footed Honeyguide (*Melignomon eisentrauti*) as recently as 1981, and the biology of both remains largely unknown. The mysterious Lyre-tailed Honeyguide (*Melichneutes robustus*), famed for sounds produced in its aerial display, indeed is known from some countries and large regions of Central Africa only thanks to those very sounds. Most of what is known about honeyguides comes from investigations of five or six species, and even for those the information is incomplete. There are few fossils of honeyguides, dating back only to the Pliocene of South Africa.

The Indicatoridae can be divided into two subfamilies, perhaps better thought of as tribes. These are the thin-billed Prodotiscinae, with three species of *Prodotiscus* and two species of *Melignomon*, and the heavier-billed, typical honeyguides of the subfamily Indicatorinae, comprised of the Lyre-tailed Honeyguide in *Melichneutes* and the closely related genus *Indicator* with its eleven species. So far as is known, all are nest parasites, using as hosts other Piciformes, other cavity-nesters, and several avian species that build deep or covered nests. All but one of those honeyguides for which the eggs are described lay white eggs. The exception is the Eastern Green-backed

Honeyguide (*Prodotiscus zambesiae*), which lays either white or blue eggs, the latter matching those of one host group, the white-eyes (*Zosterops*). Both that species and the Western Green-backed Honeyguide (*Prodotiscus insignis*) also have a fully white outer tail; all other honeyguides have a variable amount of dark tipping of the outer tail feathers, less prominently so in juveniles, which show more white in the tail than do adults. The Prodotiscinae have a gizzard with thicker walls than that of the Indicatorinae, and the skeletal sternum is more deeply notched. The small species of *Prodotiscus* have more rounded nostrils, softer feathers, thinner skin, and a deeper keel of the sternum than do other honeyguides, as well as only ten tail feathers, and a white patch on the border of the flanks and rump, these feathers being erectile. *Melignomon* tends towards the Indicatorinae in its thicker skin, its rougher feathering, and the fact that it possesses twelve rectrices, long slit nostrils, and a less deep sternal keel; the two species may take some honey-

Subdivision of the  
Indicatoridae

[Figure: Hilary Burn]

Taxonomic uncertainties are numerous in the family Indicatoridae.

The Thick-billed Honeyguide overlaps marginally with the Lesser Honeyguide (*Indicator minor*), probably interbreeding in parts of Nigeria. However, the two are ecologically separated in western Uganda, with the Thick-billed strictly confined to forest, while the Lesser inhabits more open, wooded country. They are considered to form a superspecies. The Thick-billed differs only slightly from the Lesser in being darker grey below and deeper olive-green above, with a slightly larger bill. Their voices appear to be virtually identical.

[*Indicator conirostris*.

bee (*Apis*) wax, as well as deriving wax from insect coverings (see Food and Feeding).

It is likely that the Indicatorinae depend upon beeswax in their diet, at least during part of the year. The nostrils are raised with membranous sides on a stouter, broader bill, and the gizzard is thin-walled. Three species of *Indicator* are sexually dimorphic in plumage, and two others of the eleven species are sexually dimorphic in the colour of the gape. These include some of the best-known members of the family, such as the Greater Honeyguide (*Indicator indicator*), which leads humans to bees' nests (see General Habits). Males of these species sing in trills, series of double notes, or series of melodic phrases. Hosts of *Indicator* honeyguides are mainly piciform birds such as barbets and woodpeckers, but the Greater Honeyguide utilizes 40 or more hosts of a diverse range of species. The genus *Melichneutes*, closely related to *Indicator*, contains only the Lyre-tailed Honeyguide, notable for its highly modified tail: the central two tail feathers curve outwards, the long central undertail-coverts project between these lyre-shaped feathers, and the four outer pairs of rectrices are short and spiky, all these features being apparently related to the species' circling, diving flight display. Lyre-tailed Honeyguides are flat-bodied, with a deeper sternum and a barely thicker gizzard than the other honeyguides.

Most honeyguides are Afrotropical, but two species of *Indicator*, the Yellow-rumped Honeyguide (*Indicator xanthonotus*) and the Sunda Honeyguide (*Indicator archipelagicus*), occur in tropical Asia, the former along the southern Himalayas, and the latter in the Malay Peninsula, Sumatra and Borneo. It is reasonable to assume that their ancestor reached Asia from Africa, and that the two species then diverged from one another. They do not meet, and, reflecting the absence of other honeyguides in their ranges, the white in the outer tail is muted. Both show a feature otherwise shared only with the African Greater Honeyguide, namely the presence of bright yellow in the plumage: the rump patch in the case of the Yellow-rumped Honeyguide, and the "shoulder" of the male Sunda Honeyguide.

Assuming that the thick, tough skin, the upraised nostrils, and the guiding behaviour are derived features, it follows that the ancestral honeyguide was a small, barbet-like bird similar to species of *Prodotiscus*, but perhaps with a heavier bill, for excavating nesting cavities. Alternatively, the nest parasitism may have evolved very early in the family, with no recent ancestor a nest-excavator. In relation to the honeyguides' wax "predation" and the co-evolution of honeybees and honeyguides, it is significant that beeswax utilization by African honeyguides involves only one bee species of the genus *Apis*, namely *A. mellifera*; and, according to L. Garnery and colleagues, that species' ancestor probably entered Africa from the Middle East not much more than one million years ago. The thick skin and the nostril modifications of most honeyguides are not required for any purpose other than protection against the honeybee. The implication is that *Melignomon*, *Indicator* and *Melichneutes* evolved relatively recently. Wax can be obtained from colonies of sweatbees (*Trigona*), which are incapable of stinging, but such nests are less accessible to honeyguides than are those of the frequently absconding honeybee; *Trigona* nests are often in the ground, their entrances are small, and the wax may be deep inside. Thus, there are intriguing questions and puzzles regarding the evolution of the honeyguides.

### Morphological Aspects

The Indicatoridae are difficult to characterize in terms of their morphology. Their characteristics become apparent only upon close observation, as the birds investigate honeybee nests, or flash the dark-tipped white outer tail in chases of or pursuits by their hosts, with which they interact frequently (see General Habits, Breeding). All honeyguides seek wax as a major food, either from the waxy covering of insects such as scale insects (Coccidae), or from the wax structures of honeybees' nests. Species favouring beeswax have a thickened skin, presumably as some protection from bee stings, although attacks by honeybee swarms are at

times fatal to the honeyguides. Enzymes capable of digesting the wax seem well to be developed in the Indicatoridae, and A. R. Place and others have found similar protein substances in seabirds and various landbirds; such enzymes have so far not been found in other piciform birds.

As with many of the barbets, at least some of the species of *Indicator* have a finely fringed or brushy tongue that may be bifid, and rictal and chin bristles are present, even if short. The stronger-billed honeyguides have a notch along the sides of the bill tomlia, a trait exhibited among allies only by the barbets. Hypotarsal scuted "heels" are well developed in the naked, blind young honeyguides, as are the membranous bill hooks with which they kill any of the host's young, or destroy its eggs. There are other internal morphological attributes involving the oil-gland, muscle ligaments and the skeleton. Honeyguides have a smaller head in relation to the body when compared with the large-headed barbets, toucans and woodpeckers, which also have a larger, more specialized bill.

Rather long, narrow wings give power to the thrust of the honeyguide's body in flight, and permit an array of flight displays. These nest parasites rather readily evade their hosts, and are able to outfly them in most instances. The female honeyguide may soon tire the hosts, enabling her to gain access to their nest to lay an egg. The wings have nine functional primaries and a small tenth primary, which is vestigial or absent in species of *Prodotiscus*. All genera except *Prodotiscus* have six pairs of rectrices, as do the woodpeckers; *Prodotiscus* has five pairs, as do the barbets and toucans. The outermost tail feather is mildly to considerably reduced in the larger honeyguides.

The thick skin of most honeyguides is likely to have evolved in response to bee stings. In addition, however, it preadapts the birds, affording them added protection, in confrontations with hosts, as well as in conflicts with other honeyguides at wax sources. Despite the protection provided by this thick skin, honeyguides are not immune to bee stings. An excessively bold action around a bees' nest can precipitate an attack by the venomous insects; bodies of honeyguides have been found with up to 300 or more stings, particularly about the eyes, around the base of the bill, on the legs, and indeed all over the body.

The bill is rather generalized, and is suitable for fly-catching forays, for probing in the bark of trees, and for pulling away pieces of beeswax. The rictal and chin bristles may prevent debris from insect parts and sticky wax from contaminating the fea-

thers of the head. The legs of honeyguides differ in length from species to species, and are used by the birds in somewhat different ways while feeding on beeswax. The Scaly-throated Honeyguide (*Indicator variegatus*) crouches over wax that is of large bulk, perching and pulling; it often holds a larger piece of wax between its legs, toes clamped about the front end, with the body touching the wax. Greater Honeyguides have longer, less feathered legs; they peck from side to side in a generally upright posture, not crouching. Lesser Honeyguides (*Indicator minor*) sometimes crouch, but they do not generally clasp the wax. The more or less notched bill of adults of these species may help in freeing wax, as well as in aggressive "biting". The Greater and Scaly-throated Honeyguides, when under pressure from numbers of others at a wax source, often pick off a piece of the material and fly with it to a secluded spot; they are often chased by others, but can lift and fly with pieces as heavy as 14 g. Lesser Honeyguides and Pallid Honeyguides (*Indicator meliphilus*) rarely fly with large pieces of wax, but they do at times carry away a tiny fragment.

K. E. Stager demonstrated that the olfactory lobe of the brain is well developed in the Indicatoridae. Although olfaction may play some role in the locating of beeswax or bees' nests, it is not thought to be of great importance. Field experience indicates that bee colonies are generally known to the honeyguides of the area in question. These birds' eyesight is keen, as is their hearing; indeed, they may be able to track individual honeybees to a nest. Moreover, most honeybees' nests are located in situations previously occupied by honeybees, and hence they are regularly checked by the honeyguides, which also monitor humans and their activities. It is possible, however, that olfaction assists the birds in locating bees' nests in heavily forested areas.

The distinctive outer-tail markings of honeyguides are rather uniform among the Afrotropical species. Observations suggest that this pattern, or "flag", is a useful cue for immature honeyguides, allowing them to "tag along" after an adult, of either their own or another species, to sources of wax. Further, in all species except those of the genus *Prodotiscus*, the tail of immatures is much whiter, less dark-tipped, than that of adults. This rather constant difference in the tail pattern between adults and immatures seems to be part of the signalling system that allows immatures dominance at food sources (see General Habits).

The bare area around the eye is smaller than the corresponding naked orbital area shown by the barbets and the toucans.

The most characteristic plumage feature of most honeyguides, particularly immatures, is the strikingly white outer tail. The signal effect, further enhanced on this young, probably male, Greater Honeyguide by the white rump patch, apparently stimulates juveniles to follow others to wax sources, and human honey-hunters to stay with their "guide" (generally a female or immature). The tail pattern is also thought to play a part in the signalling system that allows immatures dominance at food sources, but it may also elicit attacks by the foster-parents on a fledgling honeyguide when the young bird's departure from the hosts' nest first reveals the pattern.

[*Indicator indicator*, Siculo, north Kenya. Photo: John Downer/Planet Earth]

Feeding primarily on insects and spiders, the Eastern Green-backed Honeyguide shows the fine, pointed bill characteristic of the genus *Prodotiscus*. These small species have more rounded nostrils, softer feathers and thinner skin than other honeyguides, and they have only ten tail feathers, as well as erectile white flank patches that are used in display. This species and Western Green-backed Honeyguide (*Prodotiscus insignis*) are the only members of the family in which adults have all-white outer tail feathers.

[*Prodotiscus zambesiae ellenbecki*, Karen, Kenya.  
Photo: Dave Richards]

The orbital skin is thick and heavy, and not likely to be of much signal importance, except that immatures have a brighter, lighter orbital area than do adults. In immature Greater Honeyguides the orbital skin is blue, this colour extending on to the crown beneath the feathers; it is yellow in young Scaly-throated Honeyguides, and pale grey in young Lesser Honeyguides. Adults of the last species appear bigger-eyed than immatures, because the orbital area is black and is seen as part of the eye by an observer; the immature shows a small-looking dark eye, the surrounding skin being pale grey and contrasting with the eye colour.

In immatures of the Scaly-throated Honeyguide, as well as those of the Spotted Honeyguide (*Indicator maculatus*), the gape, which is used in aggression, with bill held wide open, is fully pink. In adult males it is shiny black, whereas females have a pink gape that gradually gathers grey shadow marks with age. With the striking gape colour, along with plumage markings of the crown and throat, and the colour of the orbital skin, the young of these species are dominant at food sources. The immature Greater Honeyguide has a unique yellow-gold, cream and olive-brown plumage quite different from that of adults, and indeed unlike that of any other honeyguide. These immatures instantly become "superdominant" when arriving at a bees' nest, where an individual may feed for 20-30 minutes (see General Habits). When two or more immatures appear together at a food source, the older, less juvenile bird gives way to the other or others.

Apart from those species with a wholly distinct immature plumage, such as the Greater Honeyguide, there are others with markings that are more or less indicative of immaturity, such as the Scaly-throated and Spotted Honeyguides with their barred juveniles. Otherwise, the immature plumage can be distinguished in general terms by the whiter outer tail feathers, the colour of the orbital skin, and several other features, including the more pointed tail feathers; the overall colour is often darker and greener than that of adults, and the facial and other markings are muted. For example, the loreal area of the Lesser Honeyguide is white in adults, but grey in immatures, and the malar stripe is less marked in young Least (*Indicator exilis*), Dwarf, Lesser and Thick-billed Honeyguides (*Indicator conirostris*) than it is in adults of those species. Recently fledged

young honeyguides have creased, wrinkled belly skin, and the hypotarsal "heel" with spiky projections may still be evident. Remnants of the gape "wattle" at the corner juncture of the upper and lower mandibles are visible on juveniles for a period of several months after they leave the nest.

## Habitat

Honeyguides are predominantly forest and woodland species of the tropics of Africa and Asia. Always bound by their need for suitable hosts, they range into montane woodland, and to the fringes of temperate woods in parts of South Africa, on high African mountains, and along the Himalayas, where Yellow-rumped Honeyguides occasionally reach the timber-line. The Greater and Lesser Honeyguides, the most broadly distributed members of the family, extend into dry woodland, and into wooded Sahelian grassland, while Scaly-throated Honeyguides occupy dense streamside thickets in near-desert areas of southern Somalia. Although Lesser Honeyguides, in particular, have invaded dry regions as their host barbets, mainly the Acacia Pied Barbet (*Tricholaema leucomelas*), have extended their ranges, barbets nevertheless occur in some arid bushland parts of Namibia, Somalia and the northern Sahel beyond the range of any honeyguide.

The planting of trees by humans is an important aspect of the dynamics of honeyguide populations. Fruiting trees are especially attractive to barbets, which are major hosts of honeyguides. In the Sahel, such trees may favour honeyguide hosts and, in consequence, the honeyguides themselves, perhaps offering a significant argument against the elimination of trees in man's never-ending quest for fuelwood. Forest clearance has benefited honeyguides of more open country, especially in West Africa, where forest species are experiencing drastic loss of habitat. In the case of the rather strictly forest-dwelling Thick-billed Honeyguide and its very close relative, the adaptable Lesser Honeyguide of open wooded habitats and edges, the latter is expanding its range throughout formerly forested, recently cleared areas, leading to its replacement of the Thick-billed.

Beeswax can be regarded as a primary source of food for most honeyguides. Afrotropical western honeybees, the source

of the "Africanized", so-called "killer" bees in the Americas, abscond from nests frequently, and more often use holes with larger entrances than do European races of the species; they also migrate under certain conditions. Wax may thus become accessible directly to the honeyguides if the entrances to nests are sufficiently large. In dry regions of Africa, the honeybees sometimes migrate when conditions are severely dry; where bees' nests are in rocks or otherwise in the ground they may be inaccessible, and once bees are gone from such an area, and honey is therefore unavailable, human honey-hunting activities may cease, rendering the habitat marginal even for Greater and Lesser Honeyguides. As a result, very dry zones occupied by some xeric-adapted barbets, such as the Black-throated Barbets (*Tricholaema melanocephala*), Acacia Pied and Yellow-breasted Barbets (*Trachyphonus margaritatus*), can, at least seasonally, be devoid of honeyguides. The importance of this critical wax resource is such that its absence, or its inaccessibility, can render the habitat unsuitable for honeyguides. Under less severely arid conditions, that is, for most honeyguides in most places, insects are usually available as food, and the honeybees' activities do not force large-scale movements of the honeyguides, but they may influence the local concentrations of honeyguides and their foraging habits.

So far as is known, bearing in mind that information on fully half the species of Indicatoridae is very scant, the honeyguides exhibit their ancestral tree-cavity dependence by using hosts that are cavity-nesters. These nests can be in the ground, or in termite mounds, or carton-ant nests, if not in a tree. Since honeybees principally use tree cavities for their nests, this enforces a cavity relationship of honeyguides: most honeyguides seek beeswax, and insect prey as well, in cavities. Females, employing cavity-nesting birds as hosts, must search for and gain entrance to these cavities to lay their eggs. In a real sense, then, and unlike most barbets and woodpeckers but like almost all toucans, the honeyguides are secondary users of nest-cavities. They gain the advantage of primary cavity-nesters, including a clean nesting substrate and fewer parasites, by utilizing primary cavity-

nesters as hosts. The presence of trees suitable for nest-excavation, usually partly rotten, decayed trees or stubs, is therefore essential for the honeyguides, as well as for their hosts.

### General Habits

Tough and aggressive, if inconspicuous birds, the honeyguides do not take kindly to aggression by other birds of less than large size. This perhaps reflects their thick, tough skin, but only to a degree, as all their piciform relatives are, after all, also aggressive. Faster than their hosts, which naturally react aggressively to the parasites' close approach to their nests, they are often chased by host birds; before the chase ceases, however, the honeyguides are seen to be chasing the host. At least the Lesser Honeyguide, during interactions with barbet hosts engaging in duets and group pre-duet choruses, such as the Black-collared Barbet (*Lybius torquatus*), seems to utilize its speed in following and, indeed, coming to a perch with the calling group; this causes a breakdown in the normal chorus-duetting, and possibly disrupts breeding, even resulting in renesting and thus allowing another chance for parasitism by the honeyguides.

Their aggression is vital in the gatherings of honeyguides that congregate about any beeswax source. Over 50 honeyguides of four species have been attracted to beeswax feeders in one day, with as many as 37 of them netted in that period. At a source of wax, there are more or less strongly fixed dominance hierarchies within any species. Usually immatures are dominant, followed by females, and then adult males. Of course, the relative hunger of various individuals results in some reversals. More complex are the interspecific hierarchies. In observations in Kenya, Scaly-throated Honeyguides have usually been found to be dominant over the two or three accompanying species, namely the Greater and Lesser Honeyguides and, at times, the Pallid Honeyguide. The very distinctly plumaged immature Greater Honeyguide, however, is superdominant, readily driving off all other honeyguides. Although much smaller, immature Lesser

This forest-dwelling Least Honeyguide shows the zygodactyl feet typical of honeyguides, with two toes directed forwards and two backwards. Other typical features of the family include powerful, sharp claws and rough plumage, essentially olive-green above, greyish below, with bare skin surrounding the eye, and rectal and chin bristles. Apart from visiting bees' nests, foraging Least Honeyguides have been observed moving about in the canopy, gleaning insects from leaves, making flycatching sallies, inspecting various cavities and probing in moss and lichen on branches.

[*Indicator exilis exilis*, Mann's Spring (2100 m), Mt Cameroon, Cameroon. Photo: Doug Wechsler/VIREO]

Honeyguides are able on occasion to chase Scaly-throated and some adult Greater Honeyguides from the beeswax. As is often the case in the avian world, very aggressive, dominant honeyguides may become so occupied in attacking and chasing one another that lower-ranking species and individuals in the hierarchy may obtain the opportunity to eat some wax. Another tactic adopted by the Greater and Scaly-throated Honeyguides is to make off with a piece of wax, and to find a quiet nook where they can eat undisturbed. More often than not, however, the honeyguide carrying wax is chased in flight, and, being awkward and ungainly, is forced to drop the material, which may then become the focus of a squabble.

Although the habit of leading humans and other mammals to bees' nests is responsible for the name "honeyguide", it is believed that only the Greater Honeyguide actually "guides", and apparently guides only humans, to nests. In more than 15 years of close work with hundreds of Scaly-throated and Lesser Honeyguides, no instance has ever been found involving behaviour by those two species that could be associated with guiding. That is not to say that they, and others, including various forest honeyguides, do not attend humans; they do. Any humans making noise, as when cutting wood or building fires, act as attractants to honeyguides. The birds follow people engaged in such tasks, often approaching them closely, and even fly to tents and vehicles, which they may inspect. Their attention is often overlooked by the humans. Scaly-throated and Greater Honeyguides have a "search-flight", an unduly slow, very undulating, up-and-down, somewhat circular flight over people and their disturbances. Those species, and others, follow one another as well; when wax is found, an avian "bush telegraph" seems to draw in numbers of honeyguides. It is extremely probable that at least adult honeyguides in a given area know the location of many bee colonies. Why should they not? The bees frequently abscond, and nests are used over and over again by bee swarms for so long as the cavities remain usable.

The guiding Greater Honeyguides, the bulk of which are immatures and females, perch, not necessarily conspicuously, in

the vicinity of a human being, and call repeatedly (see Voice). If no attention is paid to the bird, it may call off and on, cease after several calls, or continue for up to an hour; one individual called at intervals to the observers, as they moved about a small area, paying no heed to it, for a period of some three hours. If one follows the honeyguide for a short distance and then stops, the bird may call very frequently, move to several different perches, and may then change its direction (see also Relationship with Man). By knowing the location of bees' nests in an area, a person can readily guess to which occupied nest he or she is being guided. In one instance, a female led the observers to four separate nests in less than one hour. No special displays are associated with guiding; the repetitive, insistent calling and the frequent moves, rendered conspicuous by the spread tail and bounding, upward flight to a perch, are seen also in other contexts. Experience shows that, in the vicinity of the bees' nest, the Greater Honeyguide is silent and looks on at the humans. Honey-hunters would then build a smoky fire, and climb to the nest; traditionally, they leave a large chunk of honeycomb for the guider, but it is the opening of the nest and the moving away of the honeybees that reward the individual guider and other attentive honeyguides attracted by the activities.

Guiding is not a predictable activity. In months of working with and among honeyguides, handling Greater Honeyguides almost daily, one of the two researchers would be guided on one day, perhaps several times; several days or a week would then pass with no guiding. A more common feature was incipient guiding, whereby more or less guiding calls were uttered, but not persistently, and for only a short time before ceasing. Indeed, some immature, would-be guiders appeared not to know the mode, as they would not lead an observer away, but only called, apparently at the two people, and then disappeared. This long-term study found that encounters with "investigating" Scaly-throated Honeyguides were more frequent than were incidents of guiding by Greater Honeyguides. The Scaly-throated Honeyguides flew, usually inconspicuously, over the observers, perched nearby, watched, came to the fire, and perched on the vehicle or went inside it; the birds

*Typically calling from a prominent perch, the male Greater Honeyguide is easily identified by its dark crown and throat, pale cheek patches and powerful pink bill. The main component of this species's song, often given from a traditional perch, is repeated "wit-burr", "vik-tor" or "burr-wit" sounds. This, the best-known honeyguide, is the only species that regularly guides humans to honey sources: the bird (an adult of either sex or a juvenile) draws attention by its persistent chattering calls, bobbing, tail-flirting and frequent fluttering flights between perches and towards the honey source, which it will most likely have found by using visual cues. Boran honey-hunters of Kenya traditionally use a special penetrating whistle and other sounds to keep their "guide" interested.*

Most honeyguide species appear to be attracted by human activities such as chopping wood and making fires, and numbers of honeyguides of various species will gather where humans have driven the bees away by smoking out the nest. The rough plumage and thick skin of some honeyguides may give some defence against bee stings, but birds can be killed in a major assault by a swarm. This adult Lesser Honeyguide, with the pale lore and dark malar stripe found in several species, also has the powerful, stubby bill typical of the genus *Indicator*; this is apparently well suited to scraping off bits of left-over comb.

were regularly netted by stringing a net beside the fire, the fire being a device for keeping away large mammals, as well as for boiling water for morning beverages. The disappearance of the guiding phenomenon of Greater Honeyguides in suburbs of metropolitan centres such as Nairobi, in Kenya, suggests that guiding is not a genetically deeply embedded, very highly evolved aspect of behaviour, but that it is, rather, a relatively recent "add-on" to the wax-seeking and wax-acquiring habits of this species.

Wax-eating requires water, and readily available water is a feature at most of the study sites at which there is a great deal of honeyguide activity. Those individuals seen regularly for much of a morning, and feeding frequently, appear to drink every hour or so. Most, however, show no interest in bathing, even when observing the bathing activities of other avian species.

While non-social generally, honeyguides usually come into frequent contact with others of their own species or with other species of Indicatoridae. Any beeswax source attracts small to large numbers of honeyguides, and aggressive interactions are commonplace. Away from these sites, and otherwise except when breeding, honeyguides are solitary birds. Immatures will at times approach adults without aggression, and will even perch above an active feeding site without entering into interactions. Fledglings may beg from adult conspecifics, as well as from their foster-parents or any bird resembling the fosterers. Comfort feathings, especially preening of the wings and tail, are important, and are performed in the same way as in other piciforms.

Of the comparatively few displays described for the Indicatoridae, that of the Lyre-tailed Honeyguide is by far the most interesting. This species, rather than singing from a perch, employs a fantastic aerial display. After giving several introductory "pee" notes, it goes into a steep, fast dive with the modified tail feathers spread. It is presumably the air passing through these feathers that produces the "kwa-ba, kwa-ba" series of sounds that are so characteristic of the forest areas inhabited by the Lyre-tailed Honeyguide. Lest this be considered overly distinctive within the family, far less spectacular aerial displays, with sound

at considerably lower volume, are known for the Greater, Lesser, Scaly-throated and Pallid Honeyguides; and the three *Prodotiscus* species also have aerial displays during which they call, in at least two cases over their territories. The male Greater Honeyguide, either on or off the singing territory, sometimes performs a "winnowing" display-flight in which it flutters in one or more circles over a female, making wing sounds; occasionally, it mistakes an older immature of either sex for a female.

Little is known of the roosting behaviour of honeyguides. Radio-telemetry studies of male Scaly-throated Honeyguides have shown that the birds do not roost in cavities, but instead use dense trees and bushes. Territorial males may roost in one of their song trees, a dangerous ploy, perhaps, for at least one such male was killed, probably by a Verreaux's Eagle-owl (*Bubo lacteus*), in his main song tree. Most males roost within their territory or close by, although not always at the same site every night. One singer regularly roosted 5 km downstream from its singing territory. Subordinate males around a territory are more mobile. They may roost near a particular territory on one night, several kilometres away from it on the next night, and in yet another direction on the following night. At one major wax-feeding site which was not within or even near any territory, feeding birds left the area one hour or, less often, as little as half an hour before dark, presumably to reach a favourite roosting site.

Forest honeyguides fly directly or in undulating flight, and usually not very far, although they may move about rather constantly throughout the day. They do not cross large open areas. Even woodland and thicket species, such as the Scaly-throated Honeyguide, prefer to stay within or near cover, using streamside vegetation through which to move from one site to another. On the other hand, Greater, Lesser and Eastern Green-backed Honeyguides do at times fly over open areas even as wide as a kilometre or more, often undulating their flight in the manner of some barbets and woodpeckers; through even wider areas of grassland, they may perch briefly in a shrub, herb or bush, before continuing across the opening.

Beeswax constitutes an important part of the diet of the rather secretive Scaly-throated Honeyguide, although it also takes many insects by flycatching. It is capable of carrying quite large pieces of comb, and often pecks and tears at a piece wedged beneath its body and grasped with its feet. The strong bill and raised nostrils are clearly visible here. Scaly-throated Honeyguides observed feeding on wax proved to be dominant over other honeyguide species, even the larger ones.

## Voice

Songs are known for all but one of the well-studied honeyguides, the exception being the Yellow-rumped, which appears to lack a song. The songs are often musical, unlike any woodpecker vocalizations, and are delivered in barbet-like postures that include arching of the neck, bill pointing downwards, rump feathers loosely fluffed, and tail twitching slightly with the notes. In the Scaly-throated and Spotted Honeyguides, a simple, fast trill for several seconds constitutes the song. The Lesser, Thick-billed and Least Honeyguides emit a "wew" introductory note, followed by a trill that is slower than in the previous two species, while the Sunda Honeyguide sings a fast trilled song preceded by a cat-like, rising "miaaw" note. The Greater Honeyguide begins its song with a bow and a soft "peew", followed by a varied number of double notes transcribed as "Victor" or, rather, "TOR-VIK", or "Burr-wit"; this is the only honeyguide species in which the female is known occasionally to utter, aggressively, the same song as that of the male.

Among the smaller species of *Indicator*, Willcocks's (*Indicator willcocksi*) and Pallid Honeyguides sing similar songs of repetitive, triple-noted phrases, the former sounding like "wa-will-it", and the Pallid "wa-wee-it". Apart from the Brown-backed Honeyguide (*Prodotiscus regulus*), which sings a soft trill, the rest of the small honeyguides are poorly known. The songs of the Western Green-backed, Yellow-footed and Dwarf Honeyguides are unknown. The Eastern Green-backed sings, but its song has not been described, while recent recordings of Zenker's Honeyguide (*Melignomon zenkeri*) reveal its song to be a long series of slow "psee" to "pseep" notes.

There remains the Lyre-tailed Honeyguide, which, instead of a song delivered from a perch, uses an aerial display with introductory "pee" notes followed by "kwa-ba, kwa-ba" sounds (see General Habits). The latter are presumably produced by the tail feathers, and are characteristic sounds of the forest areas where this poorly known honeyguide lives.

Honeyguides have a broad repertoire of vocalizations other than song. Some have an aggressive, song-like trill or squeaks, or piping notes. The Scaly-throated Honeyguide, as an example of a reasonably well-studied indicatorid, has a variety of such sounds: a piping, whistled "wee" series uttered aggressively by males; a song-like trill but with "pyew" sounds in it, also given by males; loud chatter calls given repeatedly by females in aggression; buzzy skizz notes; a post-copulatory wavering whistled series or a floppy aerial display with "wup, wup" sounds; and three distinct calls of the young, namely chatters, yelps and wails. Loud rustling wing sounds accompany aggressive calling and chasing by this species. It is likely that the other honeyguides have a more or less equivalent repertoire of calls, and the Lesser, Greater and Pallid certainly do.

Immature Greater Honeyguides utter an aggressive "feeer" that drives away other honeyguides in a feeding situation, this becoming an ear-splitting "pseeeear" from trapped birds held in the hand. In aggression, adults and older immatures of this species utter peeping to piping and chattering series of notes, often wavering in pitch, and resembling the begging calls of young Greater Honeyguides.

Similar calls to the last are also used as guiding calls. These consist of a chatter made up of "tya" notes compounded with peeps or pipes, thus double-noted, and varying in pitch. No calls have been heard from guiding Greater Honeyguides that differ from variations of the calls just described, which are emitted also by aggressively interacting, chasing Greater Honeyguides.

## Food and Feeding

Beeswax, chiefly the wax of honeybees of the genus *Apis*, forms the major element of the diet of most honeyguides. Noteworthy among other foods are scale insects (Coccidae), which essentially replace beeswax in the diets of the slender-billed species of the genus *Prodotiscus*. They are also important to Zenker's

Honeyguide and, probably, to the Yellow-footed Honeyguide. All honeyguides are known to eat insects and spiders. Other than scale insects, insects are represented in the diet by honeybee eggs and larvae but few adults, aculeate Hymenoptera, sweatbees, and caterpillars, including waxworms and eggs of *Galleria* that infest beeswax, along with beetles, termites, flies, mayflies, winged and wingless ants, aphids, homopterans, hemipterans and orthopterans. Diverse spiders include those of the Thomisidae and Oxyopidae. Plant fibres and some fruits, including figs (*Ficus*), are eaten. Honeyguides are occasionally noted as taking bird eggs and nestlings, but this must be rare; they are not mobbed by other birds. Since their young are raised at least to the fledging stage by diverse host species, they eat the foods of the hosts, generally insects and fruits.

Those species using beeswax secure it wherever it is accessible and not defended vigorously by honeybees, the stings of which, in numbers, readily kill a honeyguide, despite its thickened skin. In Africa, the entrances to most bees' nests are accessible to honeyguides, especially of the smaller species. When the cavity is full to its entrance with comb, the comb may be eaten by honeyguides in the cool hours of morning, before honeybees become active. For most honeyguides, in most areas, it is the recently vacated nests that yield the resource to the birds, which squeeze in, and work over the walls of the nest and its ceiling, scraping off bits of left-over comb. The stubby bill of species of *Indicator* smaller than the Greater and Scaly-throated Honeyguides may in fact be adapted to enable them to carry out such scraping more efficiently. The Yellow-rumped Honeyguide may be forced to scrape left-over bee comb from cliff faces after giant or rock honeybees (*Apis dorsata* or *A. laboriosa*) have moved off to a new site for their open colony.

All the species of honeyguide that are moderately to well known indulge in fly-catching, in which they sally from perches after insects or spiders. Small honeyguides, such as the Pallid and the two green-backed species, hover when fly-catching, at times in front of flowers such as those of *Erythrina*, *Rubus* and *Gymnosporia*. Other insects are obtained by gleaning from the bark of tree branches and foliage, and larger honeyguides sometimes work over tree trunks. Greater Honeyguides will also on occasion follow a woodpecker, snapping up insects flushed by the creeping picid. Most honeyguides, but especially those of

the genera *Prodotiscus* and *Melignomon*, will at times join mixed-species foraging flocks of insectivorous birds. When alate termites swarm, all honeyguides abandon other foraging activities and sally for these insects. So far as is known, there are no reports of honeyguides foraging for, and eating, fruits, but stomach contents of adult specimens of, for example, the Eastern Green-backed and Lyre-tailed Honeyguides have been found to include fruits such as figs and mistletoe (*Loranthus*) berries.

Newly fledged honeyguides almost immediately commence gleaning on branches and inspecting crevices in search of food, even as they beg from their foster-parents. They follow the honeyguide "signals", the white marks on the spread outer tail, to wax sources, tagging after adults and older immatures. In very rare instances, a begging fledgling has been fed by an adult of its own species, the reported cases involving young Western Green-backed and Yellow-rumped Honeyguides.

## Breeding

All honeyguide species that are sufficiently well known are brood parasites, and it is thought likely that the others also will prove to be so. Information relating to hosts, especially, is lacking for both species of *Melignomon*, for both Asian honeyguides, and for the little Dwarf and Willcocks's Honeyguides. Meagre, suggestive information regarding hosts is known for the Least, Thick-billed, Spotted and Lyre-tailed Honeyguides. Most of the available data on nest parasitism among the Indicatoridae refer to the Eastern Green-backed, Brown-backed, Lesser, Scaly-throated and Greater Honeyguides.

Breeding seasonality is clear-cut in the near-temperate Yellow-rumped Honeyguide, and in populations of Greater, Lesser and Scaly-throated Honeyguides at corresponding latitudes, all of which breed in the hemispherically equivalent spring and summer. Elsewhere, in the tropics, seasonality is far less evident. Of course, the breeding seasons of the honeyguides are attuned to those of their hosts. In addition, rainfall is a critical factor in breeding seasonality. In forests which experience an extended wet season, or where it is more or less wet all year, some individuals may have a protracted breeding period, while others may breed at one particular time of year, and others at other times; in

Watching in silence while honey-hunters gain access to a bees' nest, a honeyguide will move in to feed once they have gone; tribal peoples traditionally leave a piece of honeycomb as a reward for their "guide". Greater Honeyguides probably take a range of insects caught by flycatching and not only beeswax, but also bees, their eggs and larvae. This species's habit of perching conspicuously and flycatching, coupled with its aggressiveness, leads to frequent antagonistic encounters with a variety of other bird species.

[*Indicator indicator*, Kruger National Park, South Africa. Photo: Nigel Dennis/NHPA]

Wax, either from honeybee nests or from the waxy coverings of certain insects, is an important food item for all honeyguides. Pallid Honeyguides and also Lesser Honeyguides (*Indicator minor*) rarely fly with large pieces of wax, but they more frequently carry away a small fragment. More research is required into the processes whereby the wax is digested; enzymes capable of this are well developed in the honeyguide family, while the suggested possible role of bacteria remains disputed for the present.

[*Indicator meliphilus meliphilus*,  
Athi River, Kenya.  
Photo: P. Davey/VIREO]

unusually wet years, with rainfall extending into all months in woodland that is normally dry and wet seasonally, the honeyguides may follow the same regime. Conversely, when prolonged drought occurs, honeyguides may cease breeding activity for the year.

Most male honeyguides of the better-known species maintain a singing territory, a term considered preferable to "songpost" or "studpost", used chiefly in southern Africa. Territorial male Scaly-throated Honeyguides regularly sing from one of several trees or bushes, using certain sites and certain perches at each site. Particular sites, or trees, are sometimes used for long periods, even years, but much more often the birds shift their sites, and use different trees, so that the territory may, over time, change in shape and size. Singing territories of different males are usually not adjacent; when they are, one bird is gradually forced out. Singing male Scaly-throated Honeyguides on prime territories are usually three or more years old. Territories attract other, subordinate and younger males, some of which are transient, whereas others may be more persistent. A territory can attract up to eight or nine males at a time. The dominant, territorial male sings for long periods, and stays within his territory most of the time, thus monitoring other males and seeking mates. If he leaves the territory, a secondary male may sing tentatively, and then gradually move to occupy a singing site; such males sometimes copulate with a visiting female. Males securing a territory can hold it for as long as seven years, but most are able to do so for only one or two years. Some territories are "traditional", with examples from South Africa of singing territories of Greater Honeyguides that have persisted for decades. Young males will attempt to establish a territory where none has previously existed, but such territories are usually ephemeral. A male at a less contested, presumably poorer-quality site may be a secondary male at another male's territory, and may ultimately replace the dominant male there.

Other well-known honeyguide species more or less fit the pattern outlined above for the Scaly-throated. Greater Honeyguide territories are in more open terrain, at woodland edges, or in bushland. These territories are widely spaced and, perhaps partly for that reason, attract fewer secondary males than do those of the Scaly-throated Honeyguide. Male Yellow-rumped Honeyguides do not sing, but defend a territory at a rock face bearing colonies of the rock honeybee. In the breeding season, a territorial male challenges all conspecifics coming to "his" larder, driving off other males, and courting the females that come to the beeswax resource he controls. Subor-

dinate males tend to remain near such a territory, and may at times challenge the dominant male, as well as sneak copulations with visiting females if the territorial male is away. Should the dominant male be taken by a predator, the prime territories, at least, are taken over almost instantly by one of the secondary males; this has been found to be the case for all well-studied honeyguides. Male Brown-backed and Pallid Honeyguides at the extremes of the range, or in poor habitat, tend to initiate a territory, test it out, and then move on to sing at another site; in other words, most sing only temporarily, at various sites. Young male Lesser Honeyguides may do the same.

With the strategy of a male being to gain and hold a favourable territory, what do the females do? Breeding female Scaly-throated Honeyguides need to locate suitable feeding sites, especially for beeswax in non-lush settings. They must be able to locate host nests within a radius of travel, and they must find an accessible, suitable male with which to mate. Some females accomplish these goals within a limited area, and are rarely or never found elsewhere; presumably, these areas are optimal sites for their breeding. Other females move about much more in the breeding and non-breeding seasons. Female Scaly-throated Honeyguides seem to fight only at sources of beeswax. In contrast, at least some adult female Greater Honeyguides engage in prolonged encounters during which one or both may sing male-like songs, a phenomenon which, on current knowledge, is unique among the Indicatoridae. It is unknown whether a particular female mates with only one male, at least for one clutch, or whether all females are, as most seem to be, promiscuous, as are males.

The actual egg-laying habits of an individual are almost unknown. R. B. Payne, in his studies of specimens of Greater and Lesser Honeyguides in the well-defined breeding season of southern Africa, found the overall clutch size to be about 20 eggs, laid in distinct sets of four or five each. It is suggested that tropical honeyguides lay perhaps as many, or more, eggs, but in smaller sets of three or four. Within a set, a female lays about every second day; she therefore copulates to fertilize an egg on the day of its ovulation, and then has the next day in which to lay the egg in the nest of an appropriate host. Data are needed on other species, and from tropical populations, to test these generalizations.

Evidence exists that males, as well as females, monitor the activities and nests of their hosts. Most data relate to Lesser Honeyguides, but Scaly-throated and Spotted Honeyguides come to playback of recordings of their host woodpeckers' calls, and also to calling woodpeckers themselves, triggering aggressive interactions. Males may monitor hosts and nests with regard to

the location of their own singing territory, to the occurrence of breeding by their hosts, and to the success of their presumed offspring. They sometimes also act to keep other males away from duetting barbet pairs. A strategem, if hosts already have eggs of their own, is for a male honeyguide to interfere with the hosts, interrupting and disturbing them, thereby causing nest failure and affording a new opportunity for the parasite to lay. Females, of course, monitor the hosts' nests. There is suggestive evidence that a male Lesser Honeyguide occasionally acts in concert with a female, presumably one with which he has mated, to afford her an opportunity to gain access to the hosts' nest. An intriguing report exists of two Lesser Honeyguides assisting a host pair of Acacia Pied Barbets in preventing Rüppell's Parrots (*Poicephalus rueppellii*) from usurping the barbets' nest-cavity.

The laying female may puncture or remove one or more of the host's eggs. There are many cases of Eastern Green-backed Honeyguides indulging in this behaviour, which also occurs in some Greater Honeyguides, and perhaps less often in others. The honeyguides' own eggs are elliptical, and are white; an exception is provided by some Eastern Green-backed Honeyguides that lay blue eggs, matching in colour those of the frequent host white-eyes. The female must be quick, and may take only 10-15 seconds to lay and leave. Hosts such as barbets can kill or maim a honeyguide caught in the nest, and barbets have been seen to toss and slam a honeyguide against the nest entrance before releasing it. Female honeyguides also receive rough treatment from their partner during copulation; the male clasps the hindneck feathers or even the skin, at times leaving a bare area that may be wounded. Breeding females may require a good rehabilitation period between laying sets of eggs.

In elaborating the hosts utilized by honeyguides, one has to realize that females may have insufficient time to locate a host's nest that has eggs at the appropriate stage of development. The timing of laying must be such that it will allow close synchrony of hatching of the host's clutch and the honeyguide's own egg, or earlier hatching of the latter. Some eggs may therefore be "dumped" in the nest of a non-host species. Warblers (Sylviidae), flycatchers (Muscicapidae), white-eyes and perhaps sunbirds (Nectariniidae) seem to be the preferred hosts of the small *Prodotiscus* honeyguides. These are cup-nesters, mainly species constructing deep cups or covered nests, but some cavity-nesters such as petronias (*Petronia*) and tits (*Parus*) may possibly be used. Hosts of the *Melignomon* honeyguides are unknown, but may include barbets of the genus *Gymnobucco*. Suspected hosts of small species of *Indicator* are various of the small barbets known as tinkerbirds (*Pogoniulus*); Pallid Honeyguides are known to use Yellow-rumped Tinkerbirds (*P. bilineatus*) as hosts, and may parasitize other barbets as well.

The Thick-billed Honeyguide lays in nests of the Grey-throated Barbet (*Gymnobucco bonapartei*), and probably those of others of that genus. Of the 19 or 20 hosts of the Lesser Honeyguide, the chief victims are barbets, with nine species recorded, six of which are social; the others are three or four woodpeckers and two bee-eaters (*Merops*), and, perhaps only occasionally, a kingfisher (*Halcyon*), a swallow (*Hirundo*), two starlings (Sturnidae) and the Yellow-throated Petronia (*Petronia supercilialis*). All but the swallow are cavity-nesters, the swallow building a closed mud nest. The Spotted Honeyguide is suspected of using *Gymnobucco* barbets as hosts, as is the Lyre-tailed Honeyguide. Six woodpeckers, two barbets and a tinkerbird are recorded as hosts of the Scaly-throated Honeyguide. This honeyguide, however, is too large to fit into a tinkerbird cavity and possibly "dumped" the egg, laying it through the entrance; V. G. L. van Someren reported that, remarkably, the tinkerbirds enlarged the nest-chamber and entry tunnel in order to accommodate the nestling honeyguide.

There are about 40 hosts recorded for the Greater Honeyguide. In some areas, the majority of its eggs are laid in the nests of one or two species, especially bee-eaters, kingfishers and starlings. A roller (*Coracias*), three woodhoopoes (Phoeniculidae), the Hoopoe (*Upupa epops*), four kingfishers (Alcedinidae), eight bee-eaters, three barbets, six woodpeckers, three swallows, three starlings, two thrushes (*Myrmecocichla*), two petronias, a tit and a sunbird are the known hosts, these being cavity-nesters or, in a

few cases, builders of closed nests. The number and variety of its hosts may be related to the striking sexual and age dimorphism of the Greater Honeyguide, far exceeding that of any other indicatorid species.

So far as is known, honeyguide eggs are not removed from nests by the hosts, except in cases, perhaps of "dumping", in which the honeyguide lays before the host has commenced laying. The eggs take twelve to 18 days to hatch, an incubation period that is short by comparison with that of many host species, but in fact no shorter than in other piciforms, even including toucans. The honeyguide hatches naked, blind and weak, with a well-developed egg tooth, and small, sharp, curved membranous hooks on the tips of the mandibles; it also possesses spiny hypotarsal "heels", and it sits on these and on the belly. From this point onwards, the hatchling moves its head about, clinging to and biting anything it touches, except the foster-parents. It punctures and destroys the host's eggs one by one. If any of the host's nestlings are present, they are "bitten" and lacerated, and they weaken and die, and are then removed by the parents. There are no known cases of a fosterer's own young surviving to fledging if a honeyguide is raised in the nest. The membranous bill hooks presumably break off at as early an age of seven days in species of *Prodotiscus*, but they are present for 14 days or more in larger honeyguides, which occasionally still bear one or both hooks at fledging. On occasions, two or more honeyguide eggs are laid in the same host's nest, possibly a result of "egg-dumping"; in some such cases, albeit rarely, the hatchling honeyguides, with their thick skin, fail to cause serious injury to one another, and so may be raised together successfully.

Nestling honeyguides beg loudly, and, by securing food intended for a number of the host's young, they grow rapidly, the larger species gaining up to about 2 g in weight per day. There have been suggestions that nestling Greater Honeyguides mimic the begging calls of their specific hosts, but observations have so far not found this to be the case. The young honeyguides have several calls, and these shift developmentally. Greater Honeyguides, even where favouring one particular host, nevertheless parasitize various other species, and, moreover, the young do not vary in their mouth and facial-skin colours. Nothing in the behaviour of honeyguides suggests that individuals have either genetic or imprinted host-specificity. The eyes of the nestling honeyguide open at between ten and 20 days, by which time the chick is rather well feathered. The young of the smaller species fledge at about 21 days, while larger ones leave the nest at about 35 days of age. Nestlings do not appear at the nest entrance until a few days before fledging. While at the entrance they may see and hear monitoring adult honeyguides, perhaps their own parents.

At fledging time at a barbet's nest, the appearance of the flying, emergent honeyguide confounds the foster-parents and their helpers, which may suddenly react as to the presence of an adult, by chasing the fat young honeyguide out of the territory. Whether or not the hosts react aggressively to the young honeyguide, problems usually arise rapidly. These are due partly to the young honeyguide failing to return to roost in the nest with its foster-parents, and partly to the frequently divergent foraging habits exhibited by the hosts and the honeyguide. For example, the young honeyguide's failure to follow foster-parent barbets to fruiting trees, its lack of "enthusiasm" for ground-foraging with starling fosterers, or the inability of a young honeyguide to forage in the air or to travel far to feeding sites with fostering bee-eaters must place stress on the bond between honeyguide and host.

Problems may be fewer between *Prodotiscus* honeyguide fledglings and foster-parent warblers or white-eyes, which do not return to the nest. Those host species glean for insects close by the nest, and perhaps roost with the youngster side-by-side in a bush or tree.

Fledged honeyguides spend either no time at all or up to seven days with their foster-parents. Many are probably independent within one or two days, as indeed are some young barbets.

Juvenile honeyguides of those species which exploit beeswax seem to tag along with other honeyguides, thus arriving at a food source at which they are apt to be dominant (see Morphological

All honeyguides are apparently brood parasites. Appearing at the nest entrance within only a few days of fledging, this young Lesser Honeyguide has been reared by Black-collared Barbets (*Lybius torquatus*).

The honeyguides monitor and may even guard potential hosts and their nests, and the female honeyguide, perhaps having previously tired the nest-owners by repeated chasing, has to lay and leave quickly when a favourable opportunity arises. On hatching, after 12–18 days, the young honeyguide uses sharp mandibular hooks to puncture the hosts' eggs or fatally injure any chicks.

Begging loudly, the nestling thrives on a typical barbet diet which includes fruit, but not wax, and may be brought by the barbet parents and a helper. The fledgling thus tends to be heavy on leaving the nest and may be independent within only 1–2 days. Probably to the consternation of its foster-parents, the juvenile does not return to the nest to roost as would a young barbet, but quickly begins rather to associate with other honeyguides, following them to wax sources, where immatures are dominant.

[*Indicator minor minor*,

FLPA]

Aspects, General Habits). Furthermore, they are likely to be heavy when they leave the nest, where they have no competitors for food. This allows a period of time for them to find food before hunger becomes severe. For the first few months up to six months or more they enjoy a dominant status in their juvenile plumage, before acquiring a fully adult plumage.

## Movements

Most male honeyguides in most areas remain more or less on, or near, their singing territory (see Breeding) throughout the year. Male Yellow-rumped Honeyguides dependent upon the colonies of giant or rock honeybees on rock faces may remain in or near the singing territory through the winter if the beeswax resource is plentiful. Immature and female Yellow-rumped Honeyguides are more mobile and move widely; even territorial males forage away from their territory, to as far as 10 km. Forest-dwelling honeyguides are less well known, although males of some species, such as the Spotted and the Lyre-tailed Honeyguides, sing or display more or less regularly all year. One problem in understanding these essentially tropical birds is that much of the information available on the Indicatoridae comes from the fringe of the subtropics in southern Africa, where the birds are strictly limited by strong summer-winter seasonality, a factor alien to most honeyguide populations, which do not reach such colder regions.

Almost all honeyguides are resident, spending their entire life in the area in which they were raised. Some undertake local movements, perhaps irregularly beyond a radius of 8–20 km of the natal site. Adverse conditions cause Lesser Honeyguides to gravitate to favourable sites in or near their place of origin. In a long-term study area in Kenya where there are few breeding Lesser Honeyguides, there is in most years a sudden deluge of young Lesser Honeyguides, many of them very young, such that more individuals of this species are ringed than of the more commonly breeding Scaly-throated and Greater Honeyguides. Within the breeding season, female honeyguides sometimes move up to 8 km or so, and, exceptionally, territorial males may do so in order to forage at a particular site.

Dispersal has led to the invasion by some species, especially the Lesser Honeyguide, of certain areas in south-western Africa. It is surely no coincidence that such movements have followed closely on the heels of the expansion into these areas of host *Acacia* *Pied Barbets*.

The Yellow-rumped Honeyguide is probably the most migratory member of the family, although it could hardly be termed a true migrant. Some birds apparently move upslope in the Himalayas after breeding. Likewise, some individuals, perhaps many, migrate to lower elevations in the autumn, although territorial males and some others remain around the cliffs where they breed, so long as they can glean beeswax from the abandoned colonies of rock honeybees that have moved downslope for the winter.

Of course, many honeyguide species are poorly known, and it is possible that some movements occur of which ornithologists are as yet unaware. Nevertheless, regional observers and authorities consider that most species are sedentary. Studies show that those honeyguides which have been investigated in some detail exhibit only local movements in search of food, except for the somewhat larger-scale dispersal by immatures.

## Relationship with Man

The relationship between honeyguides and beeswax has been known to humans for a considerable time, and certainly to African honey-gathering tribesmen for millennia. Honeyguides have intrigued Western peoples and the Chinese for centuries with their wax-eating, their guiding behaviour and, more recently, their nest parasitism. The last seems to many to be cruel in the extreme, for every honeyguide is a “killer”, representing a lost brood of some host. Rather, honeyguides should be respected as highly evolved, efficient brood parasites, and unique among birds in their near dependence on beeswax.

Thus, despite the paucity of knowledge of honeyguides, the habits of these relatively drab birds have long captured people's interest. Third-century Chinese scribes wrote of “little birds of the wax combs”, this being based on second-hand reports referring to the Yellow-rumped Honeyguide of the Himalayas, a species which does not enter China. For many thousands of years, African tribespeople have noted and watched honeyguides, and followed them to bees' nests. Early religious missionaries in Africa were surprised by birds that came to altars and took pieces of wax from their beeswax candles.

Within Africa, the honeyguides have evolved investigative behaviour that involves humans, for individuals of several species of *Indicator* follow, watch and monitor human activities, especially chopping, hammering and fire-building. Early European explorers and ornithologists were intrigued by the honeyguides, especially when the birds' nest parasitism and the Greater Honeyguide's guiding behaviour came to their attention.

So far as is known, only one species, the Greater Honeyguide, has evolved the habit of leading or guiding humans to bees' nests. This behaviour allows traditional honey-hunting peoples to acquire honey more efficiently, as H. A. Isack and H. U. Reyer have shown. It has often been said that the honeyguide also guides other mammals, and particularly the ratel, or honey-badger (*Mellivora capensis*), to sources of food, presumably using much the same method as it does for humans. Although this remains a real possibility, there appears to be little real evidence to support such claims. Clearly, this is one aspect of the honeyguide's behaviour that requires further research, along with investigation into whether species other than the Greater Honeyguide lead humans in a similar way.

The honeyguide's behaviour when leading a human to a nest has already been described (see General Habits), but a further well-documented example, from Zimbabwe, is of interest. In July 1998, C. B. Cottrell encountered a female Greater Honeyguide perched 10 m away, and giving the chatter call associated with guiding. The bird, having caught the observer's attention, then flew out of sight behind a large, extensive and densely vegetated termite mound, where it chattered again, while the observer had to take a longer route around the obstruction; the bird, although unable to see the human, must have followed an appropriate route, since it reappeared alongside the observer and chattered once more. From there it flew some 30 m and settled close to a previously invisible bees' nest, thereby placing the observer in a dilemma: the nest was a commercial one, and belonged to a colleague!

There appears to have been a substantial decline in the incidence of guiding since the middle of the twentieth century, at any rate in some of the more densely populated areas. The results of a survey, initiated in 1998 by Cottrell, may shed light on this subject.

Collection of honey from wild honeybees remains locally important to people as a source of energy in the Himalayas and in parts of Africa. Even the honeycomb pieces are utilized in Africa for the making of beverages. To the extent that the comb is collected along with the honey, the impact upon honeyguides is more or less substantial (see Status and Conservation).

## Status and Conservation

Honeyguides are unique among piciform birds in that so little is known about over half of the members of the family. For these, only the most basic information is available on their distribution and a few fragments of data on their habits, two species having been discovered within the past half-century. Several seem very rare, yet this may be in part due to their inconspicuousness. Indeed, the Lyre-tailed Honeyguide is known in some areas and a few countries only from the sounds produced in its remarkable aerial display (see General Habits).

Whatever factors play roles impinging adversely on honeyguides, the greatest threat by far must be the loss of suitable habitat associated with the increasing human populations in Africa and Asia. For the Yellow-rumped Honeyguide in the Himalayas, this means ever more frequent harvesting of honey

The combination of olive-brown to black-brown upperparts and golden-yellow to cream or white underparts make this juvenile Greater Honeyguide easily distinguishable from all other members of the family, including adults of its own species. Further characteristic features include the pale lores, pale bare skin around the eye and yellow-green crown. Several honeyguide species are known to drink more or less regularly, amongst them the Greater Honeyguide. This species, in particular, apparently needs to drink when feeding on wax.

[*Indicator indicator*,

FLPA]

and the attendant destruction of the nests of rock honeybees, as documented by E. Valli and D. Summers. This over-exploitation by humans interferes with the feeding and breeding activities of this honeyguide, which has certainly become much rarer throughout most of its range during the past four decades. All of the truly forest-dependent species, such as the Spotted, Lyre-tailed and Sunda Honeyguides, are experiencing fragmentation of their habitat, this sometimes resulting in their replacement by a more open-country relative. Such has been the case with the Thick-billed Honeyguide, which has lost out to the Lesser Honeyguide.

Pressure is becoming severe on woodland honeyguides, too, both directly and indirectly. The expanding human population, ever questing firewood, eliminates dead trees and stubs used by honeyguide hosts for excavating nesting cavities; fewer cavities mean fewer nesting places for honeybees, as well. Such activities have a subtle effect on the location of singing territories by male honeyguides, probably through shifts in the location of bees' nests.

Although no species of the Indicatoridae is currently considered threatened by BirdLife International, the Yellow-footed Honeyguide is officially classified as Data-deficient. In addition, three species are classified as Near-threatened: the Dwarf Honeyguide, and the two Asian species, the Sunda and Yellow-rumped Honeyguides.

The forest-inhabiting Yellow-footed Honeyguide quite probably is threatened, but assessment of its true status is difficult since its range is incompletely known, this at a time when forest is being cleared at a staggering rate in West and Central Africa. The Lyre-tailed Honeyguide, conspicuous through its aerial displays, may possibly be threatened, or may become so shortly. So long as huge areas of lowland forest remained intact, man could arguably afford to be complacent in his lack of knowledge of such species, but this situation no longer applies. Both of these forest honeyguides, and others, urgently require study in order to acquire data on which to base methods of monitoring such species, and then measures for safeguarding them.

A further human activity having a major impact upon honeyguides is the greatly expanded practice of apiculture. As honeybees become "domesticated", and as they increasingly occupy artificial hives, the beeswax resource becomes unavailable to honeyguides. This is particularly true of suburban and near-suburban areas surrounding major and even minor cities in Africa. Nowadays, households in rural areas frequently have several

or more bee hives that they control. Honeyguides that are, naturally, attracted to artificial hives are driven away by some honey-culturists. In any event, since the surrounding areas are largely cleared, and remaining patches of natural vegetation are manicured through firewood-gathering, the effects on the structure and size of honeyguide populations are likely to be severe, although, essentially, they are unknown.

To the extent that habitat and hosts remain, it is likely that some benefits accrue to the *Prodotiscus* species through the planting of flowerbeds and the presence of some natural herbs and bushes that support scale insects, the wax covering of which is a major food resource for these honeyguides (see Food and Feeding). For the Greater Honeyguide, the most open-country member of the family, it is possible that the loss of wax that results from modern methods of apiculture is partly or even mainly offset by the widespread opening-up of formerly forested areas, which thus become accessible to this honeyguide.

So long as some honey-gathering persists in remaining natural habitat, and pastoral herd-tenders still locate and open up bees' nests, the guiding behaviour of Greater Honeyguides may survive. Perhaps it is only in very large reserves, where honey-hunting humans can co-exist with wildlife in reasonably natural situations, that we can be assured of the continuance of this unique symbiotic association.

## Subfamily PRODOTISCINAE

### Genus *PRODOTISCUS* Sundevall, 1850

#### 1. Western Green-backed Honeyguide

##### *Prodotiscus insignis*

**French:** Indicateur pygmée **German:** Liliputlaubpicks **Spanish:** Indicador Insigne  
**Other common names:** Cassin's (Sharp-billed)/Green-backed Honeyguide/Honeybird

**Taxonomy.** *Heterodes insignis* Cassin, 1856, Moonda River, Gabon.

Forms a superspecies with *P. zambesiae*, and has been considered conspecific; the two possibly meet in Angola, where the form referred to as "*lathburyi*" appears intermediate; further study required, based on fresh material. Two subspecies recognized.

##### **Subspecies and Distribution.**

*P. i. flavodorsalis* Bannerman, 1923 - Sierra Leone E, probably disjunctly, to SW Nigeria.

*P. i. insignis* (Cassin, 1856) - SE Nigeria S to N Angola, and disjunctly E in Zaire to S Sudan and W Kenya.

**Descriptive notes.** c. 10 cm; 9-13 g. Small, greenish bird with thin, flycatcher-like bill. Both sexes of nominate race various shades of green above, with erectile white patch between rump and flanks; outer tail, including tips, wholly white; olive-grey below, paler in centre. Differs from *P. zambesiae* in greener, more golden-olive upperparts, darker underparts. Immature duller, greyer, sometimes shows remnants of hypotarsal spiny "heel". Race *flavodorsalis* slightly smaller than nominate, with less olive, more yellow-green, above, and paler underparts. Voice. Almost unknown; chattering calls reported, also weak "ski-a" or "whi-hi-hi" notes.

**Habitat.** Primary and well-developed secondary forest, riverine forest, forest edges and clearings, and large trees in coffee and other plantations. Lowlands from sea-level regularly to 1000 m; to 1500 m in Liberia (Mt Nimba), to 1100-1200 m in Zaire and Angola, and at 700-2200 m in Uganda and W Kenya.

**Food and Feeding.** Insects, preferentially scale insects (Coccidae) and their exudate, also wasps, caterpillars, flies, shield-bugs (Pentatomidae), and others; also spiders; occasionally fruits. Feeds in understorey and to canopy, flits from perch to perch flashing tail-tips, is an adroit fly-catcher; often takes insects at flowers of *Erythrina*, *Gymnosporia*, and other trees. Joins mixed-species foraging flocks at times.

**Breeding.** May in Liberia; recorded in Oct-Nov in Sierra Leone; Sept-Jan in Ghana, Cameroon, Gabon and Angola; probably Jun-Sept in Zaire; Mar-Apr in Sudan, Uganda and W Kenya. Lays in cup-nests of species such as warblers (*Apalis*), sunbirds (*Nectarinia*), probably flycatchers (Muscicapidae) and white-eyes (*Zosterops*). Eggs at least 2; no information on incubation period; 1 observed fed regularly by sunbird hosts for 8-9 days after fledging; adult of present species reported feeding a juvenile, a very rare occurrence in Indicatoridae.

**Movements.** Probably only local movements.

**Status and Conservation.** Not globally threatened. Very little known; widespread but never common, and range disjunct. Not uncommon in Sierra Leone; rare to uncommon in Liberia, where possibly overlooked; scarce in Kenya, where apparently extinct in Yala River Forest Reserve. Known to occur in Gola Forests Reserves (Sierra Leone), Tai Forest National Park (Ivory Coast), Kibale Forest National Park (Uganda), and Kakamega Nature Reserve (Kenya).

**Bibliography.** Allport *et al.* (1989), Bannerman (1933, 1953), Barlow *et al.* (1997), Bates (1930), Britton (1980), Brosset (1981), Brosset & Éard (1986), Chapin (1939), Cheke & Walsh (1996), Christy & Clarke (1994), Colston & Curry-Lindahl (1986), Dean (2000), Demey & Fishpool (1994), Demey *et al.* (2000), Dowsett (1989b), Dowsett & Dowsett-Lemaire (1991, 1993), Dowsett & Forbes-Watson (1993), Elgoud *et al.* (1994), Field (1999), Fry *et al.* (1988), Gatter (1997), Gore (1994), Grimes (1987), Jackson & Selator (1938), Lewis & Pomeroy (1989), Lippens & Wille (1976), Louette (1981b), Mackworth-Praed & Grant (1957, 1970), Morel & Morel (1990), Nikolaus (1987), Pinto (1983), Serle (1954, 1965), Short & Horne (1985b), Short *et al.* (1990), Snow (1978), van Someren & Cunningham-van Someren (1949), Thiollay (1985a), Zimmerman *et al.* (1996).

#### 2. Eastern Green-backed Honeyguide

##### *Prodotiscus zambesiae*

**French:** Indicateur gris **German:** Graubauch-Laubpicks **Spanish:** Indicador del Zambeze  
**Other common names:** Slender-billed/Eastern Honeyguide/Honeybird

**Taxonomy.** *Prodotiscus zambesiae* Shelley, 1894, Zomba, Malawi.

Forms a superspecies with *P. insignis*, with which has been considered conspecific; the two may meet in Angola, where some birds possibly intermediate, including unassignable form known as "*lathburyi*"; further study required. N Tanzanian birds formerly separated as race *reichenowi*, but this is now considered a synonym of *ellenbecki*. Two subspecies recognized.

##### **Subspecies and Distribution.**

*P. z. ellenbecki* Erlanger, 1901 - S Ethiopia, Kenya and N Tanzania.

*P. z. zambesiae* Shelley, 1894 - C Angola, S Zaire and S Tanzania, S to NE Namibia, S Zimbabwe and C Mozambique.

**Descriptive notes.** c. 11 cm; 9-16.5 g. Both sexes of nominate race grey-green above, with erectile patch of white between rump and flanks; outer tail feathers white, including tips; grey-white underparts. Differs from very similar *P. insignis* in paler plumage, especially white belly and undertail-

coverts; distinguished from *P. regulus* by greener, less brown, back, no dusky tips on white outer tail feathers; from smaller species of *Indicator* by thin, pointed bill. Immature duller, greyer, paler than adult. Race *ellenbecki* slightly darker than nominate, more yellow-green above. Voice. In flight display, utters "szh-szh-" (or "skee-aa", or "zzzzzz"), dropping in pitch; also squeaky chatter; begging call of fledgling a squeaky "tz-tz-tz-".

**Habitat.** Inhabits forest, mostly woodland, streamside forest, and also gardens; woodland includes *Baikiaea*, *Brachylaena-Croton-Olea*, and miombo (*Brachystegia*). Occurs from sea-

level up to 2130 m, mostly above 300 m.

**Food and Feeding.** Eats scale insects (Coccidae) and their waxy exudates, also other Homoptera, Coleoptera, termites, caterpillars, other flying insects; also spiders; some fruits and seeds, e.g. of mistletoes (*Loranthus*). Reports of eating wax at bees' nests considered very unlikely, as *Prodotiscus* lacks the thick skin of wax-eating species of Indicatoridae. Drinks from birdbaths. Fly-catches frequently; also works over foliage and bark, e.g. of rose bushes with scale insects; flies often, spreading tail. Joins mixed-species foraging flocks.

**Breeding.** Apr-Aug and Dec-Feb in N, Aug-Feb in S, mainly in or after rainy season. Possible courtship displays over treetops with calls, 3-4 birds may fly about, tail may be fanned, one holding wings vertically when reaching another, then gliding and dropping behind; perched display involving one bowing to other with white rump-flank patch erected. Hosts include at least 3 species of white-eye (*Zosterops*), sunbird (*Nectarinia amethystina*), flycatchers (of genera *Muscicapa*, *Platysteira* and *Terpsiphone*), possibly also hole-nesting tits (*Parus*), petronias (*Petronia*) and tinkerbirds (*Pogonius*); female probably destroys hosts' eggs; occasionally 2 honeyguides in a nest. Eggs 2 or more; incubation period c. 12 days, nestling period c. 21 days; begging young have yellow-orange gape.

**Movements.** None known; possibly wanders, as often disappears from a site for long period.

**Status and Conservation.** Not globally threatened. Little known. Fairly common in Kenya and Tanzania. Habits indicate some adaptability, and may thrive if common hosts do so.

**Bibliography.** Benson & Benson (1977), Benson *et al.* (1971), Britton (1980), Chapin (1939), Clancey (1980b, 1985b, 1996), Cunningham-van Someren (1970), Dean (2000), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Friedmann (1930b, 1969, 1971), Fry *et al.* (1988), Ginn *et al.* (1989), Harrison *et al.* (1997), Leonard (1998b), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Parkes (1994), Pinto (1983), Short & Horne (1985b), Short *et al.* (1990), Snow (1978), Stevenson & Fanshawe (2001), Steyn (1996), Tarboton (2001), Vernon (1987a, 1987b), Zimmerman *et al.* (1996).

#### 3. Brown-backed Honeyguide

##### *Prodotiscus regulus*

**French:** Indicateur de Wahlberg **German:** Wahlberglaubpicks **Spanish:** Indicador Dorsipardo  
**Other common names:** Wahlberg's/Sharp-billed Honeyguide/Honeybird

**Taxonomy.** *Prodotiscus regulus* Sundevall, 1850, Mohapoani, west Transvaal.

No very close relatives. Forms named as *peasei* and *adustoides* are synonyms of nominate; *caurinus* synonymous with *camerunensis*. Two subspecies recognized.

##### **Subspecies and Distribution.**

*P. r. camerunensis* Reichenow, 1921 - disjunctly from Guinea E to SE Nigeria, thence E to N Cameroon and W Central African Republic.

*P. r. regulus* Sundevall, 1850 - EC Sudan and SW Ethiopia S (to E of forest) to S Zaire, Angola and NE Namibia, E to Indian Ocean coast and S to E Cape Province; recorded once in NW Somalia.

**Descriptive notes.** 12-13.5 cm; 9.5-16 g. Grey and brown, thin-billed, flycatcher-like bird. Both sexes of nominate race grey-brown above, with dark tip of white outer tail feathers; sometimes conspicuous, erectile white patch between rump and flanks; grey-white below. Distinguished from *P. insignis* and *P. zambesiae* by browner back, dark tips to outer tail feathers; differs from other honeyguides in more pointed, thinner bill. Immature duller, lacks dark tips of white outer tail. Race *camerunensis* darker than nominate. Voice. Song a short trill, rather like stronger song of *Indicator variegatus* and *I. maculatus*, c. 2 seconds long, from canopy; also "tsip, tseep" or

single to double "zeet"; at times "zeet-zeet" at each drop in undulating flight; "tsirr-tsirrr", and chattering call; "zzzzzz" in (courtship) flight; and "tseu, tseu" by young bird pumping tail.

**Habitat.** Woodland, including *Acacia*, *Brachystegia*, *Combretum*, mopane (*Colophospermum mopane*) and other types, also wooded grassland, streamside woods and forest borders, scrub, bushland, thickets, plantations and gardens; crosses grassland to 2 km wide. Sea-level to 2000 m.

**Food and Feeding.** Feeds extensively on waxy scale insects (Coccidae), on mistletoe (*Loranthus*) and other plants; also insect larvae, including those of beetles, Lepidoptera and others, and aphids, flies, winged termites and other insects. Reports of its seeking and eating beeswax considered unfounded. Gleans, probes in foliage and on bark at all levels, hovers before flowers for insects; hawks aerial insects from perch. Joins mixed-species foraging flocks.

**Breeding.** Probably May-Sept in W Africa; Nov-Mar in Kenya and Ethiopia, and Mar. May and Oct in Zaire; Oct-Mar in S Africa. Display with erected body feathers, especially flank-rump patch, drooped wings, tail spread, head forward and "zzzz" call, other bird called "zeep" and flew, first bird followed. Hosts are warblers (including *Camaroptera*, but especially *Cisticola*), sunbird (*Nectarinia senegalensis*), and Yellow-throated Petronia (*Petronia superciliosa*); investigates old nests of swifts (Apodidae), swallows (*Hirundo*) and starlings (Sturnidae). Eggs 5-6; details of incubation and nestling periods unknown.

On following pages: 4. Zenker's Honeyguide (*Melignomon zenkeri*); 5. Yellow-footed Honeyguide (*Melignomon eisentrauti*); 6. Dwarf Honeyguide (*Indicator pumilio*); 7. Willcocks's Honeyguide (*Indicator willcocksi*); 8. Pallid Honeyguide (*Indicator meliphilus*); 9. Least Honeyguide (*Indicator exilis*); 10. Thick-billed Honeyguide (*Indicator conirostris*); 11. Lesser Honeyguide (*Indicator minor*); 12. Spotted Honeyguide (*Indicator maculatus*); 13. Scaly-throated Honeyguide (*Indicator variegatus*); 14. Yellow-rumped Honeyguide (*Indicator xanthonotus*); 15. Sunda Honeyguide (*Indicator archipelagicus*); 16. Greater Honeyguide (*Indicator indicator*); 17. Lyre-tailed Honeyguide (*Melichneutes robustus*).

**Movements.** Probably some wandering, as irregular at some sites (e.g. in C Kenya), and sites used for singing often abandoned. Numbers appear to vary seasonally in E South Africa, with notable influxes in 1924 and 1986 suggested to be irruptions; these may be linked to sporadic records from SW Cape.

**Status and Conservation.** Not globally threatened. Considered probably commonest species of *Prodotiscus*, although no data on relative numbers. Rare in Liberia; local and uncommon in Kenya. Apparently expanding its range in parts of South Africa, as a result of tree planting.

**Bibliography.** Anon. (1998a), Ash & Miskell (1998), Baird (1979), Bannerman (1933, 1953), Benson & Benson (1977), Benson *et al.* (1971), Britton (1980), Cave & Macdonald (1955), Chapin (1939), Cheke & Walsh (1996), Clancey (1964, 1975), Colston & Curry-Lindahl (1986), Dean (2000), Deme & Fishpool (1991), Deme *et al.* (2000), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Earle & Grobler (1987), Elgood *et al.* (1994), Fabian (1981), Friedmann (1930a), Fry *et al.* (1988), Gatter (1997), Ginn *et al.* (1989), Harrison *et al.* (1997), Irwin (1981), Leonard (1998b), Lewis & Pomeroy (1989), Lippens & Wille (1976), Louette (1981b), Mackworth-Præd & Grant (1957, 1962, 1970), Maclean (1971, 1993), Manson (1985), Nikolaus (1987), Penry (1976, 1994), Pinto (1983), Priest (1948), Schmidl (1982), Serle (1950, 1957), Short & Home (1985b), Short *et al.* (1990), Skead (1951), Snow (1978), Steyn (1996), Tarboton (2001), Tarboton *et al.* (1987), Thiollay (1985a), Vernon (1974), Zimmerman *et al.* (1996).

## Genus *MELIGNOMON* Reichenow, 1898

### 4. Zenker's Honeyguide

#### *Melignomon zenkeri*

French: Indicateur de Zenker

Spanish: Indicador de Zenker

German: Weißschwanz-Honiganzeiger

**Taxonomy.** *Melignomon zenkeri* Reichenow, 1898, Yaoundé, Cameroon.

Forms a superspecies with *M. eisenrauti*, which it possibly meets in Cameroon. Monotypic.

**Distribution.** S Cameroon E to S Central African Republic and SW Uganda, S to Gabon and N & CE Zaire.

**Descriptive notes.** c. 14.5 cm; female 24–25 g. Nondescript, rather dull honeyguide. Both sexes yellow-olive to brown-olive above, with dark-tipped white outer tail; olive-grey to grey-brown below, with yellow towards centre; legs usually show some yellow (with olive, green or pink); bill pointed, relatively broad, not stubby. Distinguished from *Prodotiscus* by larger size, no white patch on upperparts, larger pointed bill. Immature darker, greener than adult, legs yellower, outer tail whiter, even all white at tips. **Voice.** Known only from one series of songs from Cameroon, though there is a remote possibility that these songs could

have been from *M. eisenrauti*, voice of which unknown. Song apparently a series of up to 32 "psee" notes, or with louder "psee" in mid-song, c. 10–20 seconds long, drops rapidly in volume near end, like slowed song of *Prodotiscus regulus* or even *Indicator variegatus* or *I. maculatus*.

**Habitat.** Lowland to lower montane forest and secondary forest, including edges, and cultivated areas with some standing trees. To 1150 m in Cameroon, 1530 m in E Zaire.

**Food and Feeding.** Little known; scale insects (Coccidae), including pupae and cocoons, and grey wax-like items mixed with insects. Tough skin and slit-like nostrils suggest that beeswax may be eaten, as does the netting of an individual near a recently cut-out bees' nest, where *Indicator* species were present.

**Breeding.** Virtually unknown. Surmised to breed during Feb-Mar (end wet season through dry) in Cameroon; Jun in Central African Republic; reported in Jan-Mar and Jul-Aug (wet and dry seasons) in E Zaire; and Jul in Uganda. No information on eggs or hosts; once chased by 2 Grey-throated Barbets (*Gynobucco bonapartei*) from perch near dead stub bearing their nests.

**Movements.** Presumably sedentary.

**Status and Conservation.** Not globally threatened. Very little known, and status uncertain. Apparent rarity possibly due to its being overlooked, since all honeyguides, even where relatively common, are rather infrequently noted by observers. More information urgently needed concerning its biology. Present in Mount Kupé National Park (Cameroon).

**Bibliography.** Bannerman (1933, 1953), Bates (1930), Bowden (2001), Bowden *et al.* (1995), Britton (1980), Chapin (1939), Colston (1981), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Dowsett-Lemaire & Dowsett (1998), Friedmann (1968, 1978a), Friedmann & Williams (1968), Fry *et al.* (1988), Lippens & Wille (1976), Louette (1981a, 1981b), Mackworth-Præd & Grant (1970), Robertson (1997b, 1998a, 1998c), Serle (1959, 1965), Smith *et al.* (1996), Snow (1978), Stevenson & Fanshawe (2001).

### 5. Yellow-footed Honeyguide

#### *Melignomon eisenrauti*

French: Indicateur d'Eisenraut

Spanish: Indicador Patiamarillo

German: Eisenrauthoniganzeiger

Other common names: Coc's/Eisenraut's Honeyguide

**Taxonomy.** *Melignomon eisenrauti* Louette, 1981, near Grassfield, north-east Liberia.

Forms a superspecies with *M. zenkeri*, which it may meet in Cameroon. Monotypic.

**Distribution.** Sierra Leone, Liberia (Mt Nimba, Wonegizi Mts), SW Ghana and SW Cameroon; reports from Ivory Coast require confirmation.

**Descriptive notes.** c. 14.5 cm; 18–29 g, males average heavier. Both sexes yellowish-olive above, with dark-tipped white outer tail; grey-white below, with green-yellow about breast and belly, white undertail-coverts; mainly yellow bill and legs, variable in depth of colour. Distinguished from similar *M. zenkeri* by distinctly paler, whiter undertail-coverts contrasting with rest of underparts, yellow bill, generally yellower legs; from *Prodotiscus* by lack of white on side of rump, stronger and yellow bill, pale yellowish legs. Immature paler, yellower below, outer tail with small or no dark tips of white feathers. **Voice.** Unknown.

**Habitat.** Mainly primary forest, also adjacent secondary forest; lowlands to at least 750 m.

**Food and Feeding.** Feeds on insects, and fruits and their seeds; probably also eats beeswax, as yellow waxy material found in stomachs. Forages in canopy up to middle heights; gleans from leaves and branches; sometimes hangs, feet upwards, to take insects. Occasionally joins mixed-species foraging flocks.

**Breeding.** Unknown. Data from specimens suggest breeding in Mar (possibly Nov-Jun) in Liberia, and Aug and Dec in Cameroon. Hosts possibly woodpeckers.

**Movements.** Presumably sedentary.

**Status and Conservation.** Not globally threatened. Data-deficient. Very poorly known. Rare throughout range, and habitat diminishing as forest cleared; easily overlooked, however, and possibly more common than thought. Described only in 1981, and now known from a dozen or so sites in at least 4 countries across W Africa; conceivably present, but undiscovered, in other forested parts of W Africa. Known to occur in Sapo National Park, Liberia, and in Gola Forests Reserves, Sierra Leone. Key to understanding both present species and *M. zenkeri* is their as yet unknown hosts.

**Bibliography.** Allport (1991), Allport *et al.* (1989), Bowden *et al.* (1995), Collar & Andrew (1988), Collar & Stuart (1985), Collar *et al.* (1994), Colston (1981), Colston & Curry-Lindahl (1986), Dickerman *et al.* (1994), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Dutton & Branscombe (1990), Field (1999), Fry *et al.* (1988), Gartshore (1989), Gartshore *et al.* (1995), Gatter (1997), Grimes (1987), Hockey (1997), Louette (1981a, 1981b), Macdonald (1980), Morel & Chappuis (1992), Serle (1959, 1965), Snow (1978), Stattersfield & Capper (2000), Thiollay (1985a), Vuilleumier *et al.* (1992).

## Subfamily INDICATORINAE

## Genus *INDICATOR* Stephens, 1815

### 6. Dwarf Honeyguide

#### *Indicator pumilio*

French: Indicateur nain

German: Kurzschnebel-Honiganzeiger

Spanish: Indicador Enano

Other common names: Pygmy Honeyguide

**Taxonomy.** *Indicator pumilio* Chapin, 1958, Tshibati, east Zaire.

No very close relationships apparent; has been linked by some authors with *I. meliphilus*, and in past with *I. exilis*. Monotypic.

**Distribution.** E Zaire to SW Uganda, W Rwanda and W Burundi.

**Descriptive notes.** c. 12 cm; 11.5–15 g. Very small honeyguide with stubby bill. Both sexes olive, green and grey, with white mark on loreal area, greenish-grey malar; brownish-olive dorsal streaks; white outer tail feathers with dark tips; pale chin streaky, green-grey throat to breast, whitish belly, flanks and undertail-coverts with some mottling or streaking. Distinguished from *I. willcocksii* by white lores, from other small *Indicator* species by less distinct malar; differs from thin-billed species of *Prodotiscus* in stubby bill. Immature has whiter outer tail, is greyer, below more streaky. **Voice.** A "tuutwi" call is only vocalization

known; thought by some to have no song, but sound resembling song of African Emerald Cuckoo (*Chrysococcyx cupreus*) reported, thus possibly like songs of *I. willcocksii* and *I. meliphilus*.

**Habitat.** Highland forest of moist and dry types, as well as openings and edges, at 1840–2400 m; up to 1500 m in SW Uganda, and perhaps elsewhere.

**Food and Feeding.** Flies, other insects, and beeswax. Insects hawked; visits both abandoned and occupied, accessible bees' nests, feeds on beeswax placed out for other honeyguides by humans.

**Breeding.** Season in E Zaire probably Aug-Dec, probably also May-Jun, possibly Feb. Eggs and hosts unknown; probably parasitizes tinkerbirds (*Pogoniulus*) or small woodpeckers.

**Movements.** Probably sedentary.

**Status and Conservation.** Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Albertine Rift Mountains EBA. Apparently not uncommon at some sites, but its forest habitat is severely threatened in places. Known to occur in Kahuzi-Biega National Park, Zaire, in Nyungwe Forest Reserve, Rwanda, and in Impenetrable (Bwindi) Forest National Park, Uganda. Is very likely easily overlooked; was first discovered, in 1950's, only through the putting-out of beeswax to attract other honeyguides, a strategy rarely, if ever, used by those seeking it. More information desirable in order to assess potential threats.

**Bibliography.** Britton (1980), Chapin (1958, 1962), Collar & Stuart (1985), Dowsett (1985, 1990), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Friedmann (1963, 1969), Friedmann & Williams (1968, 1971), Fry *et al.* (1988), Greenway (1978), Keith & Twomey (1968), Lippens & Wille (1976), Mackworth-Præd & Grant (1970), Omari *et al.* (1999), Prigogine (1971, 1978, 1980b), Snow (1978), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), Stevenson & Fanshawe (2001), Williams & Friedmann (1965), Zimmerman (1972).

### 7. Willcocks's Honeyguide

#### *Indicator willcocksii*

French: Indicateur de Willcocks

German: Guineahoniganzeiger

Spanish: Indicador de Willcocks

**Taxonomy.** *Indicator willcocksii* Alexander, 1901, Prahou, Ghana.

May form a superspecies with *I. meliphilus*; that species is very similar in size and vocally, and responds readily to playback of present species' song. Was long confused with *I. exilis*, but differs vocally. Races poorly known; form *propinquus* from Cameroon originally thought to be a distinct species, but now considered a synonym of nominate *willcocksii*. Birds collected in N Liberia (Wonegizi) thought to be *I. exilis*, but might in fact refer to present species. Three subspecies recognized.

#### Subspecies and Distribution.

*I. w. ansorgei* C. H. B. Grant, 1915 - Guinea-Bissau.

*I. w. willcocksii* Alexander, 1901 - Sierra Leone E to S Nigeria, S Cameroon and W Uganda, S to Gabon and C & CE Zaire.

*I. w. hutsoni* Bannerman, 1928 - NC Nigeria E to S Chad and SW Sudan.

**Descriptive notes.** 12-13 cm; 11-20.5 g. Small, streaky, green honeyguide with stubby bill, lacking distinctive features. Both sexes of nominate race have typical honeyguide tail pattern, with distinct dark tips on white outer feathers; below, shades of olive-grey with some flank streaks, and whiter belly to undertail-coverts. E birds tending towards greyer breast. Differs from *I. exilis* in lack of dark malar and white loreal mark, and less heavy flank streaks. Immature more yellow-green, less olive, above, darker on breast, tail feathers more pointed, outer tail whiter. Race *hutsoni* smaller, paler, less green, greyer, breast in particular greyer;

*ansorgei* also smaller, crown greyer than back and less streaky, greyer below than *hutsoni*, sometimes trace of white loreal mark. **Voice.** Repertoire largely unknown; song a series of 3-note phrases, "pa-will-it", last note with distinct snap as of bill-snap, closely resembles that of *I. meliphilus*, lacks characteristic initial note of *I. exilis*, *I. controstris* and *I. minor* songs.

**Habitat.** Inhabits primary and tall secondary forest, riverine forest, adjacent tree plantations, mosaic of forest, shrubs and grassland, and larger patches of forest where clearing occurs; race *hutsoni* found in woodland. Mainly occurs in lowlands below 1000 m, up to 1500 m in E Zaire; recorded at 1000-1800 m in W Uganda.

**Food and Feeding.** Insects, including ants, termites, and larvae of Lepidoptera; also beeswax, possibly also waxy exudates of certain insects. Hawks insects; feeds in foliage and on branches, usually in canopy.

**Breeding.** Apr-Sept in most areas; probably also Jan-Feb in Ghana, Nigeria and Cameroon, possibly Oct in Uganda. Male apparently sings from small "territory", attracting females. Eggs and hosts unknown; Speckled Tinkerbird (*Pogoniulus scolopaceus*) is possible host, and one around nest in Uganda repeatedly attacked by this honeyguide for over 1 hour.

**Movements.** Sedentary, so far as known.

**Status and Conservation.** Not globally threatened. Not uncommon in Sierra Leone, where appears to be much commoner than *I. exilis*; uncommon in Liberia; precise distribution and status in W Africa unclear. Known to occur in Korup National Park (Cameroon) and Impenetrable Forest National Park (Uganda). May possibly be under threat W of Liberia, in Guinea-Bissau, but species is too poorly known to establish this. As with many honeyguides, biology very little understood owing to lack of observations.

**Bibliography.** Allport *et al.* (1989), Britton (1980), Brosset & Énard (1986), Chapin (1939, 1962), Chappuis (1981), Cheke & Walsh (1996), Christy & Clarke (1994), Colston & Curry-Lindahl (1986), Demey & Fishpool (1991, 1994), Dickerman *et al.* (1994), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Dowsett-Lemaire & Dowsett (1998), Elgood *et al.* (1994), Field (1999), Fishpool (1993), Fishpool *et al.* (1997), Friedmann (1969), Friedmann & Williams (1968, 1971), Fry *et al.* (1988), Garshore (1989), Gatter (1997), Grimes (1987), Lippens & Wille (1976), Louette (1981b), Mackworth-Praed & Grant (1970), Prigogine (1971), Serie (1965), Short & Horne (1985b), Short *et al.* (1990), Snow (1978), Sørensen *et al.* (1996), Thiollay (1985a).

## 8. Pallid Honeyguide

### *Indicator meliphilus*

**French:** Indicateur pâle      **German:** Tavetahoniganzeiger      **Spanish:** Indicador Pálido  
**Other common names:** Eastern (Least) Honeyguide

**Taxonomy.** *Melignothus exilis meliphilus* Oberholser, 1905, Taveta, south-east Kenya.

May form a superspecies with *I. willcocksii*; closely similar in size and voice, and responds to playback of that species' song. Was long confused with *I. exilis*, but differs vocally; has been linked by some authors with *I. pumilio*. Birds from border region of SC Kenya and N Tanzania have been treated as separate species, *I. narokensis*; however, described on basis of an immature specimen which is indistinguishable from type (also an immature) of present species, so synonymous with nominate *meliphilus*. S Malawi birds, described as *appellator*, inseparable from *angolensis*. Two subspecies recognized.

#### Subspecies and Distribution.

*I. m. meliphilus* (Oberholser, 1905) - E Uganda and C Kenya S to CN & EC Tanzania; also recorded from SW Sudan (R Boro).

*I. m. angolensis* Monard, 1934 - C Angola E to S Zaire and S Malawi, and SE to EC Zimbabwe and C Mozambique.

**Descriptive notes.** c. 13 cm; 11-18 g. Small, stubby-billed, plain-faced honeyguide. Both sexes of nominate race with grey-green crown, greenish-grey face with malar not contrasting, but with distinct white loreal mark; back more olive than crown, rump more yellowish-green with only light streaking; tail with dark-tipped white outer feathers; below, yellow-grey to yellow-white or beige, greyer at sides. Differs from *I. minor* in smaller size, paler plumage, without marked malar, less streaky; from *I. exilis* in much paler plumage less strongly streaked on flanks and back, no dark malar. Immature darker, without loreal mark, outer tail feathers

pointed with little or no dusky tipping. Race *angolensis* slightly larger, somewhat darker green above with stronger streaks, greyer below. **Voice.** Song 10-25 triple-noted phrases, "a-wee-it" or "pa-wee-wit", 9-18 seconds long, starts softly, phrases of 1 or 2 notes, then louder, with final note in phrase a mechanical snap or click, song slower with slightly longer notes than that of *I. willcocksii*;

in conflicts "pweet", often in series of up to 8 notes, in male-male conflicts may lead into song; also squeaks, noisy, at e.g. barbets (Capitonidae), and raspy "skeee", and "zeet-zeet" or "zit-zit" calls; chattering notes; and "prrrrit" at *I. minor*. Also "wip, wip,-" sounds in flight display, which sometimes precedes song.

**Habitat.** Diverse woodland, especially streamside trees, *Brachystegia* woods, and forest edges; sea-level to c. 2000 m.

**Food and Feeding.** Arthropods, including winged ants (*Monomorium*), beetles, aculeate hymenopterans, hunting-spiders (Thomisidae, Oxyopidae), and reportedly fruits and flowers, latter possibly taken with insects; also wax at accessible or abandoned bees' nests. Very active forager, gleaning in leaves and on bark, sallying for insects, hovering for them, flitting about; can fly-catch in mid-song, completing song as it lands. Submissive to *I. minor*, *I. variegatus* and *I. indicator* at bees' nests, but enters nest when others fight; also cleans wax from walls of old nests. Chases, and chased by, flycatchers (Muscicapidae), drongos (Dicruridae) and barbets.

**Breeding.** Probably Mar-Sept in N, also Nov-Feb (perhaps depending upon rainfall in 1, 2 or 3 rainy seasons); possibly Apr and more likely Sept-Jan in S. Male sings from 2-7 or more trees in 250-500 m<sup>2</sup>, sites sometimes ephemeral in drier habitats; winnowing flight display in circle below canopy when 2-3 birds present, probably related to breeding; many elements in aggressive displays, "fluff-gape", tail movements including cocking. Only documented host is Yellow-rumped Tinkerbird (*Pogoniulus bilineatus*); probable others are other tinkerbirds and small N race *irroratus* of Black-collared Barbet (*Lybius torquatus*); reports of Bennett's Woodpecker (*Campethera bennettii*) and White-eared Barbet (*Stactolaema leucotis*) as hosts are considered erroneous. Eggs, and incubation and fledging periods, unknown.

**Movements.** Certainly local movements occur, distances unknown.

**Status and Conservation.** Not globally threatened. Uncommon to locally common in most of range; local and uncommon in Kenya. Estimation of numbers difficult, as likely to be inconspicuous in areas where larger relatives are common.

**Bibliography.** Anon. (1998a), Benson & Benson (1977), Benson *et al.* (1971), Britton (1980), Carter (1978a), Chapin (1939, 1954, 1962), Clancey (1980b, 1985b), Dean (2000), Dowsett (1972a), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Fry *et al.* (1988), Ginn *et al.* (1989), Harrison *et al.* (1997), Irwin (1981), Irwin & Benson (1967), Jackson & Sclater (1938), Lewis & Pomeroy (1989), Lippens & Wille (1976), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Pinto (1983), Short & Horne (1979, 1985b, 1990a), Short, Horne & Chapin (1987), Short, Horne & Muringo-Gichuki (1990), Snow (1978), Steyn (1996), Tarboton (2001), Vincent (1935), Waiyaki & Bennun (2000), Zimmerman *et al.* (1996).

## 9. Least Honeyguide

### *Indicator exilis*

**French:** Indicateur menu      **German:** Barthoniganzeiger      **Spanish:** Indicador Chico

**Taxonomy.** *Melignothus exilis* Cassin, 1856, Moonda River, Gabon.

Relationships uncertain. In the past, *I. willcocksii*, *I. meliphilus* and even *I. minor* were often confused with present species; *I. pumilio* was also on occasion linked with present species. Nominative and race *pachyrhynchus* intergrade in broad zone from E Central African Republic and SW Sudan to NE Zaire and W Uganda, where precise limits of respective ranges unclear. Form *leona*, known from a single immature bird taken near Freetown (Sierra Leone), now considered a synonym of nominate. Birds collected in N Liberia (Wonegizi) said to be very similar to *I. willcocksii ansorgei* from neighbouring Guinea-Bissau, possibly representing undescribed race of present species; alternatively, they might in fact be referable to *I. willcocksii*. Three subspecies currently recognized.

#### Subspecies and Distribution.

*I. e. exilis* (Cassin, 1856) - Senegal E to E Central African Republic and NE Zaire, S to N Angola and NW Zambia.

*I. e. pachyrhynchus* (Heuglin, 1864) - SW Sudan and extreme E Zaire, E to W Kenya and S to NW Tanzania, Rwanda and Burundi.

*I. e. poensis* Alexander, 1903 - Bioko I (Fernando Póo).

**Descriptive notes.** c. 14 cm; 12-23 g. Well-marked, dark honeyguide. Both sexes of nominate race with white loreal area outlined darkly, distinct blackish malar stripes, dark-tipped white outer tail; breast light greyish-olive, paler on flanks and belly, dark streaks on flanks. Distinguished from very similar *I. minor* and *I. controstris* by smaller size, and very dark, sharply outlined flank streaks. Immature very like smaller *I. willcocksii* and *I. pumilio*, but stronger flank streaks and distinct malar. Races *pachyrhynchus* and *poensis* paler than nominate, *pachyrhynchus* also larger. **Voice.** Song faster "wheer-wheer-" to slower "pew-pew-"

series, very like those of *I. minor* and *I. controstris* but higher-pitched; also rattly, aggressive trill, "kwiew, kwiew", and aggressive "tsa-tsa-".

**Habitat.** Primary and secondary forest, old clearings, forest-shrub-grassland mosaic, gallery forest, plantations with trees, and edges of forest villages. Often near bee nests in forest. From lowlands up to 2400 m; on Bioko, usually found up to 600 m, but recorded up to 1400 m.

**Food and Feeding.** Eats beeswax; also larvae and eggs of bees, beetles, flies and their eggs, grasshoppers, aphids, scale insects (Coccidae), leafhoppers (Homoptera), caterpillars, ants, termites, and various spiders; also some fruits. Several may gather at bees' nest where wax is accessible; spends up to 66 minutes at a time feeding. Active, sallies for flying insects, investigates cavities.

**Breeding.** Season often prolonged, e.g. Aug-Mar in Liberia; recorded Feb and May in Cameroon, Jan and Jun in Zaire. Territorial, defends singing territory; displays in flight. Hosts unknown, but likely barbets, e.g. tinkerbirds (*Pogoniulus*) and Grey-throated Barbet (*Gymnopus bonapartei*). No information on eggs, or incubation and nestling periods; young probably leave foster-parents soon after fledging. Large gonads of juveniles suggest that they can breed in first year.

**Movements.** Probably sedentary.

**Status and Conservation.** Not globally threatened. Widespread, but not common; precise distribution and status in W Africa unclear. Uncommon in Sierra Leone; locally not uncommon in NW & N Liberia; local and uncommon in Kenya. Race *poensis* not rare; has adapted to cocoa and coffee plantations and other woodland areas modified by man. Known to occur in Kakamega Nature Reserve, Kenya. Appears to be somewhat adaptable, occurring in various wooded habitats. As with little-known forest species of all kinds, more information is required on its biology before any potential threats can be assessed.

**Bibliography.** Archer & Glen (1969), Aspinwall & Beel (1998), Bannerman (1933, 1953), Barlow *et al.* (1997), Bates (1930), Bennun & Njoroge (1999), Benson *et al.* (1971), Britton (1980), Brosset & Énard (1986), Cave &

## 10. Thick-billed Honeyguide

### *Indicator conirostris*

French: Indicateur à gros bec

Spanish: Indicador Picogruoso

German: Dickschnabel-Honiganzeiger

**Taxonomy.** *Melignothos conirostris* Cassin, 1856, Moonda River, Gabon.

Forms a superspecies with *I. minor*; these two have often been merged, but they occur together in W Uganda without interbreeding; they may interbreed in Nigeria, but are so similar in appearance that hybrids are difficult to establish. Supposedly paler form, described as race *pallidus*, considered in part variant of nominate, although some *pallidus* treated as synonymous with race *senegalensis* of *I. minor*. Two subspecies currently recognized.

**Subspecies and Distribution.**

*I. c. ussheri* Sharpe, 1902 - SE Sierra Leone disjunctly E to S Ghana.

*I. c. conirostris* (Cassin, 1856) - S Nigeria E to S Central African Republic and W Kenya, S patchily to N Angola and S & CE Zaire.

**Descriptive notes.** c. 15 cm; 24.5-38 g, rarely 50 g. Dark grey-olive forest honeyguide. Both sexes of nominate race with typical dark-tipped white outer tail, usually with dark malar stripes, white chin, white loreal mark and variable flank streaks. Distinguished from *I. exilis* by larger size, less green plumage, white loreal mark less strongly outlined in black, less dark flank streaks; from similar *I. minor* by greener, less grey upperparts, and darker underparts with streaked flanks. Immature darker, greener than adult, more white on tail, with fewer and weaker facial markings. Race *ussheri* yellower on crown and mantle, much paler below.

**Voice.** Song a series of "wit" or "weet" notes introduced by "whew", varies in slow to fast delivery, sounds identical to that of *I. minor*; vocal repertoire poorly known, requires study.

**Habitat.** Lowland and submontane forest, forest-grassland mosaic, including dense secondary and riverine forest, often near bees' nests and colonies of *Gymnabucco* barbets. Rarely to 2300 m.

**Food and Feeding.** Eats beeswax, also some bees, including sweatbees (*Trigona*), and caterpillars, termites and other insects; young eat food of hosts, including figs (*Ficus*) and other fruits. Hawks insects in the air. Several may gather at a bees' nest, along with *I. exilis* and other honeyguides.

**Breeding.** Season long, at least in N & E Zaire and Cameroon; Sept-Mar in Liberia; recorded in Oct-Nov in Sierra Leone. Little known. Male with singing territory to which females come, as probably do other males. Lays in nests of Grey-throated Barbet (*Gymnabucco bonapartei*), probably also of other colonial *Gymnabucco* barbets. Eggs laid in sets of at least 4, 1 egg per nest. No other information.

**Movements.** Sedentary.

**Status and Conservation.** Not globally threatened. Common locally in Sierra Leone; uncommon in Liberia; local and uncommon in Kenya. Known to occur in Tai National Park (Ivory Coast), Mt Kupé National Park (Cameroon), La Lopé National Park (Gabon) and Kakamega Nature Reserve, Kenya. Likely to be common in extensive forest. Its range is, however, contracting and becoming fragmented with forest clearance; species is being replaced by *I. minor* at edges and in cleared areas, and thus could become threatened. Hybridization with *I. minor* could also pose a threat.

**Bibliography.** Allport *et al.* (1989), Bannerman (1933, 1953), Bates (1930), Bennun & Njoroge (1999), Britton (1980), Chapin (1939), Christy & Clarke (1994), Colston & Curry-Lindahl (1986), Dean (2000), Demey & Fishpool (1994), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Field (1999), Friedmann (1971), Friedmann & Williams (1971), Fry *et al.* (1988), Gartshore (1989), Gatter (1997), Grimes (1987), Halleux (1994), Jackson & Sclater (1938), Lewis & Pomeroy (1989), Lippens & Wille (1976), Louette (1981b), Mackworth-Præd & Grant (1957, 1970), Pinto (1983), Prigogine (1971, 1972), Serle (1965), Short & Horne (1985b, 1992b), Snow (1978), Zimmerman (1972), Zimmerman *et al.* (1996).

## 11. Lesser Honeyguide

### *Indicator minor*

French: Petit Indicateur

German: Nasenstreif-Honiganzeiger

Spanish: Indicador Menor

**Taxonomy.** *Indicator minor* Stephens, 1815, Zwartkop River, Cape Province, South Africa.

Forms a superspecies with *I. conirostris*; these two have often been merged, but they occur together in W Uganda without interbreeding; they may interbreed in Nigeria, but are so similar in appearance that hybrids are difficult to establish. In past, often confused with *I. exilis* and other small honeyguides. Several additional named races now judged untenable: *erlangeri* considered synonymous with *diadematus*; *valens* with *teitensis*; *albicularis* with nominate *minor*; and *pallidus* and *alexanderi* synonymous with *senegalensis*, although some *pallidus* are probably variant form of *I. c. conirostris*. Six subspecies currently recognized.

**Subspecies and Distribution.**

*I. m. senegalensis* Neumann, 1908 - Senegambia E to Chad and W Sudan, S to C Ivory Coast, S Nigeria, N Cameroon and N Central African Republic.

*I. m. riggenbachii* Zedlitz, 1915 - C Cameroon E to SW Sudan, S to NE Zaire, W Uganda and Burundi.

*I. m. diadematus* Rüppell, 1837 - C Sudan E to N Somalia.

*I. m. teitensis* Neumann, 1900 - SE Sudan E to N Somalia, S & W (around lowland forest) to C Angola, NE Namibia, Zimbabwe and C Mozambique.

*I. m. damarensis* (Roberts, 1928) - S Angola and N Namibia.

*I. m. minor* Stephens, 1815 - S Namibia, SE Botswana, and S Mozambique to South Africa.

**Descriptive notes.** c. 15-16 cm; 21-39 g. Both sexes of nominate race dark greyish-green above, greyer or browner when worn, with white loreal spot, strong malar stripe; dark-tipped white outer

tail; much paler below, light olive-grey, with only weak streaks on flanks; black orbital skin makes dark eye look large. Distinguished from smaller honeyguides by head pattern; from *I. exilis* by less black outlining of flank streaks, less black about loreal spot; from *I. meliphilus* by more distinct malar stripes; distinction from *I. conirostris* difficult where they meet, but usually by paler grey breast, paler and less streaked above. Immature greener than adult, without clear markings on head, orbital skin greyer so that eye appears smaller. Races vary slightly in colour tones and size: *riggenbachii* more golden-green and more streaked above,

less olive-tinged below; *senegalensis* duller than *riggenbachii*, less streaked, usually whiter breast and belly; *diadematus* duller, browner; *teitensis* somewhat yellower above, paler below; *damarensis* greyer, paler above than nominate, often tinged brown, little or no olive, also malar indistinct or absent. **Voice.** Song a distinct, soft "pyew" or "wee-wee" followed by fast to slow series of 10-30 (usually 13-22) "wit" (occasionally "wi-nk") notes, repeated every 10-180 seconds in bouts of up to 2 hours; aggressive, song-like, short "pwee-wee-wee-wee" to "pwee-wit-it" series; also squeaky, aggressive "ty-yeah" or "tyeek"; aggressive trills, slow "di-di-di-" to fast "tddddd-", wavering or regular in pitch; also, squeak-trill calls, chattery alarm call, soft "kish", and hard "kik" notes. Nestlings call "ty-ty-", "tyew-tyew" (or "pyee-pyee"), when fed "tyiiliiliili-", these respectively at c. 12, 5 and 25 per second. Mechanical sounds a wing-rustling, in display flight by male over female sounds like irregularly running motorcycle.

**Habitat.** *Acacia*, *Brachystegia* and other woodland, wooded grassland (Sahel), bushland, fragmented forest and edges, also gardens, and orchards and other plantations, including in suburbs of cities; race *senegalensis* extends S into newly cleared areas of former forest; not found inside forest. Occasionally reaches 3000 m in E Africa.

**Food and Feeding.** Beeswax; also hymenopterans (wasps, ants, rarely honeybees), caterpillars, termites, mayflies, and spiders; nestlings take berries and other fruits and insects fed by hosts. Searches for holes and crevices in trees and rocks, investigates fires and noises of humans, follows (does not guide) humans and other honeyguides to wax sources. Pugnacious and persistent at bees' nests; immatures dominant over adults, sometimes over larger honeyguides at wax sources. Hawks insects adeptly; works over bark and foliage of trees. Drinks, occasionally bathes.

**Breeding.** Recorded in all months in areas where seasons vary year to year; mainly Sept-Mar in S Africa. Male establishes singing territory, sometimes traditional site, often ephemeral in tropics, centred around 1-4 trees, sings much of day for 2-10 months in tropics, c. 6 months in S Africa; females come to territory to mate, copulations usually low in bush or tree nearby; male may perform winnowing flight display over female before copulation. Recorded hosts are 6 species of social barbet (*Stactolaema whytii*, *S. anchietae*, *S. olivacea*, *Lybius chaplini*, *L. leucocephalus* and *L. torquatus*), 3 non-social barbets (*Tricholaema diademata*, *T. leucomelas* and *Trachypus vaillantii*), Rufous-necked Wryneck (*Jynx ruficollis*) and other woodpeckers (*Campethera bennettii*, *C. abingoni*, probably *C. nubicola*, and *Dendrocopos fuscescens*), 2 bee-eaters (*Merops pusillus* and *M. oboeatus*), Striped Kingfisher (*Halcyon chelicuti*), White-throated Swallow (*Hirundo albicularis*), Violet-backed Starling (*Cinnyricinclus leucogaster*), African Pied Starling (*Spreo bicolor*), and Yellow-throated Petronia (*Petronia supercilialis*); defends some host nests against other conspecifics; male sometimes assists female to enter nest. Eggs 2-4, laid in series, up to c. 20 eggs per season; incubation period 12-16 days; hatchling with bill hooks, kills host's young, or breaks eggs; fledges at c. 38 days, then chased out of the area by some barbets; fledgling does not return to nest, may not follow foster-parents, soon leaves to search cavities for beeswax. Adult longevity sometimes more than 8 years.

**Movements.** Some local post-breeding movements by young and adults; disperses 10 km or more.

**Status and Conservation.** Not globally threatened. Common in Sierra Leone; uncommon in Somalia, where no recent records from N; locally common and widespread in Kenya, Tanzania and South Africa. Highly adaptable species, with no apparent threats.

**Bibliography.** Archer & Godman (1937-1961), Ash & Miskell (1998), Bannerman (1933, 1953), Barlow *et al.* (1997), Bates (1930), Benson & Benson (1977), Benson *et al.* (1971), Britton (1980), Brown & Britton (1980), Cave & Macdonald (1955), Celliers (1994), Chapin (1939), Cheke & Walsh (1996), Clancey (1964, 1977a), Colebrook-Robjent (1984), Colebrook-Robjent & Stjernstedt (1976), Cunningham-van Someren (1972), Cyrus (1988), Dean (2000), Dedekind (1997), Dowsett (1990), Dowsett & Dowsett-Lemaire (1991, 1993), Dowsett & Forbes-Watson (1993), Earle & Grobler (1987), Elgood *et al.* (1994), Field (1999), Forbes-Watson (1977), Friedmann (1930a), Friedmann & Williams (1971), Fry *et al.* (1988), Ginn *et al.* (1989), Gore (1990), Graaf (1996), Grimes (1987), Hamner (1997), Harrison *et al.* (1997), Hoesch (1957), Horne & Short (1988), Irwin (1981), Lewis & Pomeroy (1989), Lippens & Wille (1976), Liversidge (1991), Lockwood (1981), Longrigg (1993), Louette (1981b), Mackworth-Præd & Grant (1957, 1962, 1970), Maclean (1993), van der Merwe (1986), Moyer (1980), Payne (1992), Penny (1994), Pinto (1983), Ranger (1955), Roberts (1956), Rushforth (1999), Short & Horne (1979, 1983a, 1985b, 1988a, 1990a, 1992b, 1992c), Short *et al.* (1990), Skead (1950, 1951), Snow (1978), van Someren (1956), Spottiswoode (1994), Steyn (1996), Steyn & Myburgh (1986), Steyn & Scott (1974), Tarboton (2001), Thiollay (1985a), Underhill, G.D. (1991), Underhill, G.D. & Underhill (1992a), Underhill, L.G. (1995), Van der Merwe (1986), Winterbottom (1969), van Zijl (1994), Zimmerman *et al.* (1996).

## 12. Spotted Honeyguide

### *Indicator maculatus*

French: Indicateur tacheté

German: Tropfenbrust-Honiganzeiger

Spanish: Indicador Moteado

**Taxonomy.** *Indicator maculatus* G. R. Gray, 1847, no locality = Gambia.

Forms a superspecies with *I. variegatus*, marginally overlapping in SW Sudan and W Uganda. Proposed race *faae* synonymous with nominate *maculatus*; *theresae* with *stictithorax*. E race often listed as "*stictithorax*" but original spelling, *stictithorax*, must stand. Two subspecies currently recognized.

**Subspecies and Distribution.**

*I. m. maculatus* G. R. Gray, 1847 - Gambia to Nigeria.

*I. m. stictithorax* Reichenow, 1877 - S Cameroon E to SW Sudan, S to N Angola (Cabinda), S & E Zaire and SW Uganda.

**Descriptive notes.** c. 18 cm; 42-54 g. Both sexes olive and green, with distinct pale spots on breast; dark tail has dark-tipped white outer feathers; outermost rectrices very short. Distinguished from similar *I. variegatus* by greener upperparts, less white underparts, with throat to breast more spotted, less scaly. Immature more barred and streaked, less spotted below, with whiter tail. Race *stictithorax* has paler and greener crown; more streaky on face, more olive and yellow on underparts. **Voice.** Little known; song a trill, slightly faster than that of *I. variegatus*, "brrrrrr" for up to 3 seconds; chattering calls; also wing sounds in flight display.

**Habitat.** Primary and dense secondary forest, forest clearings, riverine forest, and much-overgrown farms and plantations; mainly at middle to lower levels, below 15 m. Ranges up to 2130 m locally.

**Food and Feeding.** Beeswax; also feeds on insects, such as larval moths and butterflies, ants, beetles and termites, and spiders; probably also fruits; young eat foods of host. Attracted to beeswax, searches abandoned bees' nests. Forages for insects mainly in canopy, but comes down to undergrowth for beeswax. Follows humans in forest.

**Breeding.** Gonadal and egg data suggest long season, probably Aug-Mar in Liberia; recorded in Dec in Sierra Leone. Male in singing territory much of year, some territories maintained by same or replacement male for up to 5 years; sometimes winnowing flight display. Hosts largely unknown, suspected to include social barbets of genus *Gymnobucco*, and Buff-spotted Woodpecker (*Campethera nivos*), latter similar in pattern to present species; Brown-eared Woodpecker (*Campethera caroli*) reported as host in Sierra Leone; in Gabon, was immediately attracted by playback of call of Golden-crowned Woodpecker (*Dendropicus xantholophus*). No other breeding information available.

**Movements.** Sedentary.

**Status and Conservation.** Not globally threatened. Rare and sporadic in Gambia, and few records in Senegal; not uncommon in parts of Sierra Leone; not uncommon in Liberia. Known to occur in Abuko Nature Reserve, Gambia, in Korup National Park, Cameroon, and in La Lopé National Park, Gabon. As a rather forest-dependent bird, it should be monitored, because forest habitat suffering clearance and fragmentation. Information on breeding and hosts essential for any conservation efforts.

**Bibliography.** Allport *et al.* (1989), Bannerman (1933, 1953), Barlow *et al.* (1997), Bates (1930), Britton (1980), Brosset & Énard (1986), Chapin (1939), Cheke & Walsh (1996), Christy & Clarke (1994), Colston & Curry-Lindahl (1986), Dowsett (1989b), Dowsett & Dowsett-Lemaire (1991, 1993), Dowsett & Forbes-Watson (1993), Dyer *et al.* (1986), Elgood *et al.* (1994), Field (1999), Friedmann (1978a), Friedmann & Williams (1971), Fry *et al.* (1988), Gartshore (1989), Gatter (1997), Germain & Cornet (1994), Gore (1990), Grimes (1987), Halleux (1994), Horne & Short (1988), Lippens & Wille (1976), Louette (1981b), Mackworth-Præd & Grant (1957, 1970), Morel & Morel (1990), Nikolaus (1987), Payne (1986), Pinto (1983), Sande (2000), Short & Horne (1985b, 1988b, 1992b, 1992c), Snow (1978), Thiollay (1985a), Wachter (1993), Williams (1951).

## 13. Scaly-throated Honeyguide

### *Indicator variegatus*

**French:** Indicateur varié **German:** Strichelstirn-Honiganzeiger **Spanish:** Indicateur Variegado  
**Other common names:** Variegated Honeyguide

**Taxonomy.** *Indicator variegatus* Lesson, 1830, Knysna, South Africa.

Forms a superspecies with *I. maculatus*, barely overlapping with it in SW Sudan and W Uganda. Despite widespread distribution, exhibits mosaic geographical pattern of variation, as well as varying individually, seasonally and with age, rendering accurate racial subdivision impossible for present; birds from S Somalia to NE Tanzania formerly separated in race *jubaensis*. Monotypic.

**Distribution.** S Ethiopia and S Sudan to S Somalia, S through E Africa (W to E Rwanda and E Burundi), and from C Angola E to E Zaire and W Tanzania, S to Zambia, E Zimbabwe and E Cape Province.

**Descriptive notes.** c. 18-19 cm; 34-55 g, rarely up to 61 g. Both sexes green and olive with black-tipped white outer tail pattern, very short outermost tail feathers; streaky crown and face, and rather variable scaly to streaky olive-grey and white throat and breast. Distinguished from *I. maculatus* by less green upperparts, paler underparts less spotted. Immature has spotted crown, criss-cross pattern of streaks, bars below, and nearly all-white outer tail; male becomes black-gaped, female pink-gaped with some dusky grey that increases in older females. VOICE. Song a trill 0.6-4 seconds long, generally a bit slower than in *I. maculatus*, in

quality churring or like policeman's whistle, soft or loud, faster or slower, occasionally croaky; alternate song 3-8 whistled pipes, during territory establishment or in interactions with other males; song-like "trill-pyew" a common, aggressive, often wavering call; females interact using aggressive chattering with gaping, in several variations; also a post-copulatory, high, whistled series; nestlings give chatter "chess" calls, yelps, and wailing calls. Wing-rustling sounds in encounters, and in "searching" flights over prospective feeding sites, humans, and other honeyguides; also "wup-wup" sounds in display-flight.

**Habitat.** Diverse woodland, forest patches, riverine woods, thickets, overgrown plantations, bamboo, juniper woods, also dense streamside thickets in some dry areas. Mostly nonobtrusive except at beeswax sources and where singing. Usually below c. 2200 m, rarely to 3350 m.

**Food and Feeding.** Beeswax eaten all year; takes bee larvae and eggs, also termites, flies, caterpillars, ants, beetles, aphids, sometimes other arthropods; nestlings eat foods of host, including fruits. Follows humans in woods, inquisitive, explores cavities; gleans along bark and limbs, visits flowers for insects; also hawks insects. Aggressive at bees' nests; females dominant over males, immatures over adults. Claps wax between legs while eating, can carry off comb weighing up to 11 g. Drinks, bathes. Sometimes joins mixed-species foraging flocks.

**Breeding.** Lays in diverse seasons in tropics, mainly Aug-Feb in S Africa. Male sings from trees or bushes in territory, territory sometimes traditional, held for up to 8 years, or sometimes shifting, even within a season; in tropics sings all year, even in moult; female may breed mainly with 1 male, or visit and copulate with several; winnowing flight by male can precede or follow copulation. Known hosts include 6 species of woodpecker (*Campethera abingoni*, *C. nubica*, *Dendropicus fuscescens*, *D. grisecephalus*, *D. goertae* and *D. namaquus*), Yellow-rumped Tinkerbird (*Pogonius bilineatus*), Whyte's Barbet (*Stactolaema whytii*), Black-collared Barbet (*Lybius torquatus*), probably also other woodpeckers and barbets, possibly also a swift (*Apus horus*) and a petronia (*Petronia superciliosa*). Female lays eggs in series of 3-5, several series in clutch, 1 egg in each nest; incubation period c. 18 days; hatching has bill hooks, kills host's young or destroys eggs; nestling period c. 28 days; fledgling does not return to nest, may beg indiscriminately from passing woodpeckers,

and from adults of its own species; independent in 1-4 days or so. Male first breeds at 3 or more years, occasionally 2, female at 2 years. Longevity 10 or more years.

**Movements.** Sedentary, but regularly moves up to 10 km, even 20 km, when seeking food; disperses to 10 km or more.

**Status and Conservation.** Not globally threatened. Relatively common, and widespread. Uncommon in Somalia; generally uncommon in Kenya and Tanzania. Fairly common in Ngoye Forest, South Africa, perhaps in part due to strong local population of Green Barbet (*Stactolaema olivacea*), which it parasitizes. Known to occur in Impenetrable (Bwindi) Forest National Park, Uganda, in Nyungwe Forest Reserve, Rwanda, and in Mkuzi Reserve, South Africa. No known threats identified.

**Bibliography.** Anon. (1998a), Archer & Glen (1969), Ash & Miskell (1998), Beel (1997), Benson & Benson (1977), Britton (1980), Brown & Britton (1980), Cave & Macdonald (1955), Chapin (1939), Clancey (1964, 1977b, 1979b, 1985a), Davey (1994), Dean (2000), Dowsett (1990), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Dowsett-Lemaire (1983b), Friedmann (1930a), Friedmann & Williams (1971), Fry *et al.* (1988), Furlong (2000), Ginn *et al.* (1989), Harrison *et al.* (1997), Horne & Short (1988), Irwin (1981), Irwin & Benson (1967), Jackson & Sclater (1938), Lewis & Pomeroy (1989), Lippens & Wille (1976), Mackworth-Præd & Grant (1957, 1962, 1970), Maclean (1993), Ndong'ang'a & Borghesio (1999), Newby-Varty (1946), Nikolaus (1987), Payne (1986), Pinto (1983), Ranger (1955), Schultz (1991), Short & Horne (1985b, 1988b, 1990a, 1992c), Snow (1978), Steyn (1996), Tarboton (2001), Tarboton *et al.* (1987), Taylor (1983), Taylor & Taylor (1988), Thomson (1993), Zimmerman *et al.* (1996).

## 14. Yellow-rumped Honeyguide

### *Indicator xanthonotus*

**French:** Indicateur à dos jaune **German:** Gelbbürzel-Honiganzeiger **Spanish:** Indicateur Indio  
**Other common names:** Himalayan/Indian/Orange-rumped Honeyguide

**Taxonomy.** *Indicator xanthonotus* Blyth, 1842, Darjeeling.

Closest relatives are probably *I. archipelagicus* and *I. indicator*. Probably derived from early Asian invasion of *Indicator* from Africa, and originating from same ancestral stock that gave rise to *I. archipelagicus*; both have bright yellow in plumage and short outer rectrix, a combination of features shared only with African *I. indicator*. Birds from NE Assam, Nagaland and Manipur to N Myanmar, described as race *fulvus*, now considered inseparable from nominate. Two subspecies currently recognized.

**Subspecies and Distribution.**

*I. x. radcliffi* Hume, 1870 - NE Pakistan (presumed extinct), and Himalayan slopes of NW India, possibly to W Nepal.

*I. x. xanthonotus* Blyth, 1842 - Nepal E to NE India, SE Tibet and N Myanmar.

**Descriptive notes.** 15-16 cm; male 29-34 g, female 25-31 g. Small-headed honeyguide with bright yellow in plumage. Male nominate race greenish-grey, with yellow to gold forehead, crown and face, conspicuous yellow or orange rump patch, white on inner webs of tertials, and broad dark ventral streaks; tail appears all dark, square-ended. Female with more restricted yellow, not gold or orange-gold, on head, and yellower rump than male. Immature duller. Race *radcliffi* plainer, greyer, yellower areas less gold and orange, and reduced, vague streaking below. VOICE. Little known, but apparently does not sing; calls include "weet" or "cheet", chipping notes, "tzt", and, in flight, "chaenp-chaenp".

**Habitat.** Rocky, wooded gorges and streams with cliffs having colonies of giant honeybee (*Apis dorsata*); usually with deciduous-coniferous forest nearby. Mainly at 1500-2300 m, but also 610-3500 m.

**Food and Feeding.** Beeswax a staple food; also takes insects in flight, mostly smaller than bees, though reported to take some bees. Gathers at bees' nests on rock faces, eats unguarded or exposed wax, and fallen pieces; also takes wax at abandoned nests. Groups of up to 50 may come to exposed wax source after breeding season.

**Breeding.** Apr-Jun. Male sets up territory along cliff face with bees' nests, drives off other males, but sometimes several males with territories if cliff extensive and has numerous bees' nests; struts, raises head, flicks wings up and down, copulates with as many as 18 females; if male absent, others take over and breed with incoming females; females visit more than one male, copulate with them. Territory sometimes defended for much of year, except when birds moulting or if numbers of young and adults seeking wax on territory become too great after breeding. Probably nest parasite, but hosts unknown. No information on eggs, incubation, nestling, or fledgling period; single report of female feeding an immature.

**Movements.** Some evidence for upslope, post-breeding movement, and some individuals probably migrate downslope for the winter, but few data available.

**Status and Conservation.** Not globally threatened. Currently considered Near-threatened. Probably extinct in Pakistan; very rare and local in India; local and uncommon in Nepal and Bhutan; rare in SE Tibet and also in N Myanmar. Conservation status perhaps merits reassessment. Lack of knowledge of this species' breeding biology, including possible hosts, and of its behaviour away from bees' nests makes it difficult to assess any threats to it; it is possible that harvesting of honey may disrupt its breeding activities in places.

**Bibliography.** Ali (1962, 1977), Ali & Ripley (1983), Ali *et al.* (1996), Baker (1934a), Bishop (1999a), Choudhury (2001), Cronin & Sherman (1977), Diesselhorst (1968), Fleming (1963), Fleming & Traylor (1968), Fleming *et al.* (1976), Friedmann (1976), Grimmett *et al.* (1998), Hussain (1978), Hussain & Ali (1979, 1993), Inskipp & Inskipp (1991), Poole (1995), Ripley (1982), Roberts (1991), Robson (2000), Short & Horne (1981), Smythies (1986), Stattersfield & Capper (2000), Underwood (1992).

## 15. Sunda Honeyguide

### *Indicator archipelagicus*

**French:** Indicateur archipelagique **German:** Malaiehoniganzeiger **Spanish:** Indicateur Malayo  
**Other common names:** Malay/Malaysian Honeyguide

**Taxonomy.** *Indicator archipelagicus* Temminck, 1832, Pontianak, Borneo.

Closest relatives are probably *I. xanthonotus* and *I. indicator*. Thought to have derived from early Asian invasion of *Indicator* from Africa, and thus from same ancestral stock as *I. xanthonotus*; bright yellow in plumage and short outer rectrix exhibited by both Asian species, and this combination otherwise shared only with African *I. indicator*. Monotypic.

**Distribution.** Forest of lowland S peninsular Thailand, possibly adjacent Myanmar, and Peninsular Malaysia (except S), Sumatra and Borneo.

**Descriptive notes.** c. 16 cm; 23-38.5 g. Non-descript olive bird with pointed bill. Male dark olive-brown above, with bright yellow patch on inner leading edge of wing, some white in outer tail, often some white on rump and uppertail-coverts; white to yellow-grey below with blotchy or vaguely streaked appearance, more streaked on thighs and flanks; eye red. Female lacks yellow in wing. Immature like female, but greener above, with more white showing in rump and uppertail-coverts, more streaky or scaly below; eye brown. VOICE. Cat-like "kiaaw" given singly, or introducing trilling song lasting 1-3 (rarely 7) seconds at c. 19

elements per second; trilling-grating calls in interactions.

**Habitat.** Lowland dipterocarp forest, also at times adjacent cocoa plantations and gardens; associates with open-nesting honeybees (*Apis dorsata* and *A. florea*). Occurs at up to 700 m, sometimes to 900 m.

**Food and Feeding.** Poorly known. Eats beeswax, also insects, including some adult and larval bees; observed around bees' nests and at flowering trees with bees present. Method used to obtain wax from exposed but bee-covered plates of comb not described. May react to human presence, but does not "guide".

**Breeding.** Breeds Jan-Aug or Sept. Male sings from several trees in territory, stretches neck, puffs throat, may flick wings as sings. Not known if nest-parasitic, and no information on any other aspects of breeding; observations of singing suggest breeding system resembling those of Afrotropical honeyguides.

**Movements.** Sedentary.

**Status and Conservation.** Not globally threatened. Currently considered Near-threatened. Generally uncommon to rare; scarce to uncommon in Thailand and Malay Peninsula, with range contraction, now apparently absent in S Peninsular Malaysia. Known to occur in Khao Nor Chuchi (Khao Pra Bang Kham Non-Hunting Area), Thailand, in Batu Punggul Forest Reserve, Peninsular Malaysia, and in Gunung Mulu National Park, Peninsular Malaysia. Clearing of forest throughout species' range makes it imperative that information be obtained on its breeding habits, in order that any potential threats can be adequately assessed.

**Bibliography.** Friedmann (1976), Gibson-Hill (1949a), Glenister (1971), Gönner (2000), Harrison (1950), Holmes (1996, 1997), Holmes & Burton (1987), Lekagul & Round (1991), MacKinnon & Philipps (1993), van Marle & Voous (1988), Medway & Wells (1976), Payne (1986), Robinson (1928), Robinson & Chasen (1939), Robson (1988, 2000), Round (1988), Short & Horne (1991), Smythies (1999), Stattersfield & Capper (2000), Strange (2000), Wells (1974, 1985, 1999), Wilkinson, Dutson & Sheldon (1991), Wong (1984, 1986).

## 16. Greater Honeyguide

### *Indicator indicator*

**French:** Grand Indicateur **German:** Schwarzkohl-Honiganzeiger **Spanish:** Indicador Grande  
**Other common names:** Black-throated Honeyguide

**Taxonomy.** *Cuculus indicator* Sparrman, 1777, Great Fish River, Cape Province, South Africa. Not very closely related to African congeners; perhaps closest to African *I. variegatus* and *I. minor* and Oriental *I. xanthonotus* and *I. archipelagicus*; possibly not too distant from *Melichneutes robustus*. Moderate individual, seasonal and altitudinal variation, along with mosaic pattern of geographical variation, makes racial subdivision impracticable. Monotypic.

**Distribution.** Sahel zone from Senegambia and S Mali across to Eritrea, S to near coast of W Africa, and S (around main forested belt) through EC Africa including E & S Zaire, much of E Africa, and from Angola, NE Namibia and N & E Botswana to Mozambique, S to Cape Province.

**Descriptive notes.** 19-20 cm; 34-62 g, mostly 40-57 g. Distinctive. Male unmistakable, brown above, with black throat, white cheeks, pink bill, yellow or golden-yellow shoulder patch, white outer-tail patches, white underparts with dark streaks on flanks; outer tail feathers short. Female duller, browner-looking, without cheek patch, has throat white (often discoloured), bill darker, pale underparts with fine flank streaks. Immature very different, olive-brown above with yellow-tipped forecrown and forehead feathers, creamy-white rump, yellow or gold on much of throat and especially breast, pearly white lower under-

parts lacking streaks; orbital skin blue at fledging; takes up to 1 year to gain adult plumage. VOICE. Song, usually by male, sometimes by female, soft "peew" and then series of "tor-vik" notes; loud "feee" or "feeeeee" aggressive note by immature, and by male in intense intraspecific and interspecific conflicts; also assorted piping, peeping, "tya" and noisy chattering notes that can be combined, and used variously in aggression as well as in guiding, in last case notes often doubled; chattering trills, "tya-trills" and piping with "feee" notes may be uttered after copulation; begging calls insistent "kreeek" or "karrreeek", also variable but not host-specific. Mechanical signals include wing-rustling, bill-snapping, and "wa-da, wa-da" in aerial display by male.

**Habitat.** Open woods, woodland edges, bushland, streamside woods, bushes in dry areas, plantations, gardens with trees, thickets, and trees lining suburban streets; often in vicinity of bees' nests. Occurs at up to 2000 m, occasionally to 3000 m in E Africa.

**Food and Feeding.** Eats mainly beeswax, also grubs and eggs of honeybees, and diverse insects, including termites, winged ants, flies and others; nestling eats foods of host, including fruits. Aggressive at bees' nests, immature always superdominant; pecks at wax while standing, often carries off pieces to 10 g or more in weight. Fly-catches for insects. Leads humans to bees' nests by giving agitated chatter, piping calls; most guides are immatures or subadults, some adults never guide; guiding behaviour very erratic, in some suburbs apparently not practised at all. Bees' nests often accessible, and frequently abandoned by bees; adults monitor several, even many, nests. Also attracted to noise of wood-chopping, and fires; follows other honeyguides. Digests wax readily, requires drinking water.

**Breeding.** Accords with breeding seasons of hosts; in dry areas of tropics breeds in wet seasons, in wet regions breeds in dry seasons; recorded in Apr in Sierra Leone; generally in austral spring-

## Family INDICATORIDAE (HONEYGUIDES) SPECIES ACCOUNTS

summer in S Africa. Male sings from one of a series of perches in singing territory, latter traditional or shifting within or between years, may give winnowing flight display in circle or ellipse over attracted female, both on territory and at feeding site. Hosts at least 1 roller (*Coracias abyssinicus*), Hoopoe (*Upupa epops*), 3 woodhoopoes (*Phoeniculus purpureus*, *Rhinopomastus cyanomelas*, *R. minor*), 4 kingfishers (*Ceyx pictus*, *Halcyon chelictus*, *H. albiventris*, *H. leucocephala*), 8 bee-eaters (*Merops pusillus*, *M. oreobates*, *M. bullockoides*, *M. superciliosus*, *M. nubicus*, *M. hirundineus*, *M. orientalis*, *M. boehmi*), 3 barbets (*Trachyphonus vaillantii*, *Tricholaema leucomelas*, *Lybius torquatus*), 6 woodpeckers (*Jynx ruficollis*, *Campethera nubicus*, *C. notata*, *C. abingoni*, *C. tullbergi*, *Dendropicus goertae*), 4 swallows (*Hirundo cucullata*, *H. semirufa*, *H. albigularis*, *Riparia cincta*), 3 starlings (*Lamprolornis chalybeus*, *L. nitens*, *Spreo bicolor*), 2 thrushes (*Myrmecocichla aethiops*, *M. formicivora*), 2 sparrows (*Passer griseus*, *Petronia supercilialis*), a tit (*Parus niger*), and a sunbird (*Nectarinia senegalensis*); other hosts likely, but may "dump" eggs, e.g. in nests of other barbets and woodpeckers, thrushes, bulbuls (*Pycnonotidae*), starlings and orioles (*Oriolidae*). Up to 20 eggs, laid in sets of up to 5, usually 1 egg per nest, frequently punctures host's eggs; incubation period unknown, short; hatchling with membranous bill hooks, lacerates and kills host's young, hooks lost in 2 or more weeks; fledges at 35-40 days, remains in trees neither returning to nest to roost nor following foster-parents; usually independent in c. 3 days. Longevity sometimes more than 12 years.

**Movements.** Essentially resident, but disperses to 20 km or more; regularly moves 8-10 km; juvenile disperses to 8 km or more in few days.

**Status and Conservation.** Not globally threatened. Fairly common, and widespread; occurs widely in the Sahel and sub-Saharan Africa, except in desert, forest and grassland; in all but desert parts of W South Africa. Probably not uncommon in Sierra Leone; status in Liberia uncertain, apparently rare; uncommon in Somalia; rather local but widespread in Kenya and N Tanzania. Reasonably adaptable in diverse habitats, and expanding into formerly forested areas. Present in numerous national parks, e.g. Murchison Falls (Uganda), Mikumi (Tanzania) and Comoe (Ivory Coast).

**Bibliography.** Ash & Miskell (1998), Balança & de Visscher (1997), Bannerman (1933, 1953), Barbour (1973), Barlow *et al.* (1997), Bates (1930), Benson & Benson (1977), Benson *et al.* (1971), Berruti *et al.* (1995), Bretagnolle (1993), Britton (1980), Carter (1978b), Cave & Macdonald (1955), Chapin (1939), Cheke & Walsh (1996), Chiweshe & Dale (2000), Clancey (1964), Dean (1985, 2000), Dean *et al.* (1990), Demey *et al.* (2000), Diamond & Place (1988), Dowsett (1990), Dowsett & Dowsett-Lemaire (1991, 1993), Dowsett & Forbes-Watson (1993), Dowsett-Lemaire *et al.* (1993), Dyer (1975), Earle & Herholdt (1987), Elgood *et al.* (1994), Field (1999), Friedmann (1930a, 1930b, 1958a, 1970), Fry (1974, 1977), Fry *et al.* (1988), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Haagner (1907, 1911), Hammer (1997), Harrison *et al.* (1997), Irwin (1981), Isack (1987, 1988a, 1988b, 1999), Isack & Reyer (1989), Jubb (1966, 1968), Kingdon (1977), Lewis & Pomeroy (1989), Lippens & Wille (1976), Liversidge (1991), Mackworth-Præd & Grant (1957, 1962, 1970), Maclean (1993), Macpherson (1975), Madge & Cunningham-van Someren (1975), Ndang'ang'a & Borghesio (1999), Nikolaus (1987), Parker (1966), Payne (1986, 1992), Penry (1994), Pinto (1983), Plowes (1948), Priest (1934), Prigogine (1971), Ranger (1955), Roberts (1956), Short & Horne (1985b, 1990a, 1992c), Skead (1950, 1951), Snow (1978), Storer (1992), Tarboton (2001), Tarboton *et al.* (1987), Traylor (1963), Tucker (1975, 1976), Verheyen (1953), Wood (1940), Zimmerman *et al.* (1996).

## Genus MELICHNEUTES Reichenow, 1910

### 17. Lyre-tailed Honeyguide

#### *Melichneutes robustus*

**French:** Indicateur à queue en lyre **Spanish:** Indicador Lira  
**German:** Leierschwanz-Honiganzeiger

**Taxonomy.** *Melichneutes robustus* Bates, 1909, Biteye, River Dja, Cameroon.

Closely related to *Indicator*, wherein perhaps closest to *I. indicator*, but separated generically on basis of unique tail and undertail-coverts, as well as voice and behaviour. Monotypic.

**Distribution.** Disjunctly from Sierra Leone and Guinea E to S Cameroon, SE Central African Republic, N Zaire and SW Uganda, S to N Angola and SC & E Zaire.

**Descriptive notes.** c. 18 cm; 47-61.5 g. Dull colours with unique lyre-shaped tail diagnostic. Male with outward-curling tail feathers, elongated central undertail-coverts nearly as long as longest rectrices, outermost tail feathers tiny. Distinguished from somewhat similar female *I. indicator* by slightly larger size, bronzy tinge above, distinctive tail. Female with shorter tail, but shape still distinctive. Immature darker, also with "bent" tail feathers. VOICE. In aerial display loud "pee-pee" sounds at 4-5 per second, grading into "ve-bek, ve-vek" or "kwa-ba, kwa-ba" sounds at c. 2 per second, latter apparently made by air passing through spread tail feathers, audible for 1 km; also has buzzy, chattery calls and "kutta-kutta" notes.

**Habitat.** Primary forest and adjacent edges, logged forest, secondary forest and plantations; attracted to bees' nests; frequents colonies of barbets of genus *Gymnobucco*. In lowlands, uncommonly to 2000 m.

**Food and Feeding.** Eats beeswax; also takes termites, other insects, spiders, and fig (*Ficus*) fruits. Foraging habits largely unknown.

**Breeding.** Season mainly inferred from aerial displays, but may display when not breeding; Oct-Dec in Sierra Leone, Nov-Apr in Liberia, Dec-Jun in most of W Africa, Sept-Nov in Nigeria and Cameroon; Dec-Mar, and more late Apr-Sept (dry season), in Gabon; Mar-Sept in Congo and Zaire. Male displays by circling upwards and diving down with wing sounds; not known if female also displays aerially. Hosts unknown, suspected are barbets of genus *Gymnobucco* and perhaps *Pogonius*. No information on eggs, or on other aspects of breeding.

**Movements.** Presumably sedentary.

**Status and Conservation.** Not globally threatened. Little known, and only occasionally common in and near primary forest. Distribution known partly from display sounds alone; relatively few specimens. Locally not uncommon in Sierra Leone, where 12 display-sites/km<sup>2</sup>; uncommon to not uncommon in Liberia, where 1 male/3-4 km<sup>2</sup>; display-sites c. 1 km apart in Gabon forest (1 site

1300 x 400 m). Known to occur in Taï Forest National Park, Ivory Coast, in Gola Forests Reserves, Sierra Leone, and in La Lopé National Park, Gabon. Probably rather vulnerable in places; information required on species' breeding biology and ecology.  
**Bibliography.** Allport *et al.* (1989), Bannerman (1933, 1953), Bates (1930), Brosset & Énard (1986), Chapin (1939, 1954), Christy & Clarke (1994), Colston & Curry-Lindahl (1986), Dean (2000), Demey & Fishpool

(1991), Dowsett (1989b), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Dranzoa (1994), Elgood *et al.* (1994), Field (1999), Friedmann (1978a, 1978b), Fry *et al.* (1988), Gatter (1997), Grimes (1987), Halleux (1994), Lippens & Wille (1976), Louette (1981b), Mackworth-Praed & Grant (1970), Pinto (1983), Prigogine (1971), Rodewald *et al.* (1994), Rougeot (1951, 1959), Serle (1957), Short & Horne (1985b), Snow (1978), Thiollay (1985a).

Class AVES  
Order PICIFORMES  
**Family PICIDAE (WOODPECKERS)**

- Small to rather large birds with straight medium-length bill, short legs with four long toes, some species with only three toes; tail of most long, with strong central feathers; long tongue with barbed tip.
- 7.5-60 cm.

- Holarctic, Neotropical, Afrotropical and Oriental.
- Forest, woodland and grassland, from cold temperate zone to tropics.
- 28 genera, 216 species, 661 taxa.
- 11 species threatened; none definitely extinct since 1600.

### Systematics

Fossil bones of woodpeckers are rarely found. According to S. L. Olson, the earliest examples from the Northern Hemisphere appear from the middle and late Miocene, some 16-12 million years ago and about 10 million years ago, respectively. In 2001, however, G. Mayr reported a fossil tarsometatarsus of a piciform bird from the late Oligocene of Germany, thus dating back about 25 million years. It appears similar in size and proportions to that of a modern *Dendropicos*, the Cardinal Woodpecker (*Dendropicos fuscescens*). A feather preserved in amber that was discovered on the Caribbean island of Hispaniola constitutes the oldest fossil record of a woodpecker in the New World. As reported by R. C. Laybourne and colleagues in 1994, it is at least 24 million years old, thus originating from before the onset of the Miocene, and it reveals close relationships with the extant Antillean Piculet (*Nesocittes micromegas*). Furthermore, holes found in the petrified woods of Arizona and Wyoming, which are 40-50 million years old, suggest that woodpeckers were present in the Americas at a very much earlier period.

In fact, on the basis of the DNA-DNA hybridization data obtained by C. G. Sibley and J. E. Ahlquist, one may speculate that the true woodpeckers diverged from their closest relatives at a very early stage, some 50-53 million years ago. Careful analysis of data from the mitochondrial cytochrome *b* gene and the nuclear-encoded  $\alpha$ -fibrinogen intron 7 suggests that the piculets of the modern subfamily Picumninae diverged from the other woodpeckers 9-15 million years ago, and that the base of the Picini branch dates back to about 7.5 million years. Modern genera were probably established about five million years ago.

Piciform birds are among the oldest of all avian forms. Morphological analyses and molecular data suggest that the woodpeckers (Picidae), the honeyguides (Indicatoridae), the barbets (Capitonidae) and the toucans (Ramphastidae) descended from a common stock. Classical morphological analyses, biochemical data of proteins and DNA all support the notion that the closest relatives of the woodpeckers are the honeyguides, with which they are then linked to the barbets. Neither morphological nor molecular data supply any evidence for a close relationship with the jacamars (Galbulidae) and the puffbirds (Bucconidae), both of which have traditionally been included in the Piciformes but are now regarded as forming a separate order, the Galbuliformes. Unfortunately, all relevant analyses of morphology and molecular genetics that have been made have examined only relatively few species from each of the major groups. No study so far undertaken on these birds has

been based on a sufficiently large set of species that was properly representative of the group in terms of geographical origins and lineages. As a consequence, and because the phylogenetic relationships among woodpeckers are far from solved, as will be discussed below, it is difficult to determine precisely where the Picidae originated.

Several attempts have been made to classify the woodpeckers. None, however, has been so all-embracing and comprehensive as the monograph of L. L. Short, published in 1982, which was preceded by extensive taxonomic work on this family by that same author. Short's arrangement was adopted by Sibley and B. L. Monroe in 1990, and was also followed by H. Winkler and D. A. Christie in their 1995 monograph of the Picidae. The few DNA data available to Sibley, Ahlquist and others at the time when they conducted their genetic research into avian taxonomy had not produced any evidence conflicting with the views put forward by Short.

The system proposed by Short rests on some essential assumptions. The first of these is that specialized woodpeckers originated at several different times from more generalized ancestors. The second, and probably the most crucial one, is that the taxonomic value of external morphological and behavioural

Woodpeckers are one of the oldest avian forms, having diverged from their closest relatives as long ago as 50 million years. The largest branch of the family, with 61 species, is the Campylopteri tribe, to which the Rufous-bellied Woodpecker belongs. Most members of the family are associated with trees, and representatives can be found from sea-level to high altitudes, and across every continent except Australasia, Oceania and Antarctica.

[*Dendrocopos hyperythrus*

lates to the not so unlikely possibility that species of one group mimic those of another with which they are sympatric and with which they are likely to interact interspecifically. Such an argument was posited by M. L. Cody to explain the similarities between the Asian *Chrysocolaptes* and *Dinopium* and between the American *Dryocopus* and *Campephilus*.

There is no doubt that this current system poses many problems. Any changes would, of course, mean altering our views about which character states are convergent. Convergence and parallelism seem to be rather common among woodpeckers, and an analysis of molecular data may be the only method of sorting out those characters that are evidence for common ancestry. In the following paragraphs, the problems are discussed in the context of the currently accepted classification of the Picidae. Although, in the light of existing knowledge of the family, this taxonomic arrangement seems to be the most sensible one to follow, there can be little doubt that a major revision of the whole group is called for. This is indicated by several molecular studies which have been undertaken since the late 1990's. These recent investigations do not yet permit a comprehensive analysis to be carried out, but they do point out some very important findings which are worthy of further attention and discussion.

An interpretation of the correct sequence of phylogenetic events depends very much on where one places the origin of typical woodpecker features. It may be assumed that woodpecker radiation started with a rather generalized picid, one that looked and behaved like, for instance, the present-day *Melanerpes*, and that from this early non-specialist the specialists, such as *Campephilus*, derived much later. Alternatively, the "woodpecker niche" may have been first conquered by a specialist, which was the ancestor of both specialized and generalized woodpeckers. At present, a great deal more data are needed to enable one scenario to be favoured over the other.

The grouping and the gross phylogenetic relationships of the subfamilies of the Picidae seem rather clear. The two wrynecks in the subfamily Jynaginae form a very distinct sister-group to the remaining woodpeckers. The latter contain two major radiations: the diminutive piculets in the subfamily

Picumninae, with 31 species, and the true woodpeckers which constitute the largest subfamily, the Picinae, totalling 183 species. These three subfamilies represent deep branches in the phylogeny of the woodpeckers.

The true woodpeckers are split into six tribes. The Colaptini, containing the flickers (*Colaptes*) and allies, and the Melanerpini, which includes the *Melanerpes* species, the sapsuckers (*Sphyrapicus*) and related picids, together comprise seven genera which, with the exception of a single species, are confined to the New World. The sole exception is the colaptine Rufous Woodpecker (*Celeus brachyurus*), which lives in Asia. The Picini tribe of seven genera of "typical" Old World picids, such as the Eurasian Green Woodpecker (*Picus viridis*) and the flamebacks (*Dinopium*, *Chrysocolaptes*), occurs only in the Palearctic and Oriental Regions, while the three somewhat aberrant genera *Meiglyptes*, *Hemicircus* and *Mulleripicus* together form the tribe Meiglyptini, which is confined to southern Asia, where it is found almost exclusively within the tropics. The Campephilini includes two genera of large, mostly black or blackish woodpeckers, the "logcocks" (*Dryocopus*) and the "ivory-bills" (*Campephilus*); the latter are confined to the Americas, while the former genus is widespread in Eurasia, too. Finally, the largest tribe of all, the Campetherini group of "pied" woodpeckers and allies, occurs on all continents inhabited by the family; this is due to the fact that it contains the widespread genera *Dendrocopos* and *Picoides*, as well as the two Afrotropical genera *Campethera* and *Dendropicos*.

Short considered the Campephilini to be an offshoot of the Colaptini, while the latter tribe is thought itself to be connected with the Campetherini. The African genus *Campethera* shares many characteristics with South American *Colaptes*, *Piculus* and *Celeus*. Generally, the plumage in these two groups is often greenish and the underparts are barred or spotted, and that pattern can easily shift between bars and spots in both groups. Other details of plumage coloration, such as yellow tail shafts or malar stripes as the conveyors of sexual signals, are also shared. The greatest plumage similarities are exhibited by the young of these groups. The genera *Piculus* and *Campethera* both possess large man-

*The taxonomy of the woodpeckers is complex and not well understood. The Orange-backed Woodpecker, living in the lowland forests of South-east Asia, is currently placed in a monotypic genus within the Picini tribe of predominantly Asian woodpeckers. It was previously placed in the related genus Chrysocolaptes, although it differs considerably from the latter in plumage colours, behaviour and calls. It seems likely that this handsome picid is more closely related to the Maroon and Bay Woodpeckers (Blythipicus rubiginosus and B. pyrrhotis). Further work is required to determine whether these three species would, in fact, be better combined in a single genus.*

[*Reinwardtipicus validus xanthopygius*, West Kalimantan, Borneo  
Photo: J. M. Lammertink]

*The plumage differences between some picid taxa are so small that there remains uncertainty over their taxonomic status. A prime example from Africa is the Grey-headed Woodpecker, which has recently been split from the Grey Woodpecker (Dendropicos goertae), a decision by no means supported by all taxonomists. Such are the similarities in the vocalizations, plumage and behaviour of the two that field identification on the periphery of their ranges is problematic, and exacerbated by the existence of hybrids. These two species, together with the Olive Woodpecker (Dendropicos griseocephalus), form a superspecies, and all three are sometimes placed in a separate genus Mesopicos.*

[*Dendropicos spodocephalus rhodogaster*, Serengeti, Tanzania.  
Photo: Ferrero-Labat/Auscape]

Among the polytypic woodpeckers, it is not unusual for the races to be regarded as forming two or more groups, which some taxonomists would in many cases prefer to treat as separate species.

The Green-barred Woodpecker is typically divided into two intergrading groups.

The "melanochloros group" contains two races which are arboreal, living in the forests and savannas of Brazil and parts of Bolivia, Paraguay and Argentina. These tend to have stronger green and yellow hues on the wings and underparts than do the more southerly races of the "melanolaimus group".

The latter three, *melanolaimus*, *nigroviridis* and *leucofrenatus*, are generally browner above, with a white rump, have heavier black streaking on the throat, and are more terrestrial. They reside in the pampas and Chaco woodland of Bolivia, southern Brazil and

Argentina, the southernmost populations being at least partially migratory. The taxonomy is complicated by the fact that members of the two different groups interbreed along the River Paraná and the River Uruguay.

Many authors consider this species to form a superspecies with the Spot-breasted Woodpecker (*Colaptes punctigula*), which is widely distributed across northern South America. Both species, along with the Black-necked Woodpecker (*Colaptes atricollis*) of the Peruvian Andes, are often referred to collectively as "forest flickers"; these are sometimes placed in a separate genus

*Chrysomitris*, distinct from the terrestrial *Colaptes* flickers. To display aggression, as in this photograph, the woodpecker fans its tail feathers, directing the underside at its opponent, and flicks its wings to reveal a flash of yellow on the underside.

[*Colaptes melanochloros leucofrenatus*, Salado Depression, Buenos Aires, Argentina. Photo: Yves Bilal/Ardea]

Until very recently, the Eurasian Three-toed Woodpecker has been treated as conspecific with its close relative the American Three-toed Woodpecker (*Picoides dorsalis*), which is smaller and darker. Apart from plumage differences, however, evidence gathered from DNA analyses, as well as the considerable geographical separation of the two taxa, suggests that they should be regarded as two separate species forming a superspecies. In addition, a number of rather distinctive races in Asia, some of them also isolated from the main range of the species, may prove to be genetically distinct. This is yet another instance in which much more research is clearly required in order to clarify the taxonomy.

[*Picoides tridactylus tridactylus*,  
Patienemi, Finland.  
Photo: Marc Duquet/Bios]

dibular glands, and have similar features in the tracheal and other muscles, as well as showing some similarities also to *Celeus*, and both have peculiar asymmetrical testes.

The Melanerpini, according to Short's reasoning, are derived from the same old ancestral group as the Colaptini and the Campetherini. The Meiglyptini and the Picini are more specialized woodpeckers which, like the Campephilini, are assumed to have arisen later. Their common ancestors may have been among the Campetherini, assumed to have been distributed over the whole of the Old World and to have been later replaced by their more modern phylogenetic offspring.

Recently published results of phylogenetic analyses of mitochondrial and nuclear DNA, conducted by W. S. Moore and his co-workers, have revealed some interesting data that can only partly be incorporated in the present system. Not only do these pertain to the relations among the tribes, as described above, but they also challenge the current assignment of genera to these tribes, and they may even render obsolete the present arrangement of species into genera. The most important result of these studies, and seemingly a rather robust one, is an apparent very close relationship between South American colaptine *Veniliornis* and the North American *Picoides* group, particularly the Hairy Woodpecker (*Picoides villosus*), currently placed in the Campetherini. *Veniliornis* also shares with the American *Picoides*, and with the African *Dendropicos* species, a derived anatomical condition, namely the absence of an accessory leg muscle, *M. semitendinosus*, that is present in most other woodpeckers. The possible taxonomic consequence would be to include *Veniliornis* in the Campetherini. The data further indicate that the ivory-bills form a clade with the melanerpine woodpeckers, whereas the *Dryocopus* species would belong to a line that includes the flickers, which themselves show some affinities with the Old World Picini. Despite the intriguing possibilities thrown up by these recent studies, there is certainly a need for DNA analyses to be carried out on more picid species, particularly Asian ones, before a new comprehensive system of woodpecker relationships and taxonomy can be built.

The two wryneck species in the genus *Jynx* probably represent an old lineage of picids that has branched off very early from the one that eventually led to the true woodpeckers. They form one superspecies with an Old World distribution. The

wrynecks are cryptically coloured, with brown, grey and black patterns matching the structure of a typical bark surface. They move along branches in a rather passerine-like manner, and frequently descend to the ground. The foot is a zygodactyl, yoke-shaped, four-toed perching foot. The feathers of these sexually monomorphic birds are soft, and this is particularly true of the long tail feathers, which are more or less rounded at the tip. The short bill is somewhat curved, and pointed, with the nostrils rounded and exposed and only partly covered by feathering. The tip of the tongue is only slightly pointed and is smooth, without any barbs. Having a short, curved, pointed bill, the wrynecks cannot excavate their own nest, but they do breed in natural cavities and in old holes made by other woodpeckers.

The 31 piculets exhibit many specializations that characterize the Picidae. The feature that distinguishes them most conspicuously from other woodpeckers is the tail, which has short and only slightly pointed feathers. The plumage is soft, and is dominated by brown to greenish colours with black markings. The forehead and crown, which are more or less densely spotted and streaked, bear the signals for sexual recognition, with orange or red on males and white on most females. These tiny birds move rapidly along thin branches, and they may hammer vigorously and with persistence. In all these activities, the tail is only rarely used as a support. As with most woodpeckers, the nostrils are covered by feathers, and the bill is pointed, slightly curved on the culmen, and compressed laterally. The long tongue has a rounded tip with fine bristles. The members of this subfamily are sufficiently "woodpecker-like" to be able to excavate their own breeding holes. Their calls are not unlike those of other woodpeckers, and some species drum (see Voice). Indeed, drumming is regularly heard from several picumnines, among them the Speckled Piculet (*Picumnus innominatus*) and the two Asian species of *Sasia*, and, in the Neotropics, the White-barred (*Picumnus cirratus*) and Mottled Piculets (*Picumnus nebulosus*).

The relationships between the South American piculets and the Old World picumnines have never been thoroughly investigated. The Asian Speckled Piculet is very similar to its American congeners, with which it shares a colour pattern found in no other avian species: laterally converging white bars on the outer tail feathers and a white stripe on the central feathers. While

All 14 members of the genus *Dendropicos* are restricted to Africa, and most occur only in dense primary forest. As a consequence, there remain significant gaps in knowledge of their distribution and ecology, and of the relative distinctness or otherwise of various races. The race *johnstoni* of Elliot's Woodpecker has a much brighter plumage than that of the nominate race, and it favours the highlands of south-east Nigeria and south-west Cameroon, whereas the nominate race occupies lower altitudes in that region. The highland form is considered by some to be a separate species, but it appears to interbreed with the nominate race in Cameroon.

[*Dendropicos Elliotii johnstoni*,  
Mann's Spring, Cameroon.  
Photo: Doug Wechsler/  
VIREO]

many other features may be convergent owing to the diminutive size of these species, there is no obvious reason why this particular tail pattern should have evolved independently in the two groups. On the other hand, one could argue that it is very unlikely that a species which must have been separated for a very long time would not have diverged genetically to a greater extent than its present taxonomic status implies. Thus, the relationship between these geographically isolated groups of South

American and Old World piculets, along with the other Asian-Neotropical relationships found among woodpeckers, which are discussed below, are certainly among the most interesting problems of avian phylogeny and biogeography.

Within the South American piculets, species limits and general taxonomy are still far from clear. Scant knowledge about the behaviour and ecology of these birds in many parts of the continent, together with considerable geographical variation within individual species and relatively frequent interbreeding, largely prevents the drawing of any firm conclusions. It is possible that these tiny woodpeckers underwent differentiation only recently, and that they are in fact all closely related and form but a few species or superspecies.

As has been shown in recent studies of the piculets of Venezuela by M. Lentino and colleagues, a greater pool of data may well change our perception of these woodpeckers in many ways. This is well illustrated by the situation regarding the picumnine *nigropunctatus*, which lives in the delta of the River Orinoco. Originally described by J. T. Zimmer and W. H. Phelps, Sr., in 1950, as a new species, *Picumnus nigropunctatus*, this very poorly known taxon was subsequently considered by Short, in 1982, to be a synonym of the subspecies *salvini* of the Golden-spangled Piculet (*Picumnus exilis*). The taxon *salvini* had been named in 1893, but with no type locality, and the single specimen had apparently been obtained in Colombia, from among skins purchased in Bogotá, the true origin of which is notoriously obscure. Unfortunately, however, very few specimens of these piculets were available at the time when Short conducted his researches, and he was able to compare only the type specimens of the two piculets; nor, it seems, did he manage to compare either with the subspecies *obsoletus* of the Scaled Piculet (*Picumnus squamulatus*). Only some years later, from 1998 onwards, were Lentino and others able to examine a relatively large series of skins of *nigropunctatus*, obtained mostly after Short's work appeared. It then became clear that the taxon exhibited several significant plumage differences from *salvini*, to the extent that to treat the two as synonymous would appear to be stretching the imagination too far. Moreover, a further twist to the tale was revealed. The form *salvini* was found to be so similar to *obsoletus* as to suggest that the two were, in fact, almost certainly referable to the same taxon. Following these careful analyses of larger sam-

The two discrete racial groups of the rather dingy Brown-capped Woodpecker are frequently treated as separate species.

The three races in the western "nanus group" live in the Indian Subcontinent, and have a red orbital ring but no dark malar stripe. By contrast, birds of the eastern "moluccensis group", distributed in the lower part of Peninsular Malaysia and through the Sunda Islands, have darker eyes but no orbital ring, and possess a dark malar stripe and heavier underpart streaking. At just 13 cm in length and weighing a mere 15 g, these woodpeckers are easy to overlook in the highest branches and twigs of secondary forest, plantations and parkland trees.

[*Dendrocopos moluccensis nanus*,

National Park, India.  
Photo: Otto Pfister]

Determining the boundary line between a subspecies and a full species can be exceedingly difficult. Disputes remain over the clinal variation shown by such species as the Crimson-mantled Woodpecker, of which five races are recognized along the Andes. The photograph shows a male of the race *brevirostris*, which is intermediate between the northern races and the very distinct *atriceps* of south-eastern Peru and north Bolivia. The latter, with its black crown and dusker upperparts, could perhaps be thought a distinct species, but the existence of this intermediate race is one argument for not treating it as such.

[*Piculus rivolii brevirostris*, Sierra Sabanilla, Zamora-Chinchipe, Ecuador.  
Photo: Doug Wechsler/VIREQ]

ples, the Venezuelan researchers' suggestion that *nigropunctatus* is a genuine species, and that the type of *salvini* may well be a misidentified Scaled Piculet of the subspecies *obsoletus*, does seem an eminently sensible one.

While such stories are not so rare in avian taxonomy, they do underscore the point that much work has still to be done with regard to the systematics of the South American piculets. Similar confusion has hitherto existed, for example, in the subspecific designation within the Ochraceous Piculet (*Picumnus limae*) and between that and the Tawny Piculet (*Picumnus fulvescens*). In 1961, a new form, *saturatus*, was described from north-east Brazil, as a subspecies of the Ochraceous Piculet. Based on a single male specimen, it was distinguished from typical *limae* mainly by the intense ochre to ferruginous coloration of the underparts and neck sides. In the same year, a new species, the Tawny Piculet, was described from the same region, in this case from a female specimen. At the time, neither set of describers appeared aware of the other's discovery, which was unfortunate, since the two piculets were very similar in general plumage. Short, in his 1982 monograph, put forward the possibility that the two represented the same taxon. Meanwhile, O. M. O. Pinto, one of the original describers of *saturatus*, had stated, in 1978, that he now considered that taxon to be synonymous with *fulvescens*, which he regarded as a subspecies of *P. limae*. Pinto's conclusion had been overlooked by Short and also by later authors, including Winkler and Christie. Close examination of the specimens, along with comparison of published illustrations, does, indeed, show that the two are more or less identical in appearance, except that one is a male and the other a female; the synonymization of the two taxa seems perfectly logical. In addition, the Tawny Piculet appears not to be very much like the Ochraceous Piculet, and the relationship of the two species remains to be determined.

The merger of the single African species with two of the three Asian species in what, according to modern taxonomy, constitutes the genus *Sasia* seems to be less problematic. Nevertheless, their relationship with the other piculets remains to be studied more thoroughly. The three species of this genus possess a bare area around the eye, and they lack the white tailstripes. They are further distinguished by a very round cross-section of the upper mandible, and by having zygodactyl feet on which the first toe is

greatly reduced in the African Piculet (*Sasia africana*) and absent in the Rufous (*Sasia abnormis*) and the White-browed Piculets (*Sasia ochracea*).

By far the largest of all the Picumninae is the Antillean Piculet, which appears to be rather isolated from the other extant woodpeckers. It inhabits the Caribbean island of Hispaniola, where it, or a very similar ancestor, has lived since at least 24

One of the commoner woodpeckers in Peninsular Malaysia and the Greater Sundas, the Crimson-winged Woodpecker forms a superspecies with the Lesser Yellownape (*Picus chlorolophus*). In the past, it was often treated as a subspecies of the latter, which occurs at higher elevations in Malaysia and Sumatra. The two may meet at about 1000 m, although the Crimson-winged Woodpecker is only infrequently recorded at such altitudes in these areas, favouring lowland forest and plantations. There are certainly no known records of hybridization between the two species.

[*Picus puniceus puniceus*, near Baluran National Park, Java.  
Photo: Tony Tilford/Oxford Scientific Films]

Although the Gilded Flicker is very similar to the Northern Flicker (*Colaptes auratus*) and, indeed, is not significantly divergent genetically from the "cafer group" of that species, it seems better to treat the two as *allospecies*. They appear to be segregated by their habitat preferences during the breeding season, even though they associate freely at other times of the year. Gilded Flickers live in arid scrubland and desert with large cacti, which they exploit for nesting purposes. Having excavated a hole in a live cactus, the flickers have to wait until the sap has dried before using the cavity for nesting.

million years before the present. Its bill is long, slightly curved and pointed. The behaviour of this odd piculet is reminiscent of that of a barbet rather than that of a woodpecker. While the Antillean Piculet certainly represents a very old stock, its relationship to other woodpecker lineages is still obscure. Until more information is available, it seems best to place it in its own tribe, the Nesotitini.

The Andaman Islands, in the northern Indian Ocean, host a distinctive subspecies of the Fulvous-breasted Woodpecker. The noticeably pale bill, the large rounded or heart-shaped spots on the upper breast, and the prominent barring on the belly and flanks are all clearly apparent on this male. This isolated race is smaller and proportionately longer-tailed than other races, which occur from the Himalayan foothills of northern Pakistan eastwards to Java and Bali. This species is one of a handful of woodpeckers in which the females have longer wings and a longer tail than do the males, although the reason for this is not clear.

The true woodpeckers assigned to the subfamily Picinae are characterized by unique features of the bill, tongue and skull, as well as by distinctive variants of the zygodactyl toe arrangement and by a specialized tail. These features and details of the moulting pattern, as well as their early development, are intimately related to the habits of these birds. These habits are typified by the foraging method, which to a greater or lesser degree includes subsurface feeding that is carried out mainly on trees, but which has in some cases changed into, or been complemented by, the digging-up of ant or termite nests on the ground (see Food and Feeding). This predominant foraging mode goes along with the birds' hole-nesting habits. Woodpeckers excavate their own nesting holes mainly into dead wood, although some ground-foraging species dig their nests into the ground (see Breeding). Woodpeckers hop bipedally along branches, and their climbing style derives from this locomotor pattern. The typical structural adaptations found in the picine woodpeckers are all connected with these habits. The central feathers of the noticeably graduated tail are strong and pointed, with especially strong shafts and vanes and with stiff barbs; they are more or less clearly curved forwards at the tip. These characteristics are most fully developed in the medium-sized to large arboreal species. The bill is usually straight, with ridges, and with a pointed or chisel-like tip. In most species, the nostrils are protected by covering feathers. The exceptionally long, extensible tongue has a barbed tip, with a high diversity of barb arrangements among species. The precise length of the tongue and the arrangement of the tongue-bones also vary greatly.

The Picinae woodpeckers are most diverse in southern Asia and in South America, but they are also widespread in the Holarctic Region and in Africa. Within this large subfamily of true woodpeckers, as already mentioned, several tribes can be recognized.

The Melanerpiini comprise 27 species in three genera that are restricted to the New World. They include moderately specialized and hence very generalist and successful woodpeckers. They are able to make use of all typical woodpecker locomotory styles, and all species are excellent fliers. In fact, many melanerpines regularly cover long distances over open areas, while some are short-distance migrants and the sapsuckers are

genuine long-distance migrants. It is, therefore, not surprising that flycatching is a common foraging technique among these picids, nor that this group has successfully colonized all the major Caribbean islands, where some endemic species have also evolved. The niche breadth of these woodpeckers is further augmented by a more or less well-developed ecological and morphological sexual dimorphism, particularly on islands. The bill is long, usually pointed, and slightly to strongly curved, and can be used for excavating, for probing, and for taking fruit, acorns

and nuts, and the occasional lizard or nestling bird. The various species either are boldly patterned in black and white with areas of red and yellow, or exhibit finer black and white horizontal barring; no clear-cut line can, however, be drawn between these two types of patterning. Sexual differences in plumage coloration are either well marked or absent, and juveniles differ from the adults more conspicuously than is the case with most woodpeckers. Sociality, living in family groups, or even in co-operative groups with complex interrelations, is widespread among the members of this tribe. In this regard, it is worth noting here that many social species of woodpecker are rather monomorphic, which is possibly an adaptation designed to reduce aggression (see Morphological Aspects, General Habits). Among the Melanerpini, however, there is no convincing relationship between the degree of sexual dimorphism and sociality, since the tribe contains completely monomorphic species, such as the Guadeloupe Woodpecker (*Melanerpes herminieri*), that are no more inclined to social living than are other species. Many melanerpine species are frugivorous, or take nuts and seeds, and the most specialized sapsucking woodpeckers are found in this tribe. Most melanerpines are not only conspicuous visually, but also striking vocally, being garrulous and loud.

The largest genus in this tribe is *Melanerpes*, containing 22 species. These were formerly split in two major groups, the "ladder-backed" *Centurus* and the boldly patterned *Melanerpes*. Between these extremes, however, many intermediate patterns occur, and the group is in all respects rather uniform, so that distinguishing several genera would not seem to be justified. Splitting would also blur the distinctiveness of the other two genera. The four species of North American sapsuckers in the genus *Sphyrapicus* are placed within this tribe because they exhibit many anatomical, behavioural and ecological similarities to *Melanerpes*. Meanwhile, there is overwhelming evidence from molecular data, too, that these birds are indeed close relatives of *Melanerpes*. They show similar colour patterns to the members of that genus, and the juvenile plumage may likewise be distinct, while sexual dimorphism is either well expressed or absent.

All *Sphyrapicus* species are more or less migratory, and the sapsucking habit is well developed. Sapsuckers show their greatest diversification along the Pacific coast of North America. An analysis of their DNA, conducted by C. Cicero and N. K. Johnson, has clarified the relationships among them, indicating that Williamson's Sapsucker (*Sphyrapicus thyroideus*) is closest to the ancestral species. The best-known of the four, the

No other picid exhibits such an amazing variation in plumage and size as does the Greater Flameback.

This extraordinary species, which extends from western India to the Philippines, occurs as 13 races, the reddish rump being the only feature common to all. In particular, the six races in the Philippines, all smaller than the others and with red eyes, differ so much in appearance that each could be taken for a separate species. Indeed, some of these highly distinctive taxa, isolated on islands, may have evolved into full species, but DNA analysis and detailed studies of their vocalizations and ecology are required before this issue can be resolved.

The two wryneck species, the only members of the Old World subfamily Jynaginae, probably represent an ancient lineage of picids that branched off very early from the one that eventually led to the true woodpeckers. Although wrynecks have cryptic plumage, matching the colours of bark, they spend more time on the ground than do most woodpeckers. Some individuals of the Ethiopian race of the Rufous-necked Wryneck show extensive rufous on the underparts, as is evident in this photograph.

[*Jynx ruficollis*  
*aequatorialis*,  
Debre Zeyit, Ethiopia.  
Photo: Göran Ekström]

This photograph of a Crimson-bellied Woodpecker captures very well the position of the legs and feet when climbing. The legs are short in proportion to the size of the bird, and the feet are large and strong, with powerful, curved claws providing maximum grip, even on the smoothest of bark or, in some cases, even on telegraph poles. The fourth toe on each foot is extended to the outside of the body, counteracting the forces exerted by gravity and by the woodpecker's own pecking actions. The varied lifestyles and body size of woodpeckers, however, dictate the precise morphology. Members of the genus *Campephilus* are among the largest woodpeckers and need to do more than most to maintain their hold on a vertical surface. They cling to the substrate with the legs directed more outwards, and often with all toes pointing more or less forwards. A callus at the "heel" is pressed against the trunk in order to support the efforts of the claws and tail.

[*Campephilus haematogaster*  
*haematogaster*,

Photo: Luis Mazariagos]

Yellow-bellied Sapsucker (*Sphyrapicus varius*), is a widespread species. This and the Red-naped Sapsucker (*Sphyrapicus nuchalis*) sometimes hybridize in western Canada, but genetic analysis supports their status as separate species, while the Red-breasted Sapsucker (*Sphyrapicus ruber*), which also interbreeds to a limited extent with both, may be the most recently evolved member of this group.

In Cuba and its nearby islands there lives a woodpecker which has been assigned to a genus of its own. This is the Cuban Green Woodpecker (*Xiphidiopicus percussus*), a very green-looking species which, nevertheless, exhibits a colour pattern that is somewhat reminiscent of that of the sapsuckers. The latter, incidentally, migrate regularly to the Caribbean islands. The Cuban Green Woodpecker does not show some of the more derived morphological character states that are common to *Melanerpes* and *Sphyrapicus*. It lacks, for instance, a characteristic tie between certain tendons of the toes. It remains to be shown whether this indicates that this little-known species represents the remnant of an ancestral species, or whether this picid has secondarily lost these specializations again during its long, separate evolution on an island.

Within the Picinae, the largest of the six tribes is the Campeotherini, comprising a great diversity of very small to medium-sized woodpeckers. It currently includes five genera, with a total of 61 species, which occur in Asia, Europe, Africa and the Americas. These picids move and behave like typical arboreal woodpeckers. They not infrequently descend to the ground, and one species has evolved into a typical ground woodpecker. The

bill is rather straight, with a pointed or chisel-like tip. The feet show the typical arrangement of arboreal woodpeckers; the first toe is of little significance, and has been lost in three of the *Picoides* species, namely the closely related and recently split Eurasian Three-toed (*Picoides tridactylus*) and American Three-toed Woodpeckers (*Picoides dorsalis*) and the similar-looking Black-backed Woodpecker (*Picoides arcticus*) of the Nearctic. The tail is moderately long, with typically strong central feathers. On most campeotherine species, at least the outer tail feathers show light spots which may be fused to form large white areas.

The African genus *Campeothera* contains twelve species which have the back greenish in colour. Sexual differences in coloration frequently involve the moustachial stripes and the colour of the forecrown or crown. On males, the crown is red with more or less black streaking and, in most species, there is a red moustache. Females lack the red moustache, which instead is black, or greenish-black, or spotted black and white; in addition, red on the head is restricted to the rear crown or is absent altogether, and the black crown is often spotted with white. Features related to arboreal feeding are only moderately expressed in this seemingly primitive genus. The bill is more curved than that of woodpeckers more adapted for excavating, and is therefore also mainly pointed or with only a slightly developed chisel-tip.

There has been a fair amount of confusion over the taxonomy of these Afrotropical species, some of which present real difficulties in field identification. Perhaps the greatest dilemma is that which surrounds the status of the Nubian (*Campeothera*

The development of the woodpecker's tail is as crucial to its tree-climbing niche as is that of its feet. As this photograph of a Lesser Yellow-nape illustrates, true woodpeckers have a stiff tail, with pointed central feathers and strong barbs. The outermost rectrices are greatly reduced and probably functionless, whereas, on many picids, the central feathers are slightly curved at the tip, to allow firmer contact with the substrate. During climbing, and when the bird is alert, the tail's function is to keep the body away from the surface; only when the woodpecker is relaxed does the tail serve as an additional prop. The lower vertebrae and the pygostyle bone are enlarged in order to provide sufficient space for the large tail muscles. It is interesting to note that the central feathers that develop on the tail of juvenile picids are shorter than those which will grow from the second calendar-year, giving the tail a graduated shape. During the annual moult, at least in the case of the true woodpeckers, this central pair of rectrices is replaced after the other tail feathers.

[*Picus chlorolophus wellsi*, Kurunegala, Sri Lanka. Photo: T. S. de Zylva/FLPA]

*nubica*), Bennett's (*Campethera bennettii*) and Reichenow's Woodpeckers (*Campethera scriptoricauda*) in eastern and southern Africa. Although Sibley and Monroe recognized the three as distinct species, others have treated Reichenow's Woodpecker as a subspecies of one or the other of the first two. Indeed, Reichenow's is almost identical to the nominate race of Bennett's Woodpecker, differing only in its shorter wings, slightly smaller size and some details of the head pattern, and the two appear also to have more or less the same vocalizations. The similarities between these three picids are such that in areas where their ranges come close together, as in, for instance, Rwanda, there is disagreement over which taxon is present in some places. Further research is clearly required in this region. Although this may eventually indicate that this group involves only one or two species, the treatment of it as comprising three species may help to promote detailed studies both in the field and in the laboratory. Comparable research should also clarify the taxonomic status of the Mombasa Woodpecker (*Campethera mombassica*), some-

times lumped with the relatively widespread Golden-tailed Woodpecker (*Campethera abingoni*). In this case, however, there appear to be clear differences between the two in morphology, voice and drumming behaviour, and their treatment as separate species seems justified.

Another instance where it has been suggested that a single species should be split relates to the Green-backed Woodpecker (*Campethera cailliautii*). The western subspecies *permista* of this small but rather noisy picid is distinguished by having plain green upperparts and fully barred underparts, whereas all other races are spotted or barred above and spotted below. For some years the two forms were considered to be different species, the eastern one being referred to as the "Little Spotted Woodpecker", but the two appear to hybridize regularly across an extensive zone where they meet, from southernmost Sudan to north-west Angola.

Also wholly African are the 14 species of the genus *Dendropicos*, which also often show some greenish coloration. They seem generally to be more arboreal than the members of

A strong bill is necessary for the frequent hammering and digging activities so typical of the Picidae.

The majority of woodpeckers, therefore have a long or longish bill that is fairly straight and has a broad base. In addition, the nostrils are equipped with specialized feathers to protect them from flying debris.

For birdwatchers, the holes and other cavities drilled in trees provide the most visible evidence of a woodpecker's presence, especially in the case of such species as the Golden-tailed Woodpecker. This picid, although widespread across sub-Saharan

Africa, is rather unobtrusive among dense trees and thickets. The greenish to brownish upperparts, usually with an element of pale barring or spotting, that characterize the genus *Campethera* are well shown by this female.

The males of most species in this solely African genus have the entire top of the head red.

[*Campethera abingoni*  
abingoni,  
Kruger National Park,  
South Africa.

Photo: Alan Wilson/Aquila]

the preceding genus, and this is reflected in the fact that they possess strong claws, and a bill that is only slightly curved. Sexual dichromatism in this genus pertains to the crown or the nape, areas which are not red on females; white frontal markings are present on females only of the Bearded Woodpecker (*Dendropicos namaquus*). As with *Campethera*, the underside may be plain, spotted, barred or streaked, and some species, notably the Fire-bellied Woodpecker (*Dendropicos pyrrhogaster*), also show extensive red coloration on the underbody. The yellow shafts of the central tail feathers are a characteristic that is common to both of these genera, and it has been used to separate them from the other brownish woodpeckers of the tribe. The yellow shafts are shared also with the African Ground Woodpecker (*Geocolaptes olivaceus*), which represents a monotypic genus having features related to its ground-foraging habits. The long and curved bill and the moderately stiff tail feathers are typical of species which forage on the ground. Compared with its arboreal relatives, the plumage colours of *Geocolaptes* are dull. It

seems most likely that the Ground Woodpecker branched off from *Campethera*. Its social behaviour probably evolved convergently with that of some of the terrestrial flickers, which also, incidentally, have flight-feathers with yellow or orange shafts.

It is worth mentioning that several authors have preferred to split the genus *Dendropicos* into three, with the Grey Woodpecker (*Dendropicos goertae*) superspecies then united with Elliot's Woodpecker (*Dendropicos elliotii*) in *Mesopicos*, and the larger and somewhat more specialized Bearded, Fire-bellied and Golden-crowned Woodpeckers (*Dendropicos xantholophus*) placed in *Thripas*. While there may be some merit in this, at least with regard to the general appearance of the taxa in question, the similarities of all are probably too great to be ignored, and merging them in a single genus, as did Short, appears to be the better option.

Within the genus *Dendropicos*, a number of issues relating to species limits still need to be resolved. In particular, the Grey-headed Woodpecker (*Dendropicos spodocephalus*) is considered

Among the common features possessed by the woodpeckers of the genus *Celeus* are a well-developed crest, a short bill, and unfeathered nostrils. The plumage is dominated by rufous, black, brown and cream, or by just one or two of those colours. In the case of the mainly brown species, as illustrated by this female Pale-crested Woodpecker, the coloration is perhaps related to the shady areas of the forest in which these picids live. *Celeus* woodpeckers differ from most others in having feet that are not specialized for climbing tree trunks, the fourth toe being shorter than the front toes. This is probably because most members of the genus, as fruit-eaters, have less need to climb vertical trunks.

[*Celeus lugubris kerri*, Bonito, Mato Grosso do Sul, Brazil. Photo: Edson Endrigo]

by many authors to be no more than a subspecies of the Grey Woodpecker. Although it exhibits fairly obvious plumage differences from the latter, such as a larger and brighter red patch on the underparts, the subspecies *abessinicus* of the Grey Woodpecker, which is geographically close to it in eastern Sudan and north and west Ethiopia, is intermediate in plumage. Moreover, there appear to be no differences between these two picids in their behaviour and vocalizations, and there may well be a good case for treating them as conspecific, as did Short and others.

The 34 species of pied woodpecker, lumped into one single genus *Picoides* by Short, were included by him within the Campetherini. They are widely spread over Eurasia and the Americas, while one species occurs in sub-Saharan Africa and two survived in the Palearctic enclave of northern Africa. These are arboreal, rather advanced woodpeckers of small to medium size. The bill is straight, and chisel-tipped, with strong ridges that render the feather-covered nostrils slit-like. The stiff and ventrally curved tail provides evidence of the arboreal habits of these woodpeckers. The first toe varies in length, but is usually short, and, as already mentioned, it is completely absent in three species. The plumage is patterned in black, or sometimes brown, and white. Sexual markings are found on the crown and the nape, those of the males being red or yellow, whereas the females have these areas black or brown or have the bright markings reduced in extent. In the case of some Asian species, and also the American Red-cockaded Woodpecker (*Picoides borealis*), the sexual badges are greatly reduced and are confined to small markings at the side of the crown or nape. The Red-cockaded Woodpecker is also the only species in this group that is known to be social and to be a communal breeder.

Short felt that primitive pied woodpeckers, such as the Philippine Woodpecker (*Dendrocopos maculatus*) and the Sulawesi Woodpecker (*Dendrocopos temminckii*) of Asia, show such a close resemblance to the Afrotropical *Dendropicos*, such as the Abyssinian Woodpecker (*Dendropicos abyssinicus*), that he included the whole group in the Campetherini. He also merged the former genus *Dendrocopos* with *Picoides*, which before that contained only two species, namely the Black-backed Woodpecker and the "Three-toed Woodpecker", the latter being the two three-toed picids of the Holarctic, at that time combined as one species. The loss of one toe was judged to be of minor taxonomic

significance, and not a valid generic character. The coloration, behaviour and distribution of the three-toed woodpeckers suggest a close relationship with the Nearctic and Central American Hairy Woodpecker. *Picoides*, as defined by Short, would be one of the larger bird genera, and attempts have been made to split it up into smaller units. H. Ouellet, working partly with insufficient data, did not question the close relationship between the American group and the three-toeds, but he split the other Eurasian species as *Dendrocopos*, proposing the separation of all the American species as *Picoides*. This probably does make sense. Curiously enough, in addition to the case of this analysis based on colour pattern, these two groups have never been equally represented in morphological or molecular analyses, the problem in this context being a lack of material for the Asian pied woodpeckers. Clearly, the American species form a closely knit group which is probably also monophyletic. Behaviour, vocalizations and coloration suggest that the Hairy Woodpecker, the White-headed Woodpecker (*Picoides albolaryvatus*) and Strickland's Woodpecker (*Picoides stricklandi*) are close relatives, and the Red-cockaded Woodpecker appears to belong to this group, too. This grouping is also supported by DNA studies. The two South American species, the Striped Woodpecker (*Picoides lignarius*) and the Chequered Woodpecker (*Picoides mixtus*), would then form another group together with the three smaller Central and North American species, the Ladder-backed (*Picoides scalaris*), Nuttall's (*Picoides nuttallii*) and Downy Woodpeckers (*Picoides pubescens*). It is in this assemblage that molecular studies appear also to place *Veniliornis*, a genus currently included in the Colapini.

Dividing up Short's *Picoides* further is not an easy task. To split the small Asian species from *Dendrocopos* would probably be the most sensible course. This would involve grouping the Pygmy (*Dendrocopos kizuki*), Grey-capped (*Dendrocopos canicapillus*), Brown-capped (*Dendrocopos moluccensis*), Philippine and Sulawesi Woodpeckers in a separate genus. Molecular data suggest that the three-toed woodpeckers, *arcticus*, *tridactylus* and *dorsalis*, have branched off this lineage. The medium-sized Eurasian species, such as the Great Spotted (*Dendrocopos major*) and White-backed Woodpeckers (*Dendrocopos leucotos*), seem to belong together. On the other hand, the position of the smaller Lesser Spotted Wood-

The degree of sexual dimorphism exhibited by the Picidae varies considerably, being far more marked in some species than in others.

The most striking difference in plumage between the sexes is displayed by the Williamson's Sapsucker of North America. While the male, shown here, sports pied upperparts, a red throat patch and a lemon-yellow belly, the female is far less gaudy, being mostly buff with dark brown barring. For some years during the nineteenth century, the sexes were, in fact, treated as two different species. The female was first described in 1852, and the male was described five years later, in 1857, as another species of sapsucker. It was not until individuals of the two "species" were found together feeding young that scientists realized their mistake, and the male and female were then taxonomically united. Williamson's Sapsucker is, incidentally, one of the exceptionally few woodpecker species in which the adults have been documented feeding the nestlings of another species, in this case young Red-breasted Sapsuckers (*Sphyrapicus ruber*) in Oregon, the only US state where the two species' ranges overlap. While such behaviour, presumably a response to a strong feeding stimulus, appears to be very rare among non-passerine birds, it is not uncommon for passerines of one species to feed the nestlings or the fledged brood of another, even quite unrelated species.

Maslowski/FLPA]

pecker (*Dendrocopos minor*) remains problematic, since DNA data suggest a close relationship with the North American *pubescens* woodpeckers. Ouellet separated the Brown-backed Woodpecker (*Dendrocopos obsoletus*) by placing it with other African species in the genus *Dendropicos*. There are, however, good reasons for retaining this species with other Old World pied woodpeckers in the genus *Dendrocopos*, one of these being the coloration of the shafts. It is interesting to note that

Sibley and Monroe, in their treatise on the distribution and taxonomy of the world's birds, largely followed the classification proposed by Short for the Picidae, but they split his *Picoides* in the way suggested by Ouellet, including the latter's treatment of the Brown-backed Woodpecker. The Arabian Woodpecker (*Dendrocopos doriae*) shows many similarities to African woodpeckers and to the Asian pied woodpeckers, and its current distribution is not of much help, because it lives in an area with an avifauna in which both the Afrotropical and the Palearctic biogeographical regions are well represented. For the time being, it is probably wiser to retain it in *Dendrocopos*.

Among this array of pied woodpeckers, several taxonomic problems remain to be resolved at the species level. The Brown-capped Woodpecker, for example, may turn out to comprise a species pair. It occurs as two discrete populations, one in India and Sri Lanka and the other in Peninsular Malaysia and the Sunda Islands. Besides being separated geographically, the two groups exhibit a number of plumage differences. The Indian woodpeckers are only lightly streaked below and do not have a dark moustache, whereas the eastern ones have heavily dark-streaked underparts and a conspicuous blackish moustache; the latter also lack the red eyering shown by the western birds, which is possibly a significant difference. The South-east Asian population has been regarded by a number of authors as a separate species, the Sunda or Malaysian Pygmy Woodpecker, and further research may support this treatment.

The "Three-toed Woodpecker", in the classical conception, covers a huge Holarctic range. Recent molecular data, however, strongly urge the splitting of the North American forms as a separate species, *Picoides dorsalis*, which may also show some ecological differences from the Eurasian populations. Moreover, in Asia, the geographical isolation and distinctive coloration of the Chinese form *funnebris* would probably justify its separation at the species level, and it is even possible that the isolated Alpine-Carpathian populations in Europe should be assigned species rank. In this connection, one should not be confused by the fact that A. C. Bent called the American *dorsalis* the "Alpine" Three-toed Woodpecker.

An interesting situation is presented by the Hairy Woodpecker in North and Central America. This widespread picid demonstrates spectacular clinal variation from the tropical montane part

Some members of Picidae are relatively large. In the Crimson-crested Woodpecker, a species found across the northern Neotropics, the male measures up to 38 cm in length and can weigh as much as 280 g. Even so, this is only half as heavy as the largest picids, the Ivory-billed (*Campephilus principalis*), Imperial (*Campephilus imperialis*) and Great Slaty Woodpeckers (*Mulleripicus pulverulentus*), each of which can weigh 550 g or more.

[*Campephilus melanoleucos melanoleucos*, Hato Piñero, llanos of Venezuela. Photo: Kevin Schafer]

In stark contrast to the preceding species, the piculets are really tiny woodpeckers, amply demonstrating the range of variation in size found within the family. At 10 cm in length, and weighing as little as 7-12 g, the White-barred Piculet is dwarfed by the larger species of woodpecker. The piculets forage on the most fragile of twigs, hunting for ants and taking sap. It is interesting to note that ants form the principal items in the diet of the largest picids, too.

[*Picumnus cirratus cirratus*, Poços de Caldas, Minas Gerais, Brazil. Photo: Haroldo Palo Jr/ NHPA]

Despite having diverged from the other woodpeckers between nine and 15 million years ago, the subfamily of piculets, the Picumninae, retains many of the specializations that characterize the picids as a whole. Like the "true" woodpeckers in the subfamily Picinae, piculets have a strong bill capable of digging cavities, and a long tongue with fine bristles. Apart from their tiny size, the most obvious differences are the short tail, with only slightly pointed feathers, and the soft plumage, dominated by sombre colours. Of the 31 piculets, 27 are classified in the genus *Picumnus*, found in South America but with a single species in Asia. Three others, including the two here, are combined in the genus *Sasia*. These are so short-tailed as to appear tailless. They also have a bare patch around the eye, very obvious in the African Piculet, as well as a more rounded upper mandible; as shown by the photograph of a Rufous Piculet, the first toe is more or less absent. The presence of a piculet in Africa, a continent in which the Picidae is under-represented compared with Asia and the Neotropics, is perhaps surprising. Evolving thousands of kilometres away from its congeners, the African Piculet appears to be the only member of its subfamily that avoids ants in its diet.

[Above: *Sasia africana*, near Limbe, Cameroon. Photo: Doug Wechsler/VIREO.]

Below: *Sasia abnormis abnormis*, Danum Valley Conservation Area, Sabah, Borneo. Photo: Doug Wechsler/VIREO]

of its range northwards to the boreal forest. Birds from the former area are small and brown-looking, while the northern populations are medium-sized and contrastingly patterned in pitch-black and dazzling white. The northernmost subspecies, *septentrionalis*, with conspicuous lines of white wing spots and pure white underparts, is markedly bigger than the plain-winged, brown-bodied form *sanctorum* from south Mexico to Panama, so much so, in fact, that the two give every appearance of belonging to different species. Nevertheless, they are connected by ten other forms of variably intermediate appearance.

The third tribe of true woodpeckers, the Colapteni, represents an almost exclusively American lineage, probably most closely related to the African members of the Campetherini. This tribe comprises four distinct genera, one of which, *Celeus*, is rather different and possibly merits higher taxonomic rank. The others are *Veniliornis*, *Piculus* and *Colaptes*. The genus *Veniliornis*, containing 13 Central and South American species, shows many similarities to the campetherine lineage, particularly to the pied woodpeckers. This has, in the past, been attributed to convergent evolution, since this genus is made up of rather arboreal species. As already discussed in some detail, a new interpretation of the phylogeny of this group may soon emerge and, when more evidence becomes available, the whole of the Campetherini and Colapteni assemblages will almost certainly have to be reshuffled taxonomically. The bill of *Veniliornis* is well adapted for excavating, as it is strong and straight, with ridges and slit-like, feather-covered nostrils. The species in this genus have green and often more or less red upperparts, a characteristic which distinguishes them from the pied woodpeckers, but is strongly reminiscent of some of the African picids. Sexual badges are revealed on the crown, which is bright red on males and dark, sometimes streaked pale olive, on females.

In the ten Central and South American woodpeckers in the genus *Piculus*, the sexual signals invariably include the malar region, and in some species the crown, sometimes conspicuously coloured in red and yellow, is also involved. Green to bronze colours predominate in the remainder of the plumage, and the shafts are yellowish to brown. These are mainly arboreal species. The bill, however, is slightly curved and rather pointed, whereas the claws are well developed. The tail, too, is moderately "arboreal-adapted", being only slightly curved ventrally. These features have led to the conclusion that this genus represents an intermediate stage between the arboreal *Veniliornis* and the more terrestrial flickers.

The flickers, combined in the genus *Colaptes*, are represented by nine species. The so-called "forest flickers", comprising the Black-necked (*Colaptes atricollis*), Spot-breasted (*Colaptes punctigula*) and Green-barred Woodpeckers (*Colaptes melanochloros*), bear a superficial resemblance to species of the preceding genus. The other six are largely or highly terrestrial,

Most woodpeckers are sexually dimorphic in colour, with males wearing the more prominent sexual badges. In broad terms, the amount of red in the malar region and on the crown is the key difference between the sexes. The females of most species have these parts of the plumage dull or blackish, as shown by this female Scarlet-backed Woodpecker. If the bright colour is present on both sexes, it usually covers a smaller area on the female. The Scarlet-backed Woodpecker, found in arid scrub along the coast from south-west Colombia to north Peru, is one of many poorly known picids. The travelling enthusiast can still contribute much to our understanding of these intriguing birds.

[*Veniliornis callonotus* major, Olmos, Lambayeque, Peru. Photo: J. Dunning/VIREO]

and possess a long to very long, curved and pointed bill. One species, the threatened Fernandina's Flicker (*Colaptes fernandinae*) of Cuba, has the nostrils exposed and not covered by feathers. The tail is long, but is not especially stiff and curved as in arboreal woodpeckers. The feet are large, with well-developed claws, and a relatively long first toe. It is worth noting, too, that even the structure of the skull lacks the typical expression of features related to wood-working. The sexual badges of *Colaptes* are restricted to the malar region. Otherwise, the plumage is predominantly brownish in the case of the ground-dwelling species and greenish in the forest flickers. The shaft colours are yellow to orange. The flickers in general are well known for their conspicuous visual and vocal displays. The social and group behaviour of the ground-dwelling species, however, has been little investigated.

Recent molecular analyses, including of *Piculus* and *Colaptes* species, suggest, however, that these two genera cannot be upheld. It seems that the Neotropical flickers and *Piculus* may form an assemblage of closely related species that share an ancestry with the somewhat separated North American flickers. One can surmise, therefore, that *Piculus* should possibly be merged with South American *Colaptes* and that, if any generic split is to be made, it should separate the Neotropical *Colaptes-Piculus* species from the North American flickers of the *auratus* group, which were already recognized by Short as being rather different. At present, what can be stated with some degree of certainty is that the species in these two genera need to be rearranged. The North American flickers are a renowned example of interbreeding in the central-plains hybrid zone, discussed further below. The so-called "Red-shafted Flicker" and "Yellow-shafted Flicker", together with the Gilded Flicker (*Colaptes chrysoides*), were united by Short in one polymorphic and widely distributed species. These three are, however, clearly recognizable genetically, as well as ecologically.

Additional investigation should also shed light on the relationships of some of the little-known picids in the genera *Veniliornis* and *Piculus*. For example, the superspecies made up by the Rufous-winged (*Piculus simplex*), Stripe-cheeked (*Piculus collopiterus*), Lita (*Piculus litae*) and White-throated Woodpeckers (*Piculus leucolaemus*) is just one case in which the currently accepted taxonomic arrangement may be found to be unsubstantiated.

Within the colapetine woodpeckers, the eleven species in the genus *Celeus* are rather distinct and probably most closely related to *Colaptes* and *Piculus*. Nevertheless, one member of the Picini tribe, the Banded Woodpecker (*Picus miniaceus*) of the Malay Peninsula and the Greater Sundas, also displays close resemblances to *Celeus*, and one could speculate that the sole Old World member of the latter genus, the Asian Rufous Woodpecker, is merely a highly convergent offshoot of the *Picus* stock. It also exhibits an anatomical resemblance to *Meiglyptes*. The main colours of *Celeus* are brown, black and cream. The various spe-

The sexual dimorphism displayed by the Heart-spotted Woodpecker is unique among the Picidae in that the female sports the brighter colours. The photograph shows her creamy-white forehead and forecrown, features that are black on the male. The posture of this individual, sitting passerine-like across a branch high in the treetops, is typical of the species. Although this is a very short-tailed picid, its tail still has the stiffness, the pointed central rectrices and the strong bars that characterize most members of the family. One peculiarity of the two *Hemicircus* species, however, is the frequent presence on the back of a strange resin-like substance, the origin and function of which remain ■ mystery.

[*Hemicircus canente*, Goa, India. Photo: Neil Bowman/FLPA]

Among the many endemic species on the large Caribbean island of Cuba is a woodpecker that merits a genus of its own.

The male Cuban Green Woodpecker is significantly heavier than the female; indeed, males in the highlands are double the weight of lowland females. This may enable the sexes to use different techniques to exploit different sources of food, as has been shown to be so for two other Caribbean picids, the Hispaniolan and Guadeloupe Woodpeckers (*Melanerpes striatus* and *M. herminieri*). Certainly, the Cuban species' diet is variable, from large invertebrates to the eggs of other birds, including heron (*Ardeidae*) species.

VIREO]

cies have a greater or lesser degree of barring, and possess a crest that is more or less well developed. The bill is not long, and in most cases is curved, while the nostrils are not covered by feathers either in the Neotropical species or in the one Asian species, whereas they are covered in the Picini. The feet also reveal that these woodpeckers are not specialized trunk-climbers and that they do little excavating. The fourth toe is shorter than or equal to the front toes in length; the first toe is short, as it is on most picids. The Asian species has the fourth toe reduced the most. Sexual dichromatism affects mainly the region enclosed

by the bill, the eye and the chin, and in one species, the Rufous-headed Woodpecker (*Celeus spectabilis*), also the sides of the crest. The male has red in these areas, whereas the female does not. Some *Celeus* species breed in the arboreal nests of social insects, and most members of this genus seem to be highly frugivorous; they will reach out a long distance from a trunk or branch to obtain fruits.

The South American species of *Celeus* have often been used as an example of the avian speciation process in Amazonia. Short grouped them according to coloration and bill shape. Recent observations indicate, however, that colours may be associated with the preferred forest stratum, the brown forms making use more of structures in the forest shade, and so they may possibly be subject to convergence. It remains to be seen, therefore, whether the Chestnut-coloured (*Celeus castaneus*), Chestnut (*Celeus elegans*), Pale-crested (*Celeus lugubris*) and Blond-crested Woodpeckers (*Celeus flavescens*) really do form a superspecies that is set apart both from the Scaly-breasted Woodpecker (*Celeus grammicus*) and Waved Woodpecker (*Celeus undatus*) assemblage and from the four other Neotropical species. In this connection, it could perhaps be significant that the Rufous-headed Woodpecker has become a bamboo specialist.

In its present composition, the tribe Campephilini holds two genera, distributed over Eurasia and the Americas. The 18 species are large picids, and are boldly coloured in black and white and a variable amount of red. Many of them possess a crest that can, in some cases, assume spectacular shapes, one example being provided by the Magellanic Woodpecker (*Campephilus magellanicus*). The members of this group are highly specialized for excavating wood, in which they chisel deep holes or pits. They forage on the trunks of large trees, and they descend to ant hills as well. Bark-scaling is a very common feeding technique.

The genus *Dryocopus* contains seven species, collectively known as the logcocks. Two of these are widely spread over the Northern Hemisphere, one in the Old World and the other in the New World. The remaining five species are found in the south-temperate, subtropical and tropical regions. Those living in South and Central America almost completely overlap in range with the eleven species of the genus *Campephilus*. The rare Helmeted Woodpecker (*Dryocopus galeatus*) seems to be a good intermediate between *Dryocopus* and *Celeus*, and hence between the Campephilini and the Colapini. It has a slightly curved bill which

A common feature of many woodpeckers is the possession of a crest, although this tends to be most obvious on the very largest species, such as this White-bellied Woodpecker. The crest is erected both during courtship display and in aggressive postures, but it is not always instantly apparent to the human observer which message is being conveyed. The crest is frequently raised when the woodpecker alights on a perch, and is lowered only when the bird feels secure and is ready to start foraging.

[*Dryocopus javensis*  
*javensis*,

Photo: Alain Compost/  
Bios]

is narrow and pointed, and exposed nostrils, whereas the other species of the genus *Dryocopus* have a straight bill with a well-developed chisel-tip and nostrils covered by feathers. The tail feathers are long, and curved forwards ventrally, and the central pair has strong and pointed tips. The front toes and the fourth toe are of about the same length, with the first about half their length. Visual sexual differences involve the amount of red on the crown and the malar region.

Otherwise referred to as the ivory-bills, the large woodpeckers of the genus *Campephilus* are all crested, and their sexual badges are found mainly on the crown and affect the crest coloration and the malar region. The chisel-tipped bill is long and straight, with the nostrils well protected and covered by feathers. The tail is long and stiff, and curved forwards near the tip, where the feathers are strong and pointed. All the toes are long, the fourth significantly longer than the front toes. They are directed forwards when climbing, and the tarsus may then closely touch the substrate. This genus, incidentally, houses the two picids which are the most critically endangered of all woodpeckers. These are the Imperial Woodpecker (*Campephilus imperialis*) and the Ivory-billed Woodpecker (*Campephilus principalis*), both of which may well already be extinct (see Status and Conservation).

Morphological as well as molecular data suggest that this tribe is not monophyletic at all. *Campephilus* may have branched off from the basal melanerpe lineage. This genus shows some similarity in hind-limb musculature to the southern Asian flamebacks of the genus *Chrysocolaptes*, but it differs from them morphologically in many other aspects. *Dryocopus*, on the other hand, may share an ancestry with the colapline clade, with the Helmeted Woodpecker providing a link with *Celeus*. Foot morphology, feeding habits and vocalizations, including instrumental signals, would support this interpretation, and the many similarities between these two groups of large woodpeckers could be seen as being due to convergence and, possibly, social mimicry. It remains to be shown how the Black Woodpecker (*Dryocopus martius*), which occurs across chiefly northern Eurasia, and the White-bellied Woodpecker (*Dryocopus javensis*), confined to the more southerly parts of Asia, relate to the monophyletic American *Dryocopus* species, because they, too, differ in behaviour and vocalizations. The diet of the logcocks

consists mainly of ants, whereas the *Campephilus* ivory-bills seem to forage mostly for large beetle larvae.

With seven diverse genera, the Picini represent a great Eurasian radiation of woodpeckers. Some similarities in plumage and behaviour suggest that this group shares a common ancestry with the Colapini, particularly with *Celeus*. Convergence in the features involved may be considerable, however, and, as in other cases of woodpecker systematics, a combination of traditional methods with the techniques of molecular biology will certainly help towards a better understanding of the relationships.

Within the tribe there are two genera which each contain only one species. The first is *Reinwardtipicus*, which shows some overall similarities to *Chrysocolaptes*, but morphologically and behaviourally seems to be closer to *Blythipicus*. It was separated from the former genus by Short. Both the Bay Woodpecker (*Blythipicus pyrrhotis*) and the Maroon Woodpecker (*Blythipicus rubiginosus*) are brown to reddish-brown in colour and more or less barred on the back, this coloration being most likely an adaptation to their gloomy habitat, indicating that colour may, after all, be a less useful diagnostic character. Both also have a rather long bill that is straight and chisel-tipped, and the nostrils are protected by feathers. The tail is short and has stiff central feathers, which also are curved forwards at the tip. As with other arboreal woodpeckers, the first toe is short. The rather inconspicuous sexual markings affect the sides of the nape.

Similar features and habits characterize the other monotypic genus, *Sapheopipo*, occurring only on Okinawa, an island in the Ryukyu Archipelago in the western Pacific. Its bill is slightly curved, although chisel-tipped, and the nostrils, as those of *Blythipicus*, are covered by feathers, but the tail is longer and softer than that of the latter. The fourth toe is rather long. Males have the crown and forehead feathers tipped red, and the sides of the nape are red as well. D. Goodwin, who based his 1968 classification of the Picidae on the general appearance and coloration of museum specimens, argued that this peculiar insular species is a direct descendant of the White-backed Woodpecker, a *Dendrocopos* species which is represented on other Pacific islands of the region by some distinct subspecies. Indeed, the morphology of the Okinawa Woodpecker (*Sapheopipo noguchii*) does show some similarities to the *Dendrocopos* woodpeckers.

Many woodpeckers are adorned with a crest, the prominence of which varies according to species and, in particular, with the degree of excitement of the individual. The *Celeus* species of the Neotropics are all rather obviously crested. This female Blond-crested Woodpecker, as it raises its crest in an alert or aggressive posture, reveals the elongated feathers of the nape that make up this appendage.

[*Celeus flavesceus flavesceus*, São Paulo, Brazil. Photo: Edson Endrigo]

Several members of the genus *Picus* have a scaly-looking pattern on the underparts. This is particularly well marked on the aptly named Scaly-bellied Woodpecker, which inhabits deciduous and pine forests at high altitudes on the Himalayan slopes, from Afghanistan to Darjeeling. This strong scaly appearance is produced by broad black submarginal lines on the feathers, these being clearly apparent in this photograph of a male. This noisy woodpecker frequently forages on the ground, having little option when it ventures beyond the tree-line, but it also obtains much of its insect food by pecking and hammering on trees.

[*Picus squamatus squamatus*, Sete, Nepal. Photo: Otto Pfister]

Although the majority of woodpeckers are sexually dimorphic, the Picidae tend to exhibit fewer plumage and morphological differences than do birds of many other families.

Furthermore, it has been suggested that, with the woodpeckers, sexual dimorphism is less marked among the social species, but there seem to be too many exceptions to this concept for it to be a likely phenomenon. For most woodpecker species, the sexes are differentiated by the colour of the malar stripe or, as in the case of the Yellow-fronted Woodpecker, the top of the head: whereas the male has the crown and nape red, the female is black in these areas.

Some other features distinguish the sexes, although these are generally not discernible in the field. The most common differences are in body length and bill size. Males are usually larger, and this can often be assessed when pair-members are seen together, as in this photograph. There are, however, some exceptions: female piculets tend to be larger than the males, and the same is true of some pied woodpeckers. Sexual dimorphism is not simply a means by which the males and the females can recognize one another; it can also have ecological repercussions, with the sexes exploiting different parts of the territory when foraging, and adopting different feeding techniques. These differences are also reflected in characters of the bill, feet and tail.

[*Melanerpes flavifrons*,  
Itatiaia, Rio de Janeiro,  
Brazil.

Photo: Edson Endrigo]

Sexual dimorphism is clearly apparent in these photographs of Cream-backed Woodpeckers and Golden-green Woodpeckers, both from South America. The former species is relatively unusual in that a large area of the female's head is red, although the male shows a great deal more of this colour. The female Golden-green Woodpecker, on the other hand, lacks red altogether, having a very different head pattern from that of her mate. The latter species also illustrates the great geographical variability found within some of the Picidae. Across its range, from east Panama to northern Argentina, it occurs in nine distinct races, the largest of which, *capistratus* in north-west Amazonia and *polyzonus* in south-east Brazil, are up to 80% heavier than the nominate race, shown here. The sexual badges can vary, too: males of the race *paraensis* in north-east Brazil do not have the red malar stripe exhibited by males elsewhere in the species' range. The typical colours in a woodpecker's plumage result from carotenoid pigments: *astaxanthin* and *doradexanthin* are responsible for red, while *lutein*, *zeaxanthin* and *cryptoxanthin* account for yellow and green colours. The so-called *picofulvins* are distinct *picid* pigments that produce the yellow colour of some species.

[Above: *Campephilus leucopogon*, Pantanal, Mato Grosso, Brazil.  
Photo: Haroldo Palo Jr.

Below: *Piculus chrysochloros*, Pantanal, Mato Grosso, Brazil.  
Photo: Hubert Klein/Bios]

A typical woodpecker of the subfamily Picinae has ten primaries, eleven secondaries and twelve tail feathers. The outer primary is much shorter than the others, and the outermost tail feather is greatly reduced in length, as is demonstrated in this photograph of a flying female Grey-faced Woodpecker.

The characteristically bounding flight comprises a series of rapid wingbeats interspersed with brief gliding on closed wings. Some of the bigger species, however, especially the large logcocks (*Dryocopus*) and ivory-bills (*Campephilus*), have a more sustained flapping flight, not unlike that of crows (*Corvidae*). A similar direct flight, but with more rapid beats, is adopted by the smaller *Dendrocopos* and *Picoides* species when pursuing rivals.

[*Picus canus canus*,  
near Rosenheim,  
Germany.

Photo: Marianne Bracht]

The largest genus of the Picini, *Picus*, includes 14 species, one of which, the Grey-faced Woodpecker (*Picus canus*), has a very wide distribution extending right across the northern Palearctic and through the Oriental Region. Ground-feeding is common among the members of this group, and ants form the typical diet. The corresponding adaptations are a straight to slightly curved and more or less pointed bill, and a long tongue. The tail is long and stiff. The fourth toe is of about the same length as the front toes, and the first toe is about half their size. The general plumage coloration is partly or mainly green, often with barring below. Sexual colour dimorphism is reflected in the crown and/or the moustachial stripe. Some *Picus* species have a conspicuous crest, as typified by the yellownapes of southern Asia.

Dark greenish colour, sexual markings on the crown, and a small crest are also the characteristics of the two *Gecinulus* species, both of which are bamboo specialists. The short bill is slightly curved, but the chisel-tip and the rather broad base indicate that these two woodpeckers frequently hammer. The nostrils are covered with feathers. The tail is soft and broad, which may be a secondary adaptation for climbing on bamboo. These picids possess three toes of about equal length.

The two remaining South Asian genera of the Picini, *Dinopium* with four species and *Chrysocolaptes* with two, are sympatric in many areas. The bill of *Dinopium* is short to moderately long, curved, and pointed to slightly chisel-tipped. It is long, straight, strongly built and chisel-tipped in *Chrysocolaptes*. The slit-like nostrils are only partly covered by feathers in *Dinopium*, but are fully concealed in *Chrysocolaptes*. The genus *Dinopium* has a tail that is fairly soft, long and somewhat curved, whereas the tail of the *Chrysocolaptes* species is much stronger, particularly in the central feathers with their stiffened and pointed tips. The fourth toe is slightly shorter than the front toes in *Dinopium*, which has a first toe that is short to very short and rudimentary and, in two species, has been lost altogether. By contrast, the two *Chrysocolaptes* species have the fourth toe long and more forward-directed, and the first toe is moderately long.

The dominant plumage colours in both genera are green, red, golden to yellow, black and white, and all six species are crested. The array of species and subspecies of these two structurally rather different genera reveal many parallels in coloration, rendering them rather similar where they exist in sympatry. Sexual colour differences pertain to the crown in both groups, and also affect the moustachial area in *Dinopium*. When examined closely, it can be seen that this particular region of the head is also differently patterned in the two genera, with the black stripes in different positions.

Besides the striking parallelism, the group poses some difficult taxonomic problems. These relate essentially to the populations that are presently included in one polymorphic species, the Greater Flameback (*Chrysocolaptes lucidus*). These populations exhibit a spectacular range of bright plumage colours, which could suggest that these mainly insular forms constitute separate species. The variation affects not only the colour of the back, which may be greenish-golden to red, but also the head and the neck, which show a variety of bold patterns of red, yellow, black and white. All populations, however, have in common a red lower back and rump. This is clearly a situation where genetic analyses could greatly improve our understanding of the taxonomy of the different forms.

Apparently old and therefore strongly differentiated and aberrant Asian woodpeckers form the Meiglyptini. Because of their rather odd shapes and colours, they do not seem to have much in common. This tribe comprises eight species, ranging in size from very small to very large, in three genera. The few characters which they share are a thin, long neck, a bulky body and a relatively small head. Some species possess fine spots on the head and neck or a contrasting white crown, plumage features that are not found in any other woodpecker.

The genus *Meiglyptes* consists of three small brown, black and white species. The short bill is curved and pointed, and the nostrils are only partly covered by feathers. The feet, with the fourth toe about as long as the front toes, are of the typical picid type. The tail, on the other hand, is somewhat aberrant, since it is

rather short. Both sexes have a crest on the relatively small head. Sexual differences are restricted to a red moustachial stripe or patch on the males, which is absent on females.

United in the genus *Hemicircus* are two rather small species which are predominantly black and white in colour and, as *Meiglyptes*, are also crested. The bill is of medium length, rather straight, and chisel-tipped, indicating strong pecking habits. The tail appears even shorter than that of the preceding genus, but it is stiff and is slightly bent forwards near the tip. The fourth toe is longer than the front toes, and the first is about half the length of the fourth. The males of the Grey-and-buff Woodpecker (*Hemicircus concretus*) have much red in the crest, whereas the females show only traces of cinnamon or red. The sexual dimorphism exhibited by the other species, the Heart-spotted Woodpecker (*Hemicircus canente*), is unique among woodpeckers in that the male has a black face, crown and crest, while the female's forehead and frontal part of the crown are white.

Finally, the three species of *Mulleripicus* are medium-sized to large picids which have a rather small head on a conspicuously thin and long neck. A very slender and sparsely feathered neck is, incidentally, found also in the *Dryocopus* logcocks. The bill of the three *Mulleripicus* woodpeckers does not show the specialized features related to excavating, being long, slightly curved and only slightly chisel-tipped. The nostrils are fully covered by feathers. The long tail is bent forwards towards the tip, and is stiff. The fourth toe is shorter than or as long as the front toes, and is about twice the length of the first toe. These somewhat unusual picids have a grey to black general coloration, with the head and neck finely spotted with white. The females lack any red, whereas the males either possess a red moustache or have red colour encompassing the malar region, the forehead and the orbital area. The large size of these three woodpeckers, together with some anatomical similarities to the genus *Dryocopus*, suggested to earlier authors a close relationship between the two genera.

The biogeography of woodpeckers presents many interesting aspects and problems. It is, of course, intimately linked with the problem of the phylogeny of the group. The *Picumnus* piculets are most diverse in the Neotropics. It seems sensible, therefore, to assume that they have a Neotropical origin, which leaves the

origin of the one Asian species, the Speckled Piculet, rather mysterious. There can be little doubt that the melanerpine woodpeckers represent a successful American radiation. The exact area of their origin may lie somewhere between northern South America and southern North America. The phylogeny of the Campetherini, on the other hand, poses many problems, such that their geographical origin, too, is uncertain. It seems certain that the name-giving genus *Campethera* is African and has radiated on that continent. The same can be assumed for the *Dendropicops* woodpeckers. There is no reason to doubt that the *Colaptes* and *Piculus* woodpeckers are of American origin, but the relationships between this group and *Celeus* have not yet been firmly established. The position of the Rufous Woodpecker, the sole member of *Celeus* in the Old World, where it is spread over large parts of southern Asia, clearly needs to be reanalysed as well. If the latter's position in the currently accepted system is upheld, one is left with almost exactly the same problem as that with the *Picumnus* piculets. In both cases, lowland South America may have been a secondary centre of diversification, and the relative species richness may be a misleading clue as to the ancestral area of the two groups. *Campethera* and the Colapteni probably go back to a common geographical origin, and would thus represent an example of the relationships between the tropical African and South American avifaunas. The *Campephilus* ivory-bills are clearly American, too. Much less clear, however, is the biogeography of the other large and, in many respects, similar woodpeckers currently placed together in *Dryocopus*. Even if one assumes that this genus, as it is conceived today, is monophyletic, its present distribution could be explained equally well with a Eurasian or an American origin, so long as phylogeny is not considered.

Short, in his major 1982 monograph of the group, favoured a New World origin of the Picidae. Known fossils and the high diversity of species in that part of the world could be mentioned in favour of this hypothesis, which is further supported by the fact that the primitive piculets, possibly *Campephilus* and the generalist melanerpines may all have an American origin. If one accepts this view, then the wrynecks would have invaded the Old World rather early, and without leaving a trace in the New World. The hypothesis rests on a number of suppositions, including, among other things, the current view concerning the

Many woodpeckers have a barred pattern on the wings and tail, this being particularly striking when the bird is seen in flight. As revealed by this Lesser Spotted Woodpecker leaving its hole in a dead stump, the barred effect is produced by regularly spaced rows of large, rather rounded spots on one or, often, both webs of each feather. Although competent fliers, the vast majority of picids are more or less sedentary, making only short-distance dispersive movements. Some of the normally resident species, however, occasionally undertake longer migrations. Lesser Spotted Woodpeckers living in the cold northern parts of the Palearctic, for example, sometimes turn up as far south as the Black Sea.

The woodpecker tongue is one of the most remarkable of anatomical structures to be found among birds, enabling the family to exploit food resources beyond the reach of most other vertebrates. The key features of the tongue are its length and the specially structured tip, along with the sublingual glands, which produce a sticky fluid. Associated with this are long, specialized muscles which enable the woodpecker to extend and retract the tongue, while controlling the movements of its tip. When the special tongue muscles contract, the structure becomes stiff. The tip of the tongue of typical woodpeckers is equipped with backward-pointing barbs, arranged in single rows, loosely spaced, or in dense, brush-like rows, according to species. In some picids, such as the Black Woodpecker, the barbs are grouped in clusters of three to five. In others, they are present along the whole tip of the tongue, while in certain species, such as the Middle Spotted Woodpecker (*Dendrocopos medius*), they are concentrated at the extreme tip. Those picids which carry out much of their foraging on the ground have thinner and shorter barbs, a good example of this being the Eurasian Green Woodpecker. For these terrestrial foragers, the tongue functions more as an adhesive stick than as a spear, and its tip is rounded rather than pointed.

With their numerous morphological adaptations, the Picidae are well suited not only for climbing on trunks, but also for grasping smaller branches and twigs, and for moving on flatter substrates. The Rufous-winged Woodpecker, for example, frequently forages high up in the thinner branches of trees, but also at lower levels, where it climbs up or along large limbs and trunks; it prefers the interior of forest rather than edges, the individual here having been photographed inside humid tropical forest. Similarly, the Red-crowned Woodpecker, found in deciduous habitats, forages at various heights, but prefers the middle and lower levels; it is just as capable of climbing on tree trunks as it is of grasping twigs just a few millimetres wide in the upper canopy. One species well adapted to a life spent mostly on the ground is the Eurasian Wryneck. Lacking the stiff tail of other woodpeckers and without the specialized feet, it favours more open habitats. The individual shown here, photographed while on migration through the Middle East, presents the typical view that an observer is likely to obtain of the species.

phylogeny of woodpeckers, and the assumption that generalists were at the baseline of their evolution.

The Oriental Region is, however, as likely a candidate for having been the first centre of woodpecker radiation. There, the major groups are very distinctly differentiated, but they have remained largely confined to the Oriental Region. If these woodpeckers represent an old stock, one has to explain from which lineages African and New World species derived. If the Picidae originated in America, then the Asian radiation was possibly more recent, the particular lineages must have diverged substantially

in a short time, and they may have replaced woodpeckers that represented the ancestral America-derived forms.

Africa is relatively poor in woodpeckers and lacks large species. This would seem to rule out the possibility that the Picidae have originated on that continent, although similarities with some of the smaller capitonid barbets have been noticed. It should be borne in mind, however, that the particular history of Africa and its forests, which generally harbour a comparatively less diversified avifauna, may obscure old biogeographical relationships. Relatively high geomorphological stability and the presence of

a rich barbet fauna may have hindered extensive radiation of woodpeckers. One could easily imagine that African ancestors of the Campetherini produced offshoots that led to a South American as well as an Asian radiation. The two groups may then have met again in North America and in north-east Asia.

The "Out of Africa" hypothesis suggested here, which should be considered as seriously as the preceding ones, posits that both the Oriental and the New World radiations are secondary, with the former being the older one.

From all that has been discussed here so far, it should be quite evident that, among the Picidae, numerous taxonomic problems remain to be resolved, at several levels. Some of these have already been mentioned above, but there are many others, particularly with respect to species limits, and involving taxa in virtually all genera. For example, the north-west African form *vallantii* of the Eurasian Green Woodpecker is frequently treated as a separate species, the "Levaillant's Woodpecker", primarily on the basis of some plumage differences, although these are largely bridged by the Iberian subspecies *sharpei*; yet some authors consider that *sharpei*, too, merits the status of a full species. The relationship between these picids and the Japanese Woodpecker (*Picus awokera*), which is closer in appearance to *vallantii*, as well as between those and the allopatric Scaly-bellied Woodpecker (*Picus squamatus*) of south-central Asia, has yet to be satisfactorily determined. Similar problems surround some of the South-east Asian forms of *Picus*, the field identification of which can be far from simple.

Another example concerns the small *Dendrocopos* taxon inhabiting the Sulu Islands in the Philippines. This has recently been deemed by some authors to be a distinct species, *Picoides* (*Dendrocopos*) *ramsayi*, since it differs very markedly in plumage from the Philippine Woodpecker; it has also been reported to differ vocally from populations on the other islands. While there may, therefore, be a good argument for considering *ramsayi* a full species, it would seem more prudent to conduct additional research into the situation, including further investigation of its relationship with the Sulawesi Woodpecker.

In a 2000 review of its checklist, the American Ornithologists' Union divided Strickland's Woodpecker into two species. This was based on differences in morphology, behaviour and habitat between the isolated southern populations and the birds

in the rest of the range. This split may yet prove to be warranted, but there do seem to be several important similarities between the two groups, in voice and ecology, for instance. This is just one more example of the need for additional research on the taxonomy of the Picidae.

New molecular methods of analysis have revived the discussion on species concepts and, as a logical consequence, the delimitation of species. As the preceding paragraphs have shown, many of these problems are relevant to the woodpeckers. Picids which range over huge areas may be split into different species on the basis of some more or less arbitrary genetic criteria. Small insular populations are a special problem. They occur among widespread species such as the Eurasian Three-toed Woodpecker, the Great Spotted Woodpecker and the White-backed Woodpecker, and they are particularly enigmatic in South-east Asian species such as the "pygmy woodpeckers" and the Greater Flameback. The most interesting cases, however, are those in which adjacent putative species form contact zones that contain hybrids. For the woodpeckers, such zones are relatively well known and studied. They involve closely related species. Aside from these relatively common cases of hybridization, rare cases of possible hybrids between more distantly related forms have been found, as well.

Hybrids between subspecies are known among the piculets, and in the Campetherini, the Colaptini and the Picini. Included in this list is the best-known hybrid zone of all woodpeckers, namely the one which runs through North America and which separates the western and eastern forms of the Northern Flicker (*Colaptes auratus*). The western form, *cafer*, commonly referred to as the "Red-shafted Flicker", sports a black moustache and a red nape, whereas the eastern, nominate form, the "Yellow-shafted Flicker", has the red moustache but no red on the nape. The two were for a long time treated as separate species. As their colloquial names indicate, they differ also in the colour of the shafts of the wings and tail, the feathers of which, on the underside, are, furthermore, of the same colour as the shafts. These two subspecies frequently hybridize in the region where their ranges overlap, in a zone that runs from Texas and Oklahoma north to Saskatchewan and westwards through British Columbia to Alaska. The mating behaviour of the flickers in this hybrid zone, which appears to have been stable for centuries, is still puzzling.

The structure and composition of forest habitats determine the fortunes of woodpeckers. Most species thrive in primary forest, but fewer cope with the modern methods of forest management. The Middle Spotted Woodpecker inhabits temperate forest in Europe, where its requirements are such that its population density is determined by the supply of dead wood and oaks (*Quercus*). The rough bark of oaks harbours the small arthropods, such as beetles and caterpillars, that the species favours. Meanwhile, old trees with soft, dead parts are essential for this small-billed woodpecker to excavate a nest-cavity.

The dense forests of the world's highest mountain range host several woodpeckers, the commonest of which is the Himalayan Woodpecker. This hardy species lives among extensive conifer stands and in oak (*Quercus*) and rhododendron (*Rhododendron*) mountain forest above 2000 m, at times ascending beyond the tree-line. It can also be found in mixed forest with junipers (*Juniperus*). For the Himalayan Woodpecker and several other picids, trees are themselves an important source of protein. These arboreal foragers, which only rarely descend to the ground, use anvils in which to break open pine cones for the seeds, an important food in winter.

[*Dendrocopos himalayensis albenscens*, Dachigam National Park, Kashmir.  
Photo: Gertrud & Helmut Denzau]

In some parts, in the south, hybrids seem to be more viable, and no assortative mating has been documented, adults showing no clear preference for mates of their own colour type. Extensive data on a northern population of flickers, however, did show assortative mating. Hybrids can easily be scored according to plumage characters. One study demonstrated that individuals of the same colour are more likely to mate than are differently coloured ones. This remains true even when the fact that "Red-shafted Flickers" breed a little later has been taken into account. The major reason for the stability of the hybrid zone and the distinctiveness of the subspecies involved may be purely ecological, with each subspecies best adapted to its regional climate and vegetation.

Among the Picidae, it is not so unusual for hybrids to occur also between species, mainly those which are considered to be members of the same superspecies. They are found among South American piculets, as, for example, between the White-wedged Piculet (*Picumnus albosquamatus*) and subspecies of the White-barred Piculet. In the case of the Campetherini, hybrids are known between the Little Green Woodpecker (*Campethera maculosa*) and the Green-backed Woodpecker, between the Great Spotted and the White-winged Woodpeckers (*Dendrocopos leucopterus*), and between the American Ladder-backed and Nuttall's Woodpeckers. In the Neotropics, the Little Woodpecker (*Veniliornis passerinus*) and the Dot-fronted Woodpecker (*Veniliornis frontalis*) sometimes hybridize, as also do the Chestnut and Pale-crested Woodpeckers, as well as two of the logcocks, namely the Black-bodied (*Dryocopus schulzi*) and the Lineated Woodpeckers (*Dryocopus lineatus*). In Europe, hybrid pairings are occasionally reported also between the largely sympatric Grey-faced and Eurasian Green Woodpeckers.

An interesting example of interbreeding is provided by the Syrian Woodpecker (*Dendrocopos syriacus*) in the Palearctic Region. This species occasionally hybridizes with the Sind Woodpecker (*Dendrocopos assimilis*) at the south-eastern rim of its range, in Iran, and it also hybridizes now and then with the Great Spotted Woodpecker, a species that it meets more frequently since its rather recent range expansion. Dynamic range shifts are a relatively frequent cause of hybridization in the melanerpine woodpeckers, including the sapsuckers. The Golden-fronted Woodpecker (*Melanerpes aurifrons*), for example, has only re-

cently moved into Oklahoma, where it occasionally interbreeds with the Red-bellied Woodpecker (*Melanerpes carolinus*); the two seem not to interbreed, however, in Texas, where they meet in a zone that reaches from the Gulf coast northwards to Oklahoma. Red-breasted and Red-naped Sapsuckers interbreed occasionally, although they are distinctly different in coloration. Their hybridization reflects both close genetic relatedness and the secondary contact after the last glaciation.

Gene flow within species is important when it comes to maintaining genetic diversity. It relies on dispersal, and is compromised when the range of a species is very fragmented. This is the case with the Red-cockaded Woodpecker. In this species, movement between colonies is associated with reduced availability of roosting cavities, and seems to be sufficient for the exchange of genes within populations. Overall genetic diversity is, however, low, and gene flow is about adequate to counterbalance genetic drift. All the same, the population as a whole is highly fragmented, and individual populations have already attained notable genetic differentiation.

## Morphological Aspects

The size range of woodpeckers is not especially noteworthy when compared with that of other non-passeriform birds, although extant species vary from as little as about 7 g in the case of the tiny piculets up to about 570 g in the largest species, such as the Great Slaty Woodpecker (*Mulleripicus pulverulentus*) and the Ivory-billed Woodpecker. This wide range of sizes permits woodpeckers to live in many different habitat types, and segregation by size may also be an important factor for the co-existence of sympatric species (see Habitat).

The typical picid's morphology features many distinct characteristics, all of which reflect the fundamental habits of these birds of excavating wood, removing bark, and probing deeply into crevices and bore holes, among other things, as well as climbing on vertical surfaces. They include a strong, mostly straight bill, a reinforced skull, a perching foot modified for climbing, and a stiffened tail. The tongue of woodpeckers has undergone many important modifications, rendering it one of the most remarkable anatomical structures to be found among birds.

The Magellanic Woodpecker is just about the largest picid in South America, where it is confined to the Andes of south Chile and adjacent parts of south-west Argentina. In this rather inhospitable climate, it flourishes in the mature forests of southern beech (*Nothofagus*) and cypress (*Cupressus*) that grow in the foothills of the Andes Mountains. Washed by heavy rains from clouds that develop over the Pacific Ocean, these forests gather luxuriant coats of mosses and lichens, in which the Magellanic Woodpecker probes for adult beetles and grubs. Despite its large size, it is able to cling skilfully, almost in the manner of a tit (*Paridae*), to the thinnest of branches.

This imposing woodpecker, which can be seen from sea-level up to the timber-line, generally requires big trees, such as this *Araucaria*, in addition to which it appears to favour areas with an undergrowth of bamboo. It sometimes strays from its preferred habitat into more open woodland, and will also visit disturbed forest, but it seems to be far more at home in relatively quiet tracts of forest.

Those woodpeckers which carry out a lot of excavating are armed with a straight bill, strengthened with longitudinal ridges, and with a chisel-like tip. The pecking action wears off the horny tip in such a manner that the tip maintains its chisel shape. The species which undertake a greater amount of probing or earth-working have a bill that is longer and slightly decurved. This makes it more appropriate for probing and for exerting biting force at the tip. Nevertheless, even the bill of the most specialized excavators is still well suited for a strong grip, thereby enabling the woodpecker to tear away pieces of wood or bark and to carry large food items, including fruits, seeds, pine cones and nuts. In other words, the adaptations for pecking do not compromise other bill actions. That fact certainly contributes much to the great behavioural and ecological versatility of the group.

A straight bill with a wide base is, on its own, far from sufficient to explain the ability of woodpeckers to hammer and dig into hard, live wood repeatedly and for lengthy periods of time. There are more highly specialized structures associated with the skeletal part of the bill and with the skull. The hinge between the foremost point of the skull and the upper mandible, or maxilla, is folded inwards. As a consequence, when the bill strikes a hard surface, the bone there experiences a tension rather than compression. The impact of the blow would normally rotate the upper jaw upwards. This potentially dangerous movement is prevented by the protruding overhanging frontal part of the skull. Because the blow produces tension, it can be counteracted by a special muscle. This action of this muscle is therefore an important means by which the shock is absorbed. Its efficiency in this is greatest when the bill is straight and when its line of action coincides with that of the muscle. Since it runs below the braincase, the latter does not experience the direct shock wave of the impact. The head moves in a straight line and, consequently, it is not subject to rotational forces on impact. The relatively small size of a woodpecker head, as compared with that of a human, also prevents destructive forces from building up when the bill decelerates at a rate of more than 1000 g. The ear is another organ that is very sensitive to mechanical shock, and woodpecker ears show some special features that may be related to the greater protection needed. The round window of the inner ear is less than half the size of that of other birds, its membrane is very thick at one end, and the columella has two basal plates instead of one.

Many of the particular morphological characteristics of the Picidae are associated with hammering. Among them are the neck muscle *M. longus colli* and features associated with it, such as elongated hypapophyses of vertebrae 10-15, which serve as insertion points for the neck muscle, and fused sublateral processes of vertebrae 6-10, which form gliding channels for the tendons of this muscle. The fact that highly specialized excavators occur in several different woodpecker lineages may explain why some derived character states are present in groups that are seemingly not closely related.

The nostrils of most picid species are protected by special feathers, and in the most specialized woodpeckers they are slit-like, lying under a ridge. In the two wrynecks in the genus *Jynx*, the feathering only partly covers the nostrils. A similar condition is found in the African Ground Woodpecker and in two Asian genera, *Dinopium* and *Meiglyptes*. The nostrils of the four *Dinopium* woodpeckers are close to the culmen, in contrast to the slit-like and feather-covered nostrils of the similar-looking *Chrysocolaptes* pair of picids. In the case of woodpeckers of the genus *Celeus*, and also one of the *Dryocopus* logcocks, the Helmeted Woodpecker, there are no feathers at all covering the nostrils. As a general rule, nostrils that are close to the culmen are found in ground-foraging species and in those which only rarely excavate, whereas the nostrils are far apart in species that hammer regularly and frequently.

The tongue is the most important tool for woodpeckers which probe deeply. Its length, the specially structured tip, and the associated sublingual glands, which produce a sticky fluid, determine its actions and functions. Woodpeckers can protrude and retract the tongue with ease, while at the same time being able to control the movements of its tip. For such actions, long, specialized muscles are required. These muscles insert in places very

*The mature boreal forests that extend right across the northern parts of the Northern Hemisphere are inhabited by a number of woodpecker species. A typical picid of the spruce (Picea) and fir (Abies) stands of the European taiga is the Eurasian Three-toed Woodpecker, which survives well in these forests, even in the snowy conditions of winter. Farther east, in the Siberian taiga, it lives predominantly in larch (Larix) forest. When breeding, this woodpecker prefers rather dense, shady forest with plenty of dead trees and fallen timber, where beetle larvae are easier to obtain. At other times, however, it frequently moves into more open habitat, seeking out exposed parts of trees, and visiting trees that have been blown over or have fallen under the weight of snow. During these periods, this woodpecker not uncommonly occurs in concentrations at sites where food is available in good quantity. The female shown here was one of 30-40 Eurasian Three-toed Woodpeckers which gathered in more open woodland in the Oulu area of west Finland, at the top end of the Gulf of Bothnia, during the winter of 1998/99. It is interesting that in parts of eastern Europe, such as Poland, where there are larger remnants of natural forest, this species is just as likely to be found in wet ash-alder (Fraxinus-Alnus) stands or in oak-hornbeam (Quercus-Carpinus) woodland as in pure coniferous stands.*

[*Picoides tridactylus* *tridactylus*, Oulu, Finland. Photo: Jari Peltomäki/ Windrush]

Big trees are an important element of the habitat for many of the Picidae, especially the bigger species. The commonest large picid of the northern Amazon Basin is the Red-necked Woodpecker, a male of which is shown here. Although more than 30 cm long, this handsome woodpecker is nevertheless dwarfed by the huge trees of the lowland rainforest. Here, these birds forage for beetle and moth larvae in the upper trunks and limbs beneath the canopy, often of the same trees in which smaller woodpeckers utilize the lower storeys. Within its exclusively South American range, which extends west to Ecuador and south to central Bolivia and the northern Mato Grosso region, this species is most commonly encountered in rainforest, terra firme forest and várzea forest, but it can also be found in cloudforest, in light second growth, and in riverine woodland in savanna regions.

 Bios]

One factor behind the success of the woodpeckers is that closely related species can exploit different resources. Nowhere is this better illustrated than in the Amazon rainforest, where the two *Celeus* species depicted, the Cream-coloured Woodpecker and the Ringed Woodpecker, live side-by-side. The Cream-coloured Woodpecker, one of the most brightly plumaged of the family, is found in swampy areas, along the edges of rivers and forest pools.

The slightly larger Ringed Woodpecker also lives in the rainforest, but it much prefers tall trees in tall forest, where it is a far more elusive species.

The fact that these two close relatives are able to co-exist in the same areas says much about the abundance of food in such habitats, where both species take fruits and seeds, as well as ants. The Cream-coloured Woodpecker, incidentally, is one of many picids which exhibit a wide degree of individual variation, as well as a number of intermediate populations which are difficult to assign to a particular subspecies. The male shown here, with extensive brown colour on the wings, has an appearance much closer to that of the race *tectricialis*, which intergrades with the nominate race in the area in which the photograph was taken; moreover, the nominate race is so variable that it is hardly practicable to attempt a subspecific identification.

[Above: *Celeus flavus*, Serra dos Carajás, Pará, north-east Brazil. Photo: Luiz Claudio Marigo.

Below: *Celeus torquatus torquatus*, Las Claritas, Bolívar, south-east Venezuela. Photo: Bernard Van Eiegem]

A few woodpeckers are equally at home in coastal scrub and mangrove as in inland forest. The Streak-breasted Woodpecker, for example, inhabits broadleaved evergreen forest in the southern parts of Myanmar and adjacent Thailand, but in the south of its small range, which reaches only to the central Thai-Malay Peninsula, it is perhaps more likely to be found in coastal habitats. This female is foraging for ants on a lateral branch above the mud of a mangrove forest. Interestingly, the closely related Laced Woodpecker (*Picus vittatus*), which is sometimes considered conspecific, also nests and feeds in these same coastal habitats, even where the ranges of the two overlap, in Tenasserim and western Thailand.

Elegem]

different from the insertion points usually found in birds. They sheath the long hyoid bones that provide the necessary stiffness of the total structure. These bones are elongated and thin towards the posterior end and, hence, are flexible. The degree of flexibility of the tongue is modulated by muscle action, so that, when the special tongue muscles contract, the structure becomes stiff. The long bones are wound around the back of the skull; they meet in the frontal region, or, in species with a very long tongue, they enter the bill at the nostril cavity. In some species, the hyoids do not enter the nostrils but are, instead, wound around the right eye. Among the American woodpeckers, this latter condition is incipient in the White-headed Woodpecker and fully developed in the Hairy Woodpecker. It is shown also by the two *Hemicircus* species of southern Asia, one of which, the Heart-spotted Woodpecker, exhibits the development of the condition most spectacularly. Not only do all of these species probe extensively, but they are also strong excavators. The adaptations for the latter activity leave no room for an extension of the hyoid horns and their muscles into the bill, hence this unique solution. In various picid species, the tongue has become shorter as a secondary adaptation. Examples of this are the sapsuckers and the White Woodpecker (*Melanerpes candidus*) of America.

Members of the subfamily Picinae, the true woodpeckers, have the tip of the tongue equipped with a few to many backward-pointing barbs. The number and the particular shape of these are rather variable among species, and reflect their functions. They are arranged in rows of single, loosely spaced barbs, as in, for example, the Neotropical *Piculus* and the Eurasian *Picus*, or in dense to brush-like rows, as in, for instance, *Campephilus*, some *Melanerpes*, *Sphyrapicus* and the Asian Rufous-bellied Woodpecker (*Dendrocopos hyperythrus*). In some cases, the barbs are grouped in clusters of three to five, a condition exhibited by species of *Picumnus*, *Campepthera*, *Dendrocopos*, *Dendrocopos* and *Veniliornis*, among others. They may occur along the whole tip of the tongue or be concentrated at the extreme tip. Examples of picids with barbs mainly at the very tip of the tongue include the Neotropical Golden-olive Woodpecker (*Piculus rubiginosus*) and, in Europe, the Middle Spotted Woodpecker (*Dendrocopos medius*) when compared with its more widespread congener the Great Spotted Woodpecker. The barbs become thinner and shorter in those species

which carry out much of their foraging on the ground. For these picids, the tongue functions more as an adhesive stick than as a spear, and its tip is also rounded rather than pointed.

In the head of a woodpecker, three particular types of gland can be found. The maxillary gland is usually relatively large, and is characteristic of the family. It is situated in the floor of the orbit and is easily confused with the nasal gland, located nearby. This latter gland is close to the nasal cavity in most picids. In the wrynecks and the piculets it enters the orbital region, which is reminiscent of the condition found in passerines. The largest gland, however, is the mandibular gland, without doubt the most characteristic feature of the picid glandular system. Its size may be reduced in some species, as a secondary specialization in the more habitual excavators. By contrast, species which secure their prey by using the tongue as a glue-stick possess large glands.

A particularly large oil-gland has been found in the Chestnut-coloured Woodpecker of Central America, although why this species should possess a bigger gland than do other picids is not certain. A similarly unexplained phenomenon involves two congeneric picids from the southern parts of Asia, the Heart-spotted and the Grey-and-buff Woodpeckers, on both of which a peculiar resin-like substance is not uncommonly present in the plumage of the back. Rather surprisingly, it has not been possible so far to trace the origin of this substance back to specific glands or, indeed, to any other source, and its provenance remains a mystery. Possibly associated with this is the fact that woodpeckers give off a characteristic strong, resinous odour. It has been suggested that this is connected with their food, although H. Sick maintained that the odour originated from the plumage, perhaps from oils produced by the uropygial gland, or even from the feathers themselves. Certain species, such as the Blond-crested Woodpecker and some populations of the Chestnut Woodpecker, seem to emit a more intense odour, but there seems to be no obvious explanation of why this should be so.

The legs of woodpeckers are short, with strong feet and powerful, curved claws. The tarsus and the toes are covered with well-developed, overlapping scales. The picid foot derives from the yoke arrangement, or the zygodactyl foot, found in many perching birds such as the parrots (Psittacidae), the cuckoos (Cuculidae) and the puffbirds, and in the more closely related barbets. When woodpeckers climb, however, the arrangement

Although typically associated with trees in fairly open country, and common in plantations and in built-up areas, Syrian Woodpeckers will also take advantage of more unusual habitats. Some individuals of this opportunistic species make frequent visits in winter to reedbeds, a habitat also utilized by Great Spotted and Lesser Spotted Woodpeckers (*Dendrocopos major* and *D. minor*). The reed seeds, and invertebrates concealed within the plants' stems, can be an important factor in the survival of local populations, especially in such areas as northern Greece, where other food sources may be scarce during hard winter weather.

Windrush]

of the toes takes on a different pattern, the fourth toe then being extended laterally to the outside. This enables the woodpecker to counteract the pulling forces that are exerted by gravity and by its own pecking actions. The first toe, or hallux, is not of much use in this situation and has consequently been lost in several species, including about 20% of individuals of the Himalayan Flameback (*Dinopium shorii*), all Common Flamebacks (*Dinopium javanense*) and Olive-backed Woodpeckers (*Dinopium rafflesii*) and the two *Gecinulus* species of Asia, as well as, of course, the Eurasian and the American Three-toed Woodpeckers along with the closely related Black-backed Woodpecker. The toe directed backwards may help to counteract turning moment at the foot and, together with the tail, assists in keeping the bird's body clear of the substrate. In the large ivory-bills, all toes are needed in order to negotiate the substantial gravitational forces; they are all four directed forwards, and the function of the hind toe, now no longer available, is probably taken on by a special pad located at the "heel" of the tarsus of these species.

It is not only the skull and the legs that show adaptations which relate to the pecking and climbing habits of the Picidae. The rib cage, too, exhibits such particularities. The more a woodpecker species hammers for its living, the wider are its ribs. The first sternal rib is least wide in the Eurasian Wryneck (*Jynx torquilla*); that of the American Three-toed Woodpecker, when scaled with femur length, is more than five times as wide as the wryneck's.

The list of morphological adaptations for tree-climbing would be incomplete without those found in the tail. With the exception of the wrynecks and the piculets, all woodpeckers have a stiff tail with pointed central feathers and strong barbs. In many tree-climbing species, the tail is curved ventrally at the tip. It is relatively soft and broad in the bamboo-climbing *Gecinulus* species. In the three short-tailed *Meiglyptes* "buff" woodpeckers, the Buff-rumped (*Meiglyptes tristis*), Black-and-buff (*Meiglyptes jugularis*) and Buff-necked Woodpeckers (*Meiglyptes tukki*), the tail is rather soft and lacks the typical woodpecker features. It is picine-like, however, in the latter's similarly very short-tailed relatives, the black-and-white *Hemicircus* species, both of which frequently excavate. Typical modifications of the woodpecker tail include the enlarged pygostyle bone and caudal vertebrae,

enabling the powerful tail muscles to insert there. The tail itself is more or less stiff, the central feathers especially having very rigid shafts in the case of the specialized climbers. Woodpeckers possess six pairs of tail feathers, the outermost of which is greatly reduced, in some species to a tiny feather, and is probably functionless. The central rectrices show the characteristic pointed tips and are reinforced by longitudinal ridges, which strengthen the shafts, while the barbs are curved. The vanes are therefore concave, so that the tip of each central feather makes firm contact with the substrate.

When a woodpecker clings to a vertical surface, the tail and the feet act together. The tail's function during active climbing, and even when the woodpecker is stationary and alert, is to keep the body away from the tree surface. The feet provide the pull and thrust during active climbing and when the bird is at rest. Only when the woodpecker is relaxed does the tail serve as an additional prop. It is also important during hammering, because then the forces that tend to push the woodpecker away from the tree are especially strong and have therefore to be overcome by the joint action of feet and tail.

Woodpeckers ascend a tree by means of essentially bipedal hopping. A single hop consists of two phases: a power stroke, and a very brief floating in mid-air. At the beginning of the first phase, the bill points upwards in the direction of the intended movement and the woodpecker pushes itself up along the surface, keeping the front part of the body and the head close to the substrate; at the very last moment, the tail is lifted. Then, in the second phase, the grip of the feet is relaxed, the tail is held parallel to the surface, and for a split second the woodpecker is suspended in the air, without any contact with the substrate; at the same time, the feet are brought forwards in a rapid movement and they take hold of the surface, against which the tail is also once again braced. There is a continuum between this specialized vertical hop-climbing and hopping on horizontal surfaces. Interestingly, the three most specialized ground-living species, the Ground Woodpecker of South Africa and two Neotropical picids, the Andean Flicker (*Colaptes rupicola*) and the Campo Flicker (*Colaptes campestris*), walk with alternating strides.

Collectors of specimens have quite frequently remarked that the skin of woodpeckers is tough compared with that of other birds of similar size. This may be an adaptation that allows them

Throughout the world, habitats created by humans or influenced by their activities are exploited by a variety of woodpecker species.

Indeed, some picids have adapted extremely well to the expansion of the human population since the nineteenth century.

A good example from North America is the Red-headed Woodpecker, which is widespread in the United States east of the Rockies. Not only will this attractive picid use artificial nest-sites, such as buildings and pumps, but it also feeds in gardens throughout the year. This applies both to resident populations and to those breeding in the northern and north-western parts of the range, many of which move south-east after the breeding season.

This species, the most omnivorous of the Picidae, is a frequent visitor to suburban gardens and woodlots, where it generally has easy access to a wide variety of food items. The adult shown here was feeding on cherries, one of many soft fruits consumed in large quantity by this woodpecker in the autumn. Juvenile Red-headed Woodpeckers are duller than the adults, having a brown head and some dark bars in the white wing patch. The red plumage of the head is acquired gradually, and by late winter most are very like the adults, but dark bars are often still present on the secondaries of immature birds in the ensuing spring.

An arid desert is not, at first sight, the most obvious habitat for a woodpecker, but a small number of picids have adapted to living in areas that many bird species would find too inhospitable. The diminutive Ladder-backed Woodpecker of the south-west United States is one such species, being a typical inhabitant of very arid country and deserts. Its southern races, which live in northern Central America south to Nicaragua, are more likely to be found in dry pine-oak (*Pinus-Quercus*) woodland, but do occur locally in clearings in humid forest; more surprisingly, this rather shy species also lives in mangroves in El Salvador and Honduras. The dominant plants in the desert habitat are cacti, which provide a nest-site for Ladder-backed Woodpeckers, as well as two sources of food: the fruit of the cactus, and a variety of small insects and their larvae. These woodpeckers also forage among yuccas (*Yucca*), as well as in low scrub and occasionally on the ground.

to deal better with well-armed insects such as ants, and it is interesting to note that the Picidae share this dermal characteristic with the honeyguides, which are regularly subjected to the risk of bites and stings by Hymenoptera.

Only a few picids have body parts that are bare of feathers. Extensive areas of bare orbital skin occur in *Sasia* piculets and in some true woodpeckers, the latter being mainly melanerpinines. They consist primarily of bare eyerings, which can be orange-yellowish to blackish, and which are duller and different in colour on juveniles. Often accentuated by striking plumage coloration, this bright orbital-skin colour adds to the striking facial patterns found among many melanerpinine woodpeckers. The orbital rings of other species are narrow and exhibit a wide range of colours, from red in the case of some piculets to greenish and bluish in picine woodpeckers. Iris colour varies among species. In addition, it differs between juveniles and adults, changing for example from grey to whitish in some species, such as some melanerpinines, and from brown to crimson in Great Spotted Woodpeckers.

The typical body feathers of woodpeckers in essence do not differ from those of other birds. A unique feature of the woodpeckers, however, is the curved or scimitar shape of the basal cells of the barbules of the contour feathers. The afterfeathers are variable in length, with a very short aftershaft. Picids are generally naked upon hatching and, moreover, they do not develop natal downs; instead, they grow a plumage of contour feathers resembling the ones found on the adults. As with other birds, the feathers are arranged in well-defined tracts of growth, the whole arrangement being referred to as pterylosis. A featherless area along the crest of the head and circular bare areas on the temples are features characteristic of woodpeckers.

Within the Picidae, the coloration of the plumage varies moderately among species and genera. Black and brown, white, red and green are the dominant colours. In most cases, the more conspicuous colours are seen on the head and neck, where sexual badges and specific juvenile colour patterns are concentrated.

Plumage colours may be adaptations to habitat characteristics, governed by intraspecific communication, or the result of social mimicry. They may be conservative in nature and be best explained in terms of a phylogenetic origin, or they may signal that the species in question is unpalatable to potential predators.

Tests of the latter hypothesis, using Great Spotted Woodpeckers, failed to corroborate it. Adaptation to habitat characteristics, whereby the bird achieves camouflage through the matching of its plumage with the background, is probably widespread, although corresponding quantitative data are lacking. The most convincing example of a cryptic pattern is certainly that of the two wrynecks. Dull and brown colours are found in species that occur deep in the shade of the forest understorey, as typified by the Bay Woodpecker in the Malay Peninsula and the Greater Sundas, and they may also be prevalent among picids that spend much time on brown-coloured bark or similarly brown substrates such as ant nests, as do various species of *Celeus*. Bright colours and stark contrasts are least conspicuous in the upper forest strata, and in open woodland. The various black-and-white patterns found for instance in the *Dendrocopos* and *Picoides* pied woodpeckers, and which are also rather common among the melanerpinines, may serve as appropriate examples. Woodpeckers which frequently descend to the ground, on the other hand, are generally less brightly coloured, having the head not strongly marked, and the plumage generally dominated by brown, grey or greenish colours. In many cases, these largely terrestrial picids are barred, and have a pale, white or bright yellowish, rump that is conspicuous when the bird takes off. These birds, when seen from above, are perfectly camouflaged against their background, as demonstrated supremely by a Eurasian Green Woodpecker foraging on a grassy meadow.

Several instances exist of species of different genera showing parallel variation wherever they occur sympatrically. This is best illustrated by the case of the *Chrysocolaptes* and *Dinopium* flamebacks. Both genera contain red-backed and golden-tailed forms, and sympatric subspecies of these two different genera have the same colour of the back. All subspecies of the Black-rumped Flameback (*Dinopium benghalense*) and the Common Flameback that are sympatric with the more widespread of the two *Chrysocolaptes*, the Greater Flameback, possess the red rump of the latter. The black-rumped subspecies of the former are not sympatric with red-rumped Greater Flamebacks. The large *Dryocopus* and *Campephilus* woodpeckers, which are structurally well separated from each other and yet often strikingly similar in plumage pattern, are perhaps another example of social mimicry. There have been two different hypotheses put forward

One of only three woodpeckers that can truly be described as terrestrial, the Andean Flicker is common in the grasslands of the Andean puna, where it thrives at altitudes of up to 5000 m.

These wary birds also venture into the humid shrubland of the páramo, feeding in broken, rolling country. The long bill, constituting 15% of the total length, is used to obtain larvae from deep beneath the soil surface.

Andean Flickers even nest on the ground, where they dig a metre-long tunnel in an earth bank, although natural holes in rocky cliffs are also utilized.

They often excavate roost-holes in the walls of abandoned native houses.

to explain this intriguing phenomenon. One is that competition between such pairs is intense, because the two species involved are closely related and similar in behaviour; similar plumage patterns would help to maintain interspecific territories. The species are, however, not related sufficiently closely for them to hybridize. The other hypothesis assumes "aggressive mimicry". In this case, the two different species would not match each other in strength, but, on the contrary, one species would be superior and aggressive and the other one timid. The mimicry by the latter would protect it from interference by the former, because the would-be aggressor would not dare to attack an opponent that looks like a conspecific and is likely, therefore, to be its match and to involve it in a costly fight. Scattered evidence supports the second hypothesis. In either case, if this type of resemblance concerns close relatives, parallel development of the same colour pattern is not a difficult process to conceive. These cases may become more convincing examples of convergent evolution when phylogenetic relationships have been clarified (see Systematics).

Some species are polychromatic. This means that, in a single population, various types of coloration occur. One could take as an example the *Dryocopus* woodpeckers of South America. There, the Black-bodied Woodpecker may have a white scapular stripe, but there are some individuals which lack this pattern. These forms occur close to another species of the same genus, the Lineated Woodpecker, which is represented there by the subspecies *erythroptus*, and in this subspecies we find a similar polychromatism. The significance of this variation is not at all clear, but it may be related to aggressive mimicry, as discussed in the previous paragraph.

Intraspecific variation reveals the lability of certain patterns. Breast and belly spots can easily be replaced by streaks, and crown coloration, too, is variable, as also is that of the back. A ladder-like patterning as opposed to a plain-coloured back is found, for example, in subspecies of the Grey-capped Woodpecker, the White-backed Woodpecker and Strickland's Woodpecker.

The dark parts of the plumage of many campetherine species exhibit an iridescence, a phenomenon caused by regular micro-structures in the feathers. In experiments using ultraviolet spectroscopy, the wing feathers of the Great Spotted Woodpecker were found to reflect UV radiation. The red, yellow and green colours so characteristic of many woodpeckers are due to carotenoid pigments. In particular, astaxanthin and doradexanthin are responsible for red, and lutein, zeaxanthin and cryptoxanthin for yellow and green colours. The so-called picofulvins are distinct picid pigments and account for the yellow of some species.

Irrespective of the normal variation within species, occasional instances of aberrant plumage also occur within the Picidae. Perhaps the least rare of these are examples of woodpeckers with very pale or abnormally dark areas resulting from partial albinism or melanism. A less expected case involved a male Grey-faced Woodpecker in France which had the mantle, back, uppertail and upperwings very clearly dark-barred, rather than plain green; the head was typical of the local subspecies, the nominate one, but for a pronounced thin black line running from the forecrown to the hindneck, although a similar, if less obvious, line is frequently present on this subspecies.

Most species of woodpecker are sexually dimorphic in coloration, the males wearing the more prominent sexual badges. Sexual dichromatism, however, is not extremely pronounced, and in many species both sexes are colourful. One reason for this is without doubt the fact that the nesting habitat does not require special camouflage for the incubating bird. In almost all cases of sexual colour differences, it is the male that has red or, in some cases, yellow somewhere on the head; if this bright colour is present also on the female, it invariably covers a smaller area. Experiments on flickers and pied woodpeckers have demonstrated that these badges are recognized by the woodpeckers. There are several species which show only indistinct sexual markings. The males of some small picids, including the Asian Sulawesi, Brown-capped and Pygmy Woodpeckers, and some subspecies of the Grey-capped Woodpecker, are only weakly differentiated from the females. Their badges are reduced to small red spots on the

While many species of woodpecker are more often than not observed only solitarily during much of the year, this is certainly not true of all picids. Lineated Woodpeckers, for example, commonly forage in pairs throughout all months of the year, the partners keeping in frequent vocal contact as they move through the open forest in the lowlands and hills of Central America and the Amazon Basin. Despite the propensity to remain in pairs throughout the year, however, the male and female roost separately, often in holes dug into nests of tree-living termites. This is one of several species which, although wary and easily alarmed, will readily visit large isolated trees, especially dead ones, in exposed situations. The southern part of this fairly common woodpecker's range reaches Argentina, where the plumage of both sexes differs from that of populations farther north in lacking the white stripes on the scapulars.

[*Dryocopus lineatus erythroptus*, Iguazú National Park, Misiones, Argentina. Photo: Bill Coster/NHPA]

edge of the crown. In North America, the co-operatively breeding Red-cockaded Woodpecker shows a very similar male head marking that is likewise difficult to detect in the field. Experiments by J. M. Hagan and J. M. Reed indicated that red colour bands artificially attached to males, and only to males, of this species had a detrimental consequence in terms of the number of young which such a male could successfully rear to fledging, whereas other colours did not produce the same result. One reason for this is possibly that red colour provokes more frequent or more fierce aggressive attacks from other members of the colony. The sexual markings of certain flickers are also not very conspicuous. Sometimes the male does not show any red, and is distinguished from the female only by having a black moustache, as is often the case with the Cuban Fernandina's Flicker. In the Heart-spotted Woodpecker, neither sex shows any red or yellow in the plumage: the female has the forehead and most of the crown white, while the male's forehead and forecrown are black with very fine white dots or speckles. There are several picids in which both sexes are brightly coloured red on the head, with sexual differences being minimal or non-existent. These include Lewis's Woodpecker (*Melanerpes lewis*), the Puerto Rican Woodpecker (*Melanerpes portoricensis*), the Red-headed Woodpecker (*Melanerpes erythrocephalus*) and the Red-breasted and Red-naped Sapsuckers in the New World, and the Middle Spotted Woodpecker in Europe.

So far, there has not been a satisfactory explanation for these differences in sexual dichromatism exhibited among the members of the Picidae. One suggestion is that sexual dimorphism decreases in social species, but there are too many exceptions to this concept for it to be a likely explanation. For example, the more or less territorial Guadeloupe Woodpecker is sexually monochromatic, although there are clear differences between males and females in bill length; yet on other Caribbean islands there live much more social congeners, such as the Hispaniolan Woodpecker (*Melanerpes striatus*), that are dichromatic.

In the Colapтини, the Meiglyptini and the Picini, together with African members of the Campetherini, it is frequently the malar region that bears the sexually dimorphic coloration. Females of those species either lack a malar stripe, or have the stripe broken up by spotting or streaking, or of a different colour, often lacking the red found on males. In some species of the above-mentioned groups, as well as in the piculets and, notably, the pied woodpeckers, sexual plumage differences pertain to the crown. In many instances, the crown is partially or wholly red on males, while on females the red either is absent or is reduced in extent and intensity. Looking at all these groups, there is great variation in the head pattern. The genus *Picus*, for example, displays all possible combinations of dimorphic patterns that involve the malar and the crown.

The sexes may also differ in size, and in mensural characters such as bill length. Females of *Sasia* piculets and of the Antillean Piculet are slightly larger than the males, and the female tends to be the larger in other piculets, too. Even so, there is some intraspecific variation, as exemplified by the Greyish Piculet (*Picumnus granadensis*): Short noted that, in the nominate subspecies, the male is slightly larger than the female, whereas the female is the larger in the subspecies *antioquensis*. With the exception of the Acorn Woodpecker (*Melanerpes formicivorus*) and the Grey-breasted Woodpecker (*Melanerpes hypopolius*), males of *Melanerpes* species are generally heavier and longer-billed than females, and these differences are more pronounced in insular forms. The sexes of the sapsuckers are more or less identical in terms of their size, whereas the male of the Cuban Green Woodpecker is distinctly heavier and longer-billed than the female. Among the African Campetherini, sexual differences in size and structure are negligible in the *Campethera* species, while they are manifest in several species of *Dendropicos* the males of which have a longer bill. Females of the five small Asian pied woodpeckers, the Sulawesi, Philippine, Brown-capped, Grey-capped and Pygmy Woodpeckers, along with those of the somewhat bigger Fulvous-breasted (*Dendrocopos macei*) and Stripe-breasted Woodpeckers (*Dendrocopos atratus*), tend to have longer wings and a longer tail when compared with males of the respective species, as

A few picids are highly social in their behaviour. One of these is the White Woodpecker. This highly distinctive Neotropical species is generally observed in small groups of five to eight individuals, which are sometimes accompanied by other picids, especially flickers (Colaptes). In fact, so typical is its flocking behaviour that the arrival of a chattering group of White Woodpeckers in a fruiting tree has been likened to parrots (Psittacidae) dropping from the sky. Among the Picidae, the phenomenon of group-living occurs most frequently among the tropical melanerpine species which feed on fruits and other plant material, suggesting that it may result from the clustered nature of this food source. The joint efforts of several individuals may be useful in locating fruiting trees. Moreover, as small groups cross open country in search of the next food source, the habit of flocking may also reduce the risk of predation. Although the White Woodpecker appears to be not uncommon, little else is known about the extent of its communal lifestyle, such as whether it nests semi-colonially. The complex social nature of the related Acorn Woodpecker (*Melanerpes formicivorus*) is far better known, since that species not only breeds in closely knit groups but also extends its group-living to the collective gathering and storage of food.

Woodpeckers have a well-organized daily routine. Unless there are chicks in the nest which need to be fed, the level of activity is reduced in the middle of the day. At this time the birds generally rest, as this female Chilean Flicker appears to be doing in the dry scrub of southern South America. Some individuals may doze, fluffing up the plumage and creating a more huddled appearance. A resting woodpecker may intermittently stretch its gape, commonly referred to as "yawning", or remove unwanted items from its bill by vigorously shaking its head. The woodpecker usually remains in the open during the daytime, but roost-holes are sometimes used during this midday rest.

also do females of the far more widespread Old World Lesser Spotted Woodpecker. Otherwise, males of the pied species, with the exception of the Downy and Red-cockaded Woodpeckers, are slightly heavier than females, and also have a longer bill but, often, a proportionally shorter tail. Sexual size differences are weakly developed in the colaptine woodpeckers. In the Campephilini and the Picini tribes, the general pattern is that males are slightly heavier, longer-billed and proportionally short-tailed when compared with females. Of course, some variation exists among species in the extent of this dimorphism.

Of particular interest is the way in which sexual morphological differences relate to ecological differences between the sexes. This is discussed in more detail below (see Habitat).

The coloration of young woodpeckers is usually distinct from that of the adults, and this has given rise to many speculative theories. These centre mainly on the question of whether the great diversity of colour patterns found on nestling and juvenile woodpeckers comprises "primitive" or "advanced" character states. A functional explanation would seem possible, but corresponding experimental studies have not been carried out. There are several species the juveniles of which show more red on the head than do the adults. This condition is found in the well-studied Great Spotted Woodpecker and its allies, among them the Syrian Woodpecker, the immature of which in addition possesses a more or less conspicuous red breastband which the adults lack. Juveniles of both sexes of these species have the forecrown red, whereas the red sexual badge of adult males is located at the nape. A similar age-dependent condition is presented by the Maroon Woodpecker of southern Myanmar to Sumatra and Borneo. Rather intriguingly, the reverse pattern is found in the Afrotropical *Campethera* picids, the juvenile males of which have the badge only on the hindcrown or nape, while the adult males have the entire crown red or yellow. There are some other cases in which the position of the juvenile marking differs from that of the adult: the immature Red-cockaded Woodpecker, for instance, has a red patch in the centre of the crown. The juvenile coloration of some species, such as many Colaptini and some Melanerpini, Picini and *Dryocopus*, more or less matches that of the adult. In the Black Woodpecker, for example, the sexual differences appear when the nestling is ten days old, although some individuals, probably females, do not show any red at this stage.

In fact, the extent of the red on juveniles of many species, as typified by the Great Spotted Woodpecker, varies within and among nests, and what seem to be sexual differences are already visible in these early stages. Unfortunately, however, no study based on large sample sizes has yet shown whether these apparent sexual differences agree with the actual sex of all the individuals involved.

The juvenile plumage of the wrynecks does not exhibit any conspicuous marks that could serve as signals. The young of these two Old World species differ, however, in having ■ barred underside, a pattern that is replaced by arrowhead marks in the adult plumage.

The embryonic development of woodpeckers is shorter than that of most other birds of comparable size, while the juvenile development is slower. Wrynecks and woodpeckers are naked on hatching. The pads or flaps on the base of the lower jaw extend over the edge of the bill, and are almost completely reduced upon fledging. They are certainly organs that help in the transfer of food from the parents to the nestlings in the darkness of the hole (see Breeding). The outer edge of the "heel" of the newly hatched wryneck or woodpecker bears wart-like swellings that are shed in the early phase of the nestling's development. Feathers can be seen to develop under the skin on about the sixth day, and they break through the skin three days later.

When discussing the development of the larger flight-feathers, it is necessary to consider this in connection with the peculiar moult of the Picidae. The extent of the juvenile moult varies among species. Piculets of the genus *Picumnus* shed only the feathers of the crown after they have left the nest. *Sasia* species, on the other hand, moult the feathers of the underside, too, upon leaving the nest. All piculets, however, renew their plumage in a full first moult after they have bred for the first time. Conversely, young wrynecks and true woodpeckers replace the primaries, the tail feathers and the rest of the plumage, but do not renew the secondaries and primary coverts until later. The outer primary of juveniles is longer and wider than that of adults; in addition, the tail is shorter and is different in shape, because the feathers adjacent to the central pair remain shorter. Juveniles commence their moult with the primaries. The innermost, first primary is replaced first, and the moult then proceeds outwards; only when the sixth or seventh primary has been shed does the moult of the contour

feathers begin. This moult is completed before the new outer primary has developed fully. In some species, the juvenile begins the moult when still in the nest, and some time before leaving it, which means that the first primaries are grown and then dropped without having ever been used. In these cases, therefore, the two innermost primaries remain small and thin. This pattern is developed to the greatest extreme in the Eurasian Three-toed Woodpecker, the chicks of which replace the five to seven innermost primaries before they leave the nest-hole. This is probably adaptive, since northern and montane species living in cool-temperate areas have to complete the moult before the end of the short summer season, so that they are then able to disperse or migrate. Tropical woodpeckers, in contrast to those of more temperate areas, have the innermost primary only somewhat reduced.

Tropical species lead a more sedentary life than do temperate ones, and their moult can therefore be spread over a long period. The variation in juvenile moult patterns within the genus *Picus* may serve as an instructive example. The tropical Laced Woodpecker (*Picus vittatus*) in South-east Asia has only the innermost primary reduced, whereas, in the temperate Eurasian Green Woodpecker and, even more so, in northern subspecies of the Grey-faced Woodpecker, the two innermost feathers are greatly reduced and measure only one-third or less of the corresponding adult feathers. Similar variation occurs among the pied woodpeckers. As already mentioned, the strongest reduction is found in the Eurasian Three-toed Woodpecker. Compared with that species, the juvenile innermost primaries are less reduced in the Great Spotted Woodpecker, and they are comparatively even less so in the closely related, generally more southern Syrian and Fulvous-breasted Woodpeckers. Melanerpine woodpeckers, incidentally, do not begin to shed their juvenile primaries until after they have left the nest.

Adult moult is tied in with the breeding cycle and occurs after the nesting season. Neither the wrynecks nor the true woodpeckers moult the eleven secondaries during the first moult. For those species for which data are available, there are two moult centres in the secondaries, located respectively at the first and the eighth secondary. In the genus *Colaptes*, for example, after three or four feathers have been moulted from the eighth secondary outwards on either side, moult starts at the first secondary and progresses inwards. Some deviations from the normal pattern of wing moult do, however, occur. Migratory Red-headed Woodpeckers in North America arrest the wing moult immediately after it has begun, and continue it once they arrive in the wintering areas. The related Lewis's Woodpecker completes the moult of its wings and tail early, but it does not complete the body moult until late autumn or early winter. In similar fashion, the sapsuckers terminate their juvenile moult very late in the season, such that they do not acquire adult plumage until as late as February. Of particular interest is the wing moult of the Andean Flicker, which is very variable and protracted, and therefore does not interfere greatly with its capacity for flight. This strategy is presumably crucial when one considers this open-country species' habitat utilization and vertical migration. Migratory populations of species which are partial migrants may also adapt the moult strategy to fit their behaviour. For example, large numbers of Great Spotted Woodpeckers, primarily juveniles, periodically leave the northern parts of Europe after the breeding season. Studies in Norway have shown that these migrating individuals frequently show a reduced intensity of wing and tail moult compared with non-migrants; in addition, the primary moult is sometimes arrested, just as happens with Red-headed Woodpeckers in America.

The specialized function of the picid tail requires some adaptive changes in the moult sequence, too. Species with a stiff tail that is heavily used in arboreal climbing replace the central pair of rectrices last of all. The moult begins at the second-innermost feathers and continues outwards, although some species of *Ceuleus* and *Dendropicos* may start the tail moult at the third-innermost pair of feathers. In analogy with the moult of the inner primaries, these feathers initially remain short on juveniles, causing the juvenile tail to have a graduated shape, as can be seen on, for example, young Black Woodpeckers and Eurasian Three-toed Woodpeckers. The tiny outermost rectrix may be shed before

the fourth. In the wrynecks and at least some individuals of the Cardinal Woodpecker, the tail is moulted in a reversed sequence, beginning with the outer feathers, and this is also the case with some picine species. From what is known of the Picumninae, the tail moult of these tiny woodpeckers does not appear to follow any regular pattern.

## Habitat

The various adaptations of woodpeckers, manifest in their morphology, locomotion, and foraging and nesting habits, have developed over the course of the evolution of these birds towards life in trees. The forests and woodlands of the world, with the exception of those of Australasia, are therefore the prime home of the family. A few picids have evolved partly ground-living habits, but they still nest in trees and live in wooded habitats. Woodpeckers which frequently feed on the ground are found among the African Campetherini, the flickers and the Picini. Even fewer species are completely terrestrial, and only three could really be so described. These are the aptly named Ground Woodpecker of South Africa, the Andean Flicker living in the mountains of that name, and the Campo Flicker of the pampas and savannas of South America. The vast majority of woodpeckers are, however, tied to wooded habitats, these ranging from dense tropical and boreal forests to lighter woodlands and to sparsely timbered semi-deserts. Trees offer food, protection, signalling posts and nesting sites. Numerous studies have shown that, for many species, a minimal amount of dead wood is required for a habitat to be suitable.

Tropical rainforest harbours the greatest numbers of woodpeckers. In this respect, the forests of South-east Asia and South America are the most diverse and, in both regions, as many as 13 species can be found living sympatrically within an area of about 100 ha or less. This may seem surprising when one considers the fact that woodpeckers are already highly specialized in ways that are to a greater or lesser degree similar for all species, so that it may be difficult for them to partition the habitat by developing further specializations.

As this Northern Flicker illustrates, woodpeckers use the bill to preen their body feathers and to clean the feet. A more difficult manoeuvre involves stretching a leg and foot to tend to the head, neck and bill, as this requires that the bird temporarily releases its grip on the vertical surface. Woodpeckers also maintain their plumage in prime condition by shaking the body and wings, by rubbing the face and other areas on tree bark, and by using the bill to apply preen oil to their feathers. This fatty substance, produced by the uropygial gland, is worked into the plumage with the bill, which the woodpecker then wipes clean on twigs or branches.

Bathing in water is a type of maintenance behaviour that is not very often recorded for the Picidae, but it almost certainly occurs more frequently than is apparent from observations. Water-bathing is accomplished in the open, during precipitation, or in a suitable shallow pool. During rain showers, the woodpecker stretches its wings and, often, fans the tail, to take advantage of the moisture, after which it preens in the usual fashion. Both ground-loving species, such as the Eurasian Green Woodpecker, and arboreal ones bathe in this passive manner. Woodpeckers also utilize water that has collected in a depression in a tree, such as a rot hole or at the site of a fork, or on the ground. In these situations they bathe more actively, splashing themselves rapidly for a few seconds at a time, but taking frequent short breaks, alert to the danger of potential predators. Perhaps the Eurasian Green Woodpecker in the lower photograph, a male of the Iberian race *sharppei*, having less black on its face than the nominate race shown above, is keeping an eye on the Azure-winged Magpie (*Cyanopica cyana*) in the background.

Surprisingly few woodpeckers are known to perform anting, an activity sometimes integrated with sun-bathing. One of these is the Gilded Flicker. Anting occurs among many avian species, but its function is unclear. A popular belief is that it helps to prevent the build-up of ectoparasites. Another theory is that active anting, whereby the bird rubs ants against its plumage, may be a specialized part of feeding behaviour, designed to rid the insects of their acid and render them more palatable. This seems rather unlikely in the case of picids, many of which consume a wide variety of ant species but make no attempt to treat the prey before swallowing.

In each of his two study sites in tropical lowland rainforest in Malaysia, Short found 13 species of woodpecker. These covered the full size range that exists within the family, with the tiny Rufous Piculet at the small extreme and the Great Slaty Woodpecker at the top end. Although the size ratio among these sympatric woodpeckers did not follow a regular pattern of increase, it was evident that size differences contributed greatly to niche separation. This was particularly true for those species which engage in much pecking and excavating. The less specialized forms were not so widely separated by size, and these species exploited, in the main, an almost unlimited food source, namely ants and termites. Furthermore, the 13 picids demonstrated differences in their use of the habitat. The largest of them all, the Great Slaty Woodpecker, weighing over 400 g and with some individuals over 500 g, occupies huge territories and covers relatively long distances between its feeding sites. The latter comprise big trees, often standing alone in an open area, but also small trunks on which this woodpecker may feed not far from the ground. Although this species possesses a large bill, it carries out a great deal of gleaning and probing; when excavating, it delivers several powerful blows. It is rather restless and mobile, covering large sections of a tree in its search for food, and not remaining for long at any particular site. The second largest species in the Malaysian lowland rainforest, the White-bellied Woodpecker, weighs about half as much as the previous species and requires large foraging ranges, although these are not so extensive as those of the Great Slaty Woodpecker. It is much more of an excavator, and it forages chiefly on the dead parts of live trees, and on dead trees that have fallen or are still standing. This species may excavate deep pits, and it often stays at favoured sites for long periods of time and visits them repeatedly. Smaller than the White-bellied Woodpecker by about 80 g, the Orange-backed Woodpecker (*Reinwardtipicus validus*) forages from close to the ground up to the canopy, preferring the middle strata. There, it moves about actively yet excavates frequently, in short bursts of activity. The somewhat smaller Olive-backed Woodpecker is confined to swampy sections of the forest, where it forages mainly close to the ground, moving slowly but constantly. In these Malaysian forests, three *Picus* species are sympatric: the red-dish-coloured Banded Woodpecker forages in densely vegetated, concealed sites, the Chequer-throated Woodpecker (*Picus*

*mentalis*) is found mainly between 3 m and 15 m above the ground, and the Crimson-winged Woodpecker (*Picus puniceus*) searches for food in the canopy. Two other congeneric species, the Buff-rumped and Buff-necked Woodpeckers, are also separated mainly by habitat use, the former foraging very actively in the canopy, while the latter often seeks food near the ground and in the understorey. Heavy understorey in tracts of dense primary and secondary forest is the principal habitat of the Maroon Woodpecker, which is well camouflaged by its brown colours; it specializes in extracting insects and their larvae from rotten trunks and fallen logs by hacking with its powerful bill. Also brown, but utilizing a much greater diversity of habitats and foraging sites, the Rufous Woodpecker may at times be observed feeding on the ground, on termite mounds, but it also moves constantly along branches and trunks. It gleans and probes, and occasionally taps. It searches among bamboo (*Bambusa*), as well as coconuts and arboreal ant nests, preferring to stay mainly in dense vegetation and in dark sites. The smallest woodpeckers in this forest ecosystem are the Grey-and-buff Woodpecker and the Rufous Piculet. They are not likely to interfere with the other woodpeckers, for they feed on small-sized substrates, nor are they likely to compete with each other, since they are well segregated by the strata which they use. The piculet forages in dense vegetation at low levels. The Grey-and-buff Woodpecker, on the other hand, explores small twigs and leaf clusters high in the canopy.

The same number of sympatric picid species was found by Winkler and others in South America, in a lowland rainforest lying at the same latitude as the Malaysian sites. Although these Neotropical woodpeckers are phylogenetically more uniform, niche separation among them follows similar principles to those demonstrated in South-east Asia. The smallest species was the Golden-spangled Piculet, weighing just 9 g, and the largest, each at about 200 g, were the Lineated, the Red-necked (*Campephilus rubricollis*) and the Crimson-crested Woodpeckers (*Campephilus melanoleucos*). Although these large species were seen feeding on the same trunk, albeit at different times, they were thought to be going for different prey, some seeking ants and termites, for example, and others taking grubs. The four *Celeus* species present in the same forest, the Ringed (*Celeus torquatus*), Scaly-breasted, Cream-coloured (*Celeus flavus*) and Chestnut Woodpeckers, are

kept largely apart by the fact that each one prefers a different forest stratum from those frequented by the others. Since, in the case of these woodpeckers, frugivory is of some importance, the good food supply may further foster the co-existence of so many congeners. The bark-gleaning guild in the Neotropics also contains several species of ovenbird (Furnariidae) and woodcreeper (Dendrocolaptidae). The ability to exploit different resources despite many shared specializations no doubt contributes to the great success of the woodpeckers as a family.

The principles that are seen to operate in rainforests apply to temperate zones as well. Wherever several species of woodpecker are sympatric, and occur in the same kind of habitat, they are separated ecologically by size, foraging stratum, foraging style and food preferences. It should be noted here that foraging stratum does not signify only the height, or relative height, within the forest or in a single tree. Implicit within the term are the diameter of the trunk, limb or branch, and their angle of slant, along with the condition of the bark, all of which are important niche dimensions as well. This finer subdivision of the habitat becomes especially apparent when one considers ecological differences between sexes.

Ecological sexual dimorphism is widespread among woodpeckers. In its most simple form, the sexes may differ in the parts of the territory which they use when they are feeding nestlings. Sexual differences occur also, however, when woodpeckers forage for their own sustenance. The differences pertain to foraging height, to the use of micro-habitats as just described, and to the foraging techniques applied. These ecological differences are also reflected in mensural characters of the bill, feet and tail. Sexual differences may be most pronounced during harsh ecological conditions and can, therefore, show seasonal fluctuations. One of the species that was first studied is the Hairy Woodpecker of North and Central America. Whenever food is scarce, Hairy Woodpeckers resort to foraging for wood-boring grubs, mainly by excavating; in winter, when this habit is most common, the males excavate even more than do the females. Again, sexual differences in the foraging behaviour of the Red-bellied Woodpecker are most pronounced in winter, when males more often search trunks for arthropod food. The Golden-fronted Woodpecker, another melanerpine species with some ecological sexual dimorphism, forages mostly on medium-sized to large branches

and on trunks. Studies have demonstrated that this picid's most important feeding techniques are gleaning and searching, which together constitute 50% of its foraging actions; less common are pecking and hammering, which make up 28%, and probing in crevices and holes, which account for 13%. With this species, it is the males that peck slightly less frequently than do females, and they also forage less often on small twigs.

Sexual differences in feeding ecology are widespread also among the pied woodpeckers of the genera *Dendrocopos* and *Picoides*, as, for instance, in the Hairy Woodpecker. In the case of the Old World Great Spotted Woodpecker, these differences in foraging are very slight and are noteworthy only in winter. The sexes of the White-backed Woodpecker differ morphologically, the male having the larger bill. Males of this species hammer more strongly than do females and are more persistent in their work, in addition to which they visit both live trees and taller trees more often, and forage on larger branches. With this species, too, sexual differences are most significant in the winter, and the proportions of the foraging techniques used change with the seasons; working deeply into the timber decreases from about 20% of techniques observed in winter to about 12% in the post-breeding season. Compared with their mates, female Strickland's Woodpeckers in America forage more on twigs than on trunks and large branches, especially towards the onset of the breeding season. The sexes of the Red-cockaded Woodpecker differ minimally in their morphological measurements, but they exhibit constant foraging differences, these being most pronounced in the winter months from January to March. Males of this rare but well-studied picid use mainly the upper trunk and branches, while females tend to feed on the lower trunk. A similar difference has been found to be typical for foraging Downy Woodpeckers in winter. For this widespread Nearctic species, good observational and experimental evidence has been accumulated to indicate that sexual niche segregation is maintained by intraspecific aggression: the male keeps the female away from the crown of trees by making frequent attacks on her. In the case of the White-headed Woodpecker, which is confined to the mountains of western North America, sexual differences in foraging are most pronounced in the southern part of its range. There, females feed more on trunks, whereas males rely more on cones, particularly the huge ones of the Coulter pine (*Pinus coulteri*),

Aggression between woodpeckers is very frequent in occurrence, and is often very difficult to distinguish from courtship behaviour. In many cases, however, it is directed mostly at individuals of the same sex, as these two male Northern Flickers illustrate. During antagonistic encounters, the bill is pointed upwards and the wings are raised and flicked prior to an assault, which often involves stabbing at the opponent with the bill. Aggressive behaviour decreases during the period of incubation and brood care, which may be one factor enabling locally high breeding densities of Northern Flickers to occur, although nesting times are staggered to reduce such conflicts.

[*Colaptes auratus auratus*, Long Island, New York, USA. Photo: Tom Vezo]

In the open grasslands of South America, two male Campo Flickers engage in aerial combat.

Such conflicts usually take place close to nest-sites, reaching a peak around the time of egg-laying, but they also occur at roosts. They start with agitated calls, followed by wing-flicking and swinging movements of the head and body. If the intruder does not withdraw, physical combat ensues in which the bill and the feet are deployed as the main weapons. Observations in the wild, supported by experiments using dummies, indicate that such fights are usually between individuals of the same sex, whether the intruder is a single bird or one of a pair.

[*Colaptes campestris campestris*, Pantanal, Mato Grosso, Brazil.

and, as with the Downy Woodpecker, this sexual separation appears to be maintained by male aggression. Circumstances seem to be reversed with the Eurasian Three-toed Woodpecker. In this species, it is the males that forage at lower levels, mainly on trunks, and prefer large trees, while the females forage higher up and have a greater niche breadth, using also relatively thin trees and branches and, in summer, more frequently exploiting live trees. Both sexes forage lower in winter, but, when partners forage together at that season, females restrict their feeding to higher levels, indicating that in this instance, too, the male controls the female's foraging niche. This seems also to be the case with the Middle Spotted Woodpecker. Interestingly, in the isolated North African population *numidus* of the Great Spotted Woodpecker, the sexes exhibit a greater difference than is apparent among Central European populations, and, as with the two foregoing species, it is the females that are found mainly in the crown and that prefer thinner branches.

From these few examples, it should be clear how several different species of woodpecker, as well as the two sexes of the same species, are able to divide up their shared habitat by means of micro-habitat selection and different foraging modes. There are many similar examples throughout almost the entire world range of the family.

Whether habitat-partitioning is simply the by-product of the phylogenetic history of the individual species involved, reflecting adaptations to some past ecological conditions of resource availability, or whether it has been shaped by competitive interactions is a difficult question to answer. Negative correlations between the population densities of two potential competitors may indicate that competition is responsible, but there are alternative explanations as well. Simple habitat alteration or changes in local climate, for instance, can affect two different species in dissimilar ways. Habitat use on islands may be explained by "competitive release", or it may be the result of poor resources. At any rate, woodpeckers on islands do often exhibit such changes in habitat use. Locally, Black Woodpeckers and Grey-faced Woodpeckers have been found to show negative relationships in their population densities, with the Black Woodpecker decreasing when the Grey-faced Woodpecker was increasing. On Scandinavian islands on which the latter species was absent, however, the Black Woodpecker was observed in a wider range

of habitats and at higher densities than it was on islands where both picids were present.

High population densities and flexible habitat use are also typical of many melanerpine island species. These populations expand the species' niche further by means of a greater ecological differentiation of the sexes. Thus, the best examples of ecological sexual dimorphism, relating both to morphology and to foraging behaviour, are found on islands. It has already been mentioned that the Golden-fronted Woodpecker, a mainland species, exhibits some ecological differences between the sexes. The insular Hispaniolan Woodpecker, however, displays greater sexual dimorphism, with, for instance, a difference of about 21% between males and females in bill length, while the corresponding figure for its continental relative is less than 10%. Other insular melanerpine species, such as the Guadeloupe and Puerto Rican Woodpeckers, and the peculiar Cuban Green Woodpecker, all show a morphological sexual difference of 15-19%. Parallel differences in the proportions of feeding techniques used and foraging locations exploited have also been documented for some of these species. In studies of Hispaniolan Woodpeckers, females used gleaning about 50% more than did males and they probed much less frequently, with probing accounting for 0.6% of observations of feeding, as opposed to 34% for males; and males used hammering or pecking twice as much as did females. Males of the Guadeloupe Woodpecker, too, peck more frequently than the females do. Again, these sexual differences are most pronounced during the harsh conditions of the dry season. The sexes of the Puerto Rican Woodpecker also forage in different strata and use different foraging techniques. Males peck and probe more and tend to forage in the lower and middle parts of trees; females, on the other hand, prefer to glean, and are more frequently found in the middle strata and in the canopy. The greater divergence between the sexes of insular populations is often explained as being the result of an intense intersexual competition that has not been constrained by competition from other woodpeckers.

Fire is an important factor that determines forest dynamics in many areas, and it is also, therefore, important for several woodpecker species. Trees killed by fire become easily infested by wood-boring insects, among which are some significant pest species. This is the case in the coniferous forests of the Northern Hemisphere, where American Three-toed, Black-backed and

One of the most widespread picids in North America is the Hairy Woodpecker, a female of which is shown here. This species lives in forest and woodland but also visits gardens, and is usually seen alone. A relatively sturdy woodpecker, it is dominant over all other Nearctic members of its genus apart from the slightly bigger Black-backed Woodpecker (*Picoides arcticus*). Its behaviour encompasses the full range of aggressive displays, while defensive posture is indicated by fully spread wings. Confrontations occur not only with other picids but also with members of other bird families, especially Common Starlings (*Sturnus vulgaris*), which frequently take possession of woodpecker holes.

[*Picoides villosus villosus*, northern Wisconsin, USA. Photo: S. Nielsen/DRK]

Hairy Woodpeckers concentrate around the sites of forest fires, a habit mirrored in the Old World by Eurasian Three-toed Woodpeckers. Even the presumably extinct Ivory-billed Woodpecker (see Status and Conservation) used burned areas. Moreover, Red-cockaded Woodpeckers may profit from fires, because such events keep the hardwood mid-storey in check and help to maintain the specific characteristics of the open pine woodland which this endangered species needs. Forest fires are often natural phenomena, occurring on a fairly regular basis. The same cannot be said of the slash-and-burn agriculture practised in many tropical countries, but even this may provide additional snags that can be used as roost-sites and even as nesting sites by several species of woodpecker.

Secondary or somewhat degraded forest can represent good woodpecker habitat. Indeed, even the fragmentation of forest may benefit certain species which prefer more open areas, the Eurasian Green Woodpecker being a good example. Even some of the large *Campephilus* ivory-bills can be seen in secondary and fragmented forest, where they seem to be attracted especially to single dead or dying trees. Such observations have in fact prompted the suggestion that the Ivory-billed Woodpecker could perhaps be saved from extinction by the killing of trees through girdling, fire or even poison, but this action, even if viable, would seem hardly likely to be effective at this late stage in the species' history (see Status and Conservation).

Bearing in mind what has just been said, it is not surprising that many picid species have become emancipated from primary natural forest. Indeed, secondary forest, orchards, coffee plantations, suburbs, gardens, and both small and large city parks are far from being the least suitable habitats for many woodpeckers. Good examples are provided by the many melanerpine species that are a typical component of the avifauna of suburbs, villages and gardens throughout much of the Americas. In Europe, it is notable that the range expansion of the Syrian Woodpecker was entirely related to the existence of man-made habitats. That species' widespread congener, the Great Spotted Woodpecker, frequents parks and gardens from Britain and north-west Africa in the west across to China and Japan in the east, and it attains its highest known breeding densities in suburban managed woodland. Similarly, in North America, the Downy Woodpecker is a typical inhabitant of suburbia, where it maintains stable

populations, while its relative, Nuttall's Woodpecker, is widespread in California and thrives in wooded environments in and near human settlements. Parks may, in fact, represent optimal habitats for a number of woodpeckers, because they tend to contain old trees that would long since have been removed in managed forest. Fruits and nuts in gardens and commercial orchards can in some cases provide essential sources of food, and in the Northern Hemisphere woodpeckers are common visitors to artificial feeders and birdtables in winter.

Forest-management practices in many cases determine the quality of the habitat for woodpeckers. The species which have possibly been studied most intensively in this respect are the Red-cockaded Woodpecker in North America and the Middle Spotted Woodpecker in Europe. The misfortune of the former is that its preferred habitat is also a prime target for loggers. This species requires old pine stands in the south-eastern USA that are regularly subject to fires, which prevent hardwood from becoming dominant. The pines offer secure nest-sites because they allow the woodpeckers to maintain a constant, protective flow of resin around the nesting and roosting holes, a facility which no other trees can provide.

On the opposite side of the Atlantic Ocean, most of the central European populations of the Middle Spotted Woodpecker live in managed forests, and these remain suitable for this locally endangered species only if they retain a minimum proportion of oaks (*Quercus*). Forest or woodland without suitable, and therefore old, cavity trees can be used only for foraging, although snag management and, in a few instances, the provision of artificial snags can relieve such a situation. Several studies have demonstrated that, for woodpeckers which live in forest, the relative supply of dead branches and dead or dying trees is a reliable predictor of their occurrence and population density. Old stands are in most cases, therefore, good woodpecker habitats. Species which undertake comparatively little excavation of timber may be sensitive to factors other than dead wood alone. Thus, as has been shown in a number of studies, Middle Spotted Woodpeckers, in most parts of their range, require oak trees, with their rich insect fauna and furrowed bark, as an important forest constituent.

Small woodpeckers are able to utilize as foraging habitats not only the branches and twigs of trees, but also other parts of

the vegetation. Their size permits them to exploit bushes, the stalks of herbaceous plants and, most commonly, corn, reed (*Phragmites*) and bamboo. The last occurs in the habitat of several species, although it is not clear in every case whether the woodpeckers do in fact require the presence of bamboo for their sustenance. For example, a number of picumnines, such as the Golden-spangled, White-barred and Mottled Piculets in the Neotropics, and the Speckled, Rufous and White-browed Piculets in Asia, are associated with bamboo to a certain degree, but they are not restricted to such habitats. Similarly, the small Asian Fulvous-breasted Woodpecker has been found in bamboo stands, and the southernmost subspecies of the Hairy Woodpecker frequents montane oak-bamboo forest in Central America. In South America, the Bar-bellied (*Veniliornis nigriceps*), Little and Green-barred Woodpeckers are more or less accidentally associated with bamboo, as also are the Asian Rufous, White-bellied and Black-and-buff Woodpeckers, along with the Laced Woodpecker and some other *Picus* species, and the two *Blythipicus* woodpeckers.

This tall-growing, woody-stemmed grass is, however, of greater importance for some picids. The very small Grey-and-Heart-spotted Woodpeckers apparently prefer the presence of bamboo in their habitat, while the medium-sized Lesser Yellownape (*Picus chlorolophus*) seems to be closely associated with bamboo, and uses it for foraging. The Rufous-headed Woodpecker has been found to be a near-obligate bamboo specialist in south-eastern Amazonian Peru, its population density apparently constrained by the availability of nest-sites, for which it requires trees. In south-east Asia, the Bamboo Woodpecker (*Gecinulus viridis*) is, as its name implies, confined to areas with bamboo, which may comprise pure stands or consist of patches in forest. Its close relative, the Pale-headed Woodpecker (*Gecinulus grantia*), prefers bamboo beneath forest canopy, although it can also be encountered away from this specialized grass. These last two picids forage mainly by gleaning prey from the bamboo stalks as they work methodically and slowly up them.

The dry, hollow stalks of reeds, although far narrower than bamboo stems, are exploited for the arthropods which may lurk inside them. A species which has learned to take advantage of this source of food is the Lesser Spotted Woodpecker. This picid generally inhabits open woodland and similar wooded habitats in most of its range, but in some areas it visits reedbeds from time to time. In parts of Europe, the food obtained from the reeds can be an important factor in the winter survival of local populations.

Some members of the Picidae live in semi-deserts or at the edge of true deserts. The Arabian Woodpecker, for example, occurs in environments ranging from relatively lush mountain habitats to the edge of the Arabian Desert, where grazing livestock leaves hardly anything but bare sand and a few scattered acacias (*Acacia*), just sufficient for this small woodpecker to procure its food and to drill its nest-holes. Acacias are similarly exploited by the Little Grey Woodpecker (*Dendropicos elachus*), a poorly known Afrotropical species which is confined to semi-desert on the southern edge of the Sahara. The semi-deserts of North and South America are all inhabited by woodpeckers. The large cacti found in these arid parts of the New World serve as a good replacement for trees and are regularly utilized in Central America by the Ladder-backed and Gila Woodpeckers (*Melanerpes uropygialis*), which both excavate nests in the cacti and use the fruits for food.

Grassland is another treeless habitat that has in several places been conquered by woodpeckers. In Africa, species such as the Fine-spotted Woodpecker (*Campethera punctuligera*) are found in grasslands with at times widely scattered trees and patches of bare ground, and the congeneric Bennett's Woodpecker allocates most of its foraging efforts to ground-feeding, often in grassland away from wooded areas. The most extreme example in this group of woodpeckers is, however, the Ground Woodpecker, which inhabits open rocky terrain in the uplands of South Africa, occurring mostly above 1200 m and ascending as high as 2100 m. This unique terrestrial picid lives on the grassy boulder-strewn slopes and hillsides and in open grassy country with rocky ridges, as well as frequenting barren or eroded areas in the hills. Even in the south-west of its range,

where it can be found down to sea-level, it prefers similar rocky and grassy areas, such as roadsides.

The *pampas* and the *puna* grasslands of South America are inhabited by specialized flickers. In the high Andes of west-central South America, the Andean Flicker lives in open terrain and forest edge at high elevations. It is common in the grassland of the Andean *puna* zone between 2000 m and 5000 m, and it also ventures into the humid shrubland of the *páramo* and other montane scrub and woodland. Its preferred feeding grounds are grassy areas around rocky outcrops. The remarkably long bill of this colapline is well adapted for probing and digging into the soil to obtain larvae concealed deep beneath the surface. In places where trees, cliffs, rocks or walls are lacking, buildings are used as lookouts and signalling posts. The flicker's feeding areas may be far from its nesting grounds or roost-sites, and may be situated at lower altitudes. In the lowlands of eastern South America, the Campo Flicker is another conspicuous grassland woodpecker which forages almost exclusively on the ground, searching among stones, close to decaying fallen logs and on roads. It also seeks food on termite mounds or anthills, which, as other such prominent structures as isolated trees, poles, wires, cacti and rocks, are used also as vantage points from which to survey its surroundings. This woodpecker, like its Andean congener, does use forest edge, but it never advances into the forest interior.

Highly important requisites of woodpecker habitats are sites for nesting and roosting. The Eurasian Wryneck, which is not morphologically adapted for sustained excavation of wood, uses the old holes of other woodpeckers, other natural cavities and artificial nestboxes; in eastern Asia, its nests have also been found in buildings. The species' African sibling, the Rufous-necked Wryneck (*Jynx ruficollis*), adopts the former nests of barbets or woodpeckers, or appropriates natural crevices in trees, as well as using nestboxes, hollow fence posts and holes under the eaves of houses. Most members of the family, however, construct their own nests, although there is some variation in this respect. Woodpeckers that are less inclined to excavating wood, such as the flickers, are more likely to use pre-existing holes or to make new cavities into very soft wood.

Among birds, drumming is unique to the piculets and the true woodpeckers. Contrary to suggestions in popular culture, it is not used for excavating holes but, instead, is an acoustic signal used primarily as a means of communication between partners, often in a territorial context. The head and neck are specially adapted to facilitate both drumming and frequent pecking; muscles that contract before impact act as shock-absorbers. Drumming is performed by both sexes, and both the sound produced and the frequency of rolls vary considerably according to species. The Robust Woodpecker, for instance, makes a loud double rap, one to three times per minute. Recent studies demonstrate that the drum's cadence encodes information for species recognition.

[*Campephilus robustus*, Iguazú National Park, Misiones, Argentina. Photo: J. & A. Calo]

Many woodpeckers are highly vocal. The majority of species produce a single short call, and a longer series of notes often with a rattling quality. The Golden-olive Woodpecker's vocalizations are fairly typical for the family. Its normal call is a single loud "deeeeh", while the long-distance communication is a protracted high trill; the liquid "woick-woick-woick" given during antagonistic encounters is a highly characteristic picid call. Woodpecker vocalizations often relate to specific activities, such as fighting, copulating, maintaining contact while foraging, and displaying. In the last two contexts, calls are particularly important for those species which do not drum.

[*Piculus rubiginosus*.

Ardea]

Since the typical woodpecker nest is carved into dead wood, or into trunks or branches which have soft or rotten wood at the core, trees and palms that provide corresponding resources are an essential element of the habitat for many picids. Nevertheless, a wide variety of other substrates will often suffice. For example, utility poles are frequently used for nest-building, and fence posts are perfectly acceptable as nesting sites for smaller species such as the Neotropical Red-crowned (*Melanerpes rubricapillus*) and Spot-breasted Woodpeckers, among others. Similarly, cacti are ideal tree substitutes for many of the melanerpine species. In other cases, the large nests of arboreal insects are adequate for hole-making purposes, as with the Rufous Woodpecker in Asia, the Pale-crested and Golden-green Woodpeckers (*Piculus chrysocloros*) in the Neotropics, and the Buff-spotted Woodpecker (*Campethera nivosus*) in the Afrotropics. Those species living in grassland where trees are more or less absent require no more than earth banks, termite mounds or reasonably soft ground into which to dig their burrows. The various sites used by the Picidae for nesting are discussed in more detail later (see Breeding).

Roosting sites selected by woodpeckers are similar to those used for nesting. All members of the family roost in holes and, so far as the male is concerned, the roost and the nest are in most cases one and the same place during the breeding period. While old nests are often used for roosting, or special cavities are sometimes constructed for this purpose, the requirements of a roost-site are less strict than are those of a nesting site. As a consequence, an even wider range of usage is possible, and nestboxes, buildings, arboreal termitaria and the like have been recorded, besides the usual holes excavated in wood. Outside the breeding season, single dead trees may at any one time provide shelter for several individuals of various species.

### General Habits

Many woodpeckers give the impression of being solitary and aggressive birds. The widespread temperate-zone species, such as the Great Spotted Woodpecker and its North American analogue, the Hairy Woodpecker, certainly fit this picture. With such species, observers can even find it difficult to distinguish be-

tween courtship and aggression in the behavioural repertoire, because both components appear to be present during encounters between the sexes. Moreover, the partners rarely maintain contact beyond the immediate vicinity of the nest-site, and they seem to be at most only loosely in touch with each other outside the breeding season. Pair-members of other species maintain vocal contact at least during the breeding season. Examples are the Red-crowned Woodpecker, Strickland's Woodpecker, the Arabian Woodpecker, the Fine-spotted Woodpecker, the Nubian Woodpecker and the flamebacks, to name but a few. Among tropical species, contact between pair-members outside the breeding season seems to be more common.

In the tropics, there are more picid species with juveniles that stay with their parents for an extended period of time. This prolonged contact between parents and their offspring seems to be the most important foundation for group-living among members of this family. Sociality among woodpeckers not only expresses itself in the habit of individuals of foraging together in a group, but also pertains to the sharing of a communal roost. Even the piculets follow this pattern. The Olivaceous Piculet (*Picumnus olivaceus*) lives in pairs or in groups of up to five individuals. Both parents roost in the nest before egg-laying and also during incubation, which task they share, and both also feed the young. Even after these have fledged, the whole family continues to roost in the same hole for some months. If a second brood is to be attempted, the young of the first brood stay on and roost with the parents, at least until the hatching of the new clutch of eggs. Similar behaviour by Blood-coloured Woodpeckers (*Veniliornis sanguineus*) has been observed in South America. A further example is provided by the Olive Woodpecker (*Dendropicus griseocephalus*) of Africa, the female and male of which roost together in the nest during the egg and the nestling stages. If only one juvenile is produced, as is frequently the case with this species, the whole family, consisting of both parents and a single offspring, will often roost together in the former nest for several more months. It seems that this younger individual may stay on and act as a helper during the next breeding attempt.

Among the Picidae, it is the mainly subtropical and tropical melanerpine woodpeckers that exhibit the greatest tendency towards group-living. For these woodpeckers, living in a group is closely connected with communal breeding. The general pattern

Most true woodpeckers, such as this female Black-rumped Flameback, maintain contact over long distances with a rattle-like or screaming call that has a frequency of between 1 and 2.5 kHz, ensuring good sound transmission in the forest. Contact calls from one member of a pair elicit an immediate response from the partner, but such calls are also used between a pair and its neighbours. Shorter calls are given by fledged young to indicate their location to parents. Nestlings have yet different calls, most of them associated with begging, but some are alarm calls made in the presence of an intruder. Black-rumped Flameback chicks, for example, make a hissing sound, similar to that emitted by young wrynecks (*Jynx*).

[*Dinopium benghalense*  
benghalense,  
Ranthambore, India.  
Photo: Patricio Robles Gil]

seems to be much as that described above for the campetherine Olive Woodpecker. Thus, group-living evolves through extended contact between parents and fledglings which eventually may lead to helping and to communal roosting. As with the Olive Woodpecker, males and females of the Golden-naped Woodpecker (*Melanerpes chrysauchen*) not only share incubation according to the general pattern found among woodpeckers (see Breeding), but they also roost together in the nest. The two or three young remain in the nest for more than one month, and, when fledged, they are looked after by their parents for a further couple of months. The offspring roost with the parents until the next breeding season. If the adults begin a second brood in the same season, the young of the first brood act as helpers. Sociality seems to be even more prevalent in the closely related and highly social Yellow-tufted Woodpecker (*Melanerpes cruentatus*), which is found in pairs or in groups of three to five individuals, with occasional groups containing up to twelve birds. This species is a communal breeder, with adult helpers, and up to five individuals may share a roost.

The phenomenon of group-living and communal breeding reaches its ultimate peak of development with another *Melanerpes* species, the Acorn Woodpecker. This extensively studied picid possibly has the most complex social system of all avian species. Details of its breeding behaviour are given later (see Breeding); they follow largely the pattern described above. What makes the Acorn Woodpecker's sociality so special is the fact that the group activity is not restricted to breeding, but is also essential for the creating of the larders, or acorn stores, that are so characteristic of this species (see Food and Feeding). These "granaries" may consist of 50,000 holes, each containing a single acorn. It takes a group of woodpeckers years to create such a big resource, and it requires a group to defend and maintain it. Lewis's Woodpecker also stores acorns in autumn and winter, but, unlike the Acorn Woodpecker, it uses existing cracks only, rather than drilling special holes, and each individual, or occasionally a pair, defends its own store. Similarly, Red-headed Woodpeckers gather at sites where the acorn crop or the production of beech (*Fagus*) mast is high, but they create and defend individual stores.

Communal roosting offers some energetic advantages during the colder months of the year. For example, M. A. du Plessis and co-workers found that, during the non-breeding season, the heat loss suffered by individual Acorn Woodpeckers could be

reduced by as much as 17% or more when four members of the group roosted together in the same cavity. There are also, however, some potential disadvantages involved in communal roosting. Sharing the roost with too many other individuals can be problematic, particularly when it comes to leaving in the morning. As M. T. Stanbeck observed, if two individuals try to leave the roost-hole at the same time, they can both get stuck in the exit and perish; in addition, they can thereby prevent others from leaving the roost, and these, too, will then die.

The Red-cockaded Woodpecker is another member of the family which regularly lives in groups. Again, a particular resource is an important factor in terms of determining the species' sociality, and in this case it is the availability of suitable breeding sites (see Breeding). Red-cockaded Woodpeckers possess individual roosts, and only the male stays with the nestlings during the breeding season. These roosts, however, are not very far apart from each other. Such aggregations of cavity trees used by groups of Red-cockaded Woodpeckers are termed "clusters", or colonies.

Group-living has evolved also among the terrestrial woodpeckers. Here, the critical resource seems again to be proper nest-sites. The Andean Flicker and, to a lesser extent, the Campo Flicker form loose colonies, and cases of incipient coloniality have also been described for the Northern Flicker. With the last species, the staggering of nesting times allows for close proximity of nests, since it results in a reduced level of aggression during the periods of incubation and brood care. Another reason may be that ground woodpeckers are more vulnerable to predation and that they "close ranks" because of this.

Individual woodpeckers demonstrate an excellent knowledge of the whereabouts of resources in their home range. They are well aware of the location of roosts, and are therefore able to find an alternative roosting site, even in the dark, when disturbed at the primary roost, and they seem also to be well informed about the location of feeding sites. Such knowledge may also be an important resource shared by a group. Observations on the African Ground Woodpecker, for which ant nests are a critical resource, clearly hint at such a possibility. Reduction of aggressive badges (see Morphological Aspects) and various modifications in behaviour help to maintain sociality. Among the terrestrial woodpeckers, a clear tendency towards more camouflaged plum-

Many woodpeckers utter low, intimate calls as part of courtship, immediately prior to copulation and during change-overs at the nest. This reinforces the pair-bond, but is often inaudible beyond a few metres. In contrast, when two rivals meet, as have these two male Crimson-crested Woodpeckers, the calls are noticeably louder. This large species is often rather silent, but in situations such as this it utters a shrill piping "put put puttas", sometimes continuing for minutes, before chasing away the intruder or becoming embroiled in a fight with it.

[*Campephilus melanoleucos malherbii*, Santa Marta, north Colombia. Photo: Otto Pfister]

age exists. Brownish colours prevail, and there is even intraspecific co-variation between terrestrial habits and general plumage coloration. In particular, sexual badges are reduced in the ground-dwelling woodpeckers. If this has been primarily part of the change towards more protective coloration, then it may also have fostered the evolution of sociality. The group-living Red-cockaded Woodpecker is essentially monomorphic. Similarly, the colour dichromatism of the Acorn Woodpecker is not very spectacular, either, and consists of the female having black on the frontal part of the otherwise red crown, while the male's entire crown is red. As pointed out earlier (see Morphological Aspects), however, the notion that monochromatic species are likely to be social is not true in all cases.

Finding resources that are irregular in occurrence may also require joint effort. Woodpeckers often congregate in fruiting trees. Even if they had individually found such a tree, tolerance towards other birds may be advantageous at such rich food sources and could form a first stepping stone in the evolution of sociality. The Hispaniolan Woodpecker regularly forages in groups, and particularly large numbers gather on fruiting trees. The White Woodpecker, a species that is also known to form such aggregations, often visits more open places, and to reach certain foraging sites it sometimes flies long distances. Hence, individuals or small groups can be seen crossing open country. This habit may also foster group-living, because it reduces the risk of predation. Many other melanerpine species prefer open country, and their tendency to form groups may also be associated with their general habitat preferences. For example, the migratory Lewis's Woodpecker, which occurs mostly in open woodland and orchards, is markedly gregarious, and sometimes forms large flocks in autumn. Young and adults of this species keep together in migrating flocks (see Movements). On arrival at the wintering grounds, when food stores are established, the flocks break up and probably all individuals attempt to found and defend their own stores. Flickers and Great Spotted Woodpeckers also form loose groups during their long-distance movements.

The benefits of group-living are evident also in the mixed-species flocks which commonly occur both in the tropics and in the temperate zones, and which are thought to afford foraging advantages and protection from predators to their participants.

In temperate regions, mixed flocks are formed mainly in winter, during the non-breeding season. Piculets and woodpeckers frequently join such groups. The small Striped Woodpecker of southern South America, for instance, frequently associates with ovenbirds. Small woodpeckers in the Northern Hemisphere regularly participate in flocks which have tits (*Parus*) as the core species and nuthatches (*Sitta*) and other small birds as associated species. This applies especially to the Eurasian Lesser Spotted Woodpecker, to the Japanese Pygmy Woodpecker and its tropical relative the Philippine Woodpecker, and to the American Downy Woodpecker. Studies of the Downy Woodpecker have demonstrated that this picid "understands" the tits' various alarm calls and other vocalizations and that it adjusts its vigilance accordingly. It is not only the small woodpeckers that join these roving bands of birds. Medium-sized and large woodpeckers also participate in mixed-species flocks, and a melanerpine woodpecker or a *Celeus* species is a common sight, for instance, in the mixed flocks that form temporarily in a Neotropical fruiting tree. When joining insectivorous foraging flocks, however, these picids and the *Piculus* species prefer the company of other bark-foragers such as the dendrocolaptid woodcreepers, although the large Lineated Woodpecker has, nevertheless, been observed with flocks of small antwrens (*Thamnophilidae*). In South-east Asia, the Lesser Yellow-nape and other woodpeckers regularly join the motley mixed-species flocks that are common in this region, these foraging parties containing, among others, various species of babbler (*Timaliidae*), drongos (*Dicrurus*) and other insectivores, and jays and magpies (*Corvidae*). Individuals of the yellow-nape's congener, the more terrestrial Grey-faced Woodpecker, that live in the tropics prefer the company of other ground-foragers. Even the large Great Slaty Woodpecker is known occasionally to forage together with the almost equally big White-bellied Woodpecker and the mid-sized Greater Flameback, and on rare occasions several picids will join together to forage. In disturbed forest in Sumatra, a group of five woodpeckers, all within 10 m of each other on the horizontal plane, was made up of individuals of five different species: these were the Banded, Chequer-throated, Olive-backed, Orange-backed and Buff-necked Woodpeckers.

While these various accounts of the grouping behaviour of woodpeckers are of great interest, it would be a mistake if the

impression were given that these birds are generally sociable. In most cases, they are not. Even when they join other species, they tend to stay at the periphery of the group, and conspecifics are tolerated only at some distance. There is little in their signalling behaviour that conveys any degree of "friendliness" towards others of their kind. Only in the case of the melanerpinas and the Red-cockaded Woodpecker do frequent chattering and twittering vocalizations indicate a greater affability.

Woodpeckers are diurnal birds which exhibit a well-organized daily routine. They leave the roost at sunrise and begin their chores without much delay. During the breeding season, signalling behaviour, particularly drumming, reaches a peak in the morning hours. The level of general activity is reduced around the midday period, and at this time woodpeckers may doze or engage in preening and similar behaviour. Before returning to the roost for the night, they often indulge in another bout of signalling activity. Individuals, having flown to the roost-site, do not always enter the hole immediately. This is especially true of those which are not yet familiar with a certain roost, in which case they may remain in its vicinity for a lengthy period of time, usually perching at some high vantage point, from where they often call, before finally entering the roosting cavity. A number of observations and field studies indicate that females generally enter their roosts later than do males, but further investigation is required in order to determine whether this is a widespread trait among the members of this family.

The roost is an important focal location in the life of a woodpecker. It offers protection from predators and from adverse weather conditions. There is little doubt, either, that hole-roosting contributes to the high adult survival that has been found to characterize birds which excavate their own nests, all of which invariably also roost in cavities. In most woodpecker species, the male's roost becomes the nest by default. Roosting holes are sometimes visited briefly during the day, and woodpeckers may even roost there at noon. This behaviour can mislead observers, particularly in the tropics, as it can be misinterpreted as breeding behaviour.

Roost-holes may be excavated at any season. Juvenile woodpeckers which have just dispersed from the natal territory often

engage in roost-construction as one of the first tasks that they carry out in their new home range. The demands on the quality of roost-sites are less stringent than those placed on nest-sites and, as mentioned earlier (see Habitat), old cavities, nestboxes and various other suitable structures are readily accepted for roosting. For most picids, the roost is the centre of life for each individual. In the case of the Red-cockaded Woodpecker, availability of suitable trees for the setting-up of roosts, as well as of nests, determines the group size. Suitable trees contain up to five holes, and hole-excavation can take weeks or even months. These clusters of cavity trees are used by individual groups of these social woodpeckers. Individuals of different species may share the same tree as a roost-site if it contains several holes. As already mentioned, most individuals can resort to an alternative site when disturbed at the main roost.

When threatened in the roost, woodpeckers try to leave it immediately if there is still some light. Otherwise, they press themselves against the bottom of the hole. Outside the cavity, when threatened by predators, they protect themselves by crouching against the substrate. The two wrynecks take advantage of the camouflage which their plumage offers them, but the others picids, as a rule, move quickly to conceal themselves behind a branch or on the other side of the trunk. When attacked, they spread the wings and use the formidable bill as a weapon. If taken in the fangs or claws of a predator, they utter piercing screams. At the nest, woodpeckers emit incessant alarm calls when a predator is close, and they will also launch attacks against it.

During periods when they are not engaged in other urgent activities, woodpeckers devote time to the maintenance of their plumage. This includes preening for the most part, and more rarely sun-bathing and water-bathing. The Picidae possess about the same repertoire of comfort movements as that described for other birds. The feathers are preened with the bill, something which requires some acrobatic actions if the bird is clinging to a vertical surface and the lower breast or the belly have to be reached. The bill is also used to groom the toes. Woodpeckers scratch the head, neck and bill both indirectly and directly, by moving the foot over the wing as well as under it, but whether this follows a

Beetle larvae are one of main sources of woodpecker food. Indeed, the Picidae are the only birds able to reach the larvae of insects that bore deep under the bark of trees, accounting for their great success in so many regions of the world. Ants or the adults and larvae of beetles dominate the diet of most woodpecker species. These soft-bodied invertebrates are especially important for nestlings, as illustrated by this male Grey Woodpecker returning to its nest-hole in a West African garden. Abundant in the diet of many picids are the large larvae of long-horned beetles (Cerambycidae), metallic wood-boring beetles (Buprestidae), bark beetles (Scolytidae), and the wood-boring caterpillars of carpenter-moths (Cossidae).

[*Dendropicos goertae*

systematic pattern is not clear. Some picid species seem never to lower the wing for head-scratching; others scratch the head either by bringing one foot forward under the wing or by raising it over the lowered wing, performing the latter movement even when clinging to a vertical surface. Woodpeckers frequently rub their face on bark, a kind of behaviour known to occur also among the toucans, and they use sweeping movements of the bill to distribute the fatty substances from the uropygial gland over the plumage. They clean the bill by wiping it on twigs and bark. They also shake the body along its longitudinal axis, and shake their wings. Simultaneous stretching of the leg and wing is a particularly difficult action for birds to carry out when clinging to a vertical surface, as they have to release the grip of one foot for a while; thus, the leg is sometimes only minimally stretched or is not stretched at all. By contrast, the double wing-and-neck stretch does not conflict with clinging vertically and can, therefore, be performed according to the usual avian pattern.

Resting, dozing and sleeping woodpeckers fluff up the plumage, lending them a more round-headed and short-necked appearance. Woodpeckers also exhibit gaping and retching movements, commonly referred to as "yawning", and they remove unwanted items from the bill by means of vigorous head-shaking.

Sun-bathing woodpeckers are rather rarely observed in the field, although this comfort activity is performed fairly regularly by members of the family when kept in captivity. So far as is known, woodpeckers sun-bathe only in full sunlight. A sunning Great Spotted Woodpecker will erect the feathers of the head and body, and spread the wings and tail to their fullest extent, then exposing them to the sun's rays; in addition, it turns the head such that the cheeks collect as much sunlight as possible. A very similar posture was adopted by a wild-living Eurasian Green Woodpecker which was observed sunning as it clung to a bare branch at the top of a large beech tree: in this instance, the bird's yellow rump feathers were conspicuously fluffed up, so that they glistened brilliantly in the sunlight, and the bill was held only just perceptibly open. This sunning posture appears to be the one adopted by all woodpeckers, including the *Melanerpes* and others.

Woodpeckers occasionally take a water-bath. Puddles on the ground and water that has accumulated in a suitable depression somewhere in a tree serve as an ideal bathtub, and in these they bathe in a manner similar to that of other birds. An interesting observation concerned a female Great Spotted Woodpecker which

was watched as it moved clumsily through the terminal leaf clusters of an oak tree, thrashing about in one cluster before moving on to another and repeating this behaviour. The bird's actions included brief periods of hanging upside-down while flapping, which caused much rainwater to be shed from the foliage. When the woodpecker emerged, wet and bedraggled, some seven minutes later, it shook off the excess water and proceeded to preen. The observer considered that this was an example of bathing, especially since the relatively light rain which had fallen shortly before, following a prolonged dry spell, had rapidly drained away, so that no surface puddles were present. The incident took place in south-east England in June, a period of the year during which Great Spotted Woodpeckers frequently forage among foliage in a manner very like that described (see Food and Feeding), but the tree was apparently, and rather surprisingly, more or less devoid of suitable food at the time.

Dust-bathing has been documented for only a few picid species. These are the Green-barred Woodpecker and two other *Colaptes*, namely the Northern and Campo Flickers, and also the Black Woodpecker.

Several species, covering six genera, perform active as well as passive anting. The Eurasian Wryneck, the Red-headed Woodpecker and Red-bellied Woodpeckers, the Yellow-bellied Sapsucker, the Northern and Gilded Flickers, the Scaly-breasted Woodpecker and the Eurasian Green Woodpecker have all been recorded as indulging in these activities. The function of this behaviour, which occurs among many species of bird, is not clear. It has been suggested that it may be a method of countering ectoparasites. An alternative interpretation is that it constitutes a special element of feeding behaviour whereby the birds, in rubbing the ants on the plumage, rid the insects of their acid and thus render them palatable.

The complex foraging and feeding behaviour of woodpeckers requires high cognitive skills. These can be associated with the manipulation of objects and of prey, and with spatial knowledge. The method of processing food items in anvils (see Food and Feeding) shares many characteristics with tool use. It requires that the woodpecker matches the size and shape of the object with that of the crevice in which it is placed. Even more demanding is the preparation of anvils. In addition, efficient excavation for obtaining wood-boring larvae also requires flexible adjustment to wood texture, to the type of bore holes in which the larva lives, and so forth. A knowledge of the location of re-

The diet of the critically threatened Okinawa Woodpecker is fairly typical of that of many medium-sized and large picids. This woodpecker forages mostly for large arthropods, especially beetle larvae, and spiders, but it also takes many fruits, berries and seeds when they are available. Interestingly, it has also been observed to feed a gecko to its nestlings, making it one of only a handful of woodpeckers recorded as taking reptiles or amphibians. For most picids such occurrences are probably a result of opportunism, although a species of tree-frog has been found to constitute over 10% of food items fed by Guadeloupe Woodpeckers (*Melanerpes herminieri*) to their chicks.

[*Sapheopipo noguchii*, Okinawa, Japan.  
Photo: Masakazu Kudaka]

Woodpeckers obtain their food in a number of different ways, enabling a variety of species to co-exist within the same habitat. Some, such as the Golden-fronted Woodpecker of the southern USA and Central America, hammer through the bark with a rapid series of blows, before probing and searching in the shallow pit created. Woodpeckers probably detect prey beneath the bark by using visual cues, and then make probing taps to locate a weaker point in the substrate before drilling. They may also use sound and smell to locate wood-boring beetles, but there is, as yet, no hard experimental evidence to support this theory.

[*Melanerpes aurifrons*

Ardea]

sources is very important in a woodpecker's life. Roosts may be approached from a great distance in direct flight, and the precise location of anvils seems to be perfectly well known to a woodpecker. Circumstantial evidence suggests that individuals of the Ground Woodpecker apparently learn the exact location of anthills, which they visit on a regular basis and may even de-

plete locally. In a similar way, Black Woodpeckers, too, seem to possess a detailed knowledge of the whereabouts of the ant nests in their home range, and they are able to locate these even when they are buried beneath a thick cover of snow. Knowledge of many potential feeding sites, and of the times when they have been visited, is a necessity for a foraging strategy that is known as trap-lining (see Food and Feeding).

From all this, one would expect that woodpeckers are highly intelligent birds. Particular laboratory studies of this aspect are, however, restricted to Great Spotted Woodpeckers. These picids quickly learn the task of pulling several vertically stacked drawers in the correct sequence so that a nut placed in the topmost drawer will fall into the bottom one, from which it can then be retrieved. Great Spotted Woodpeckers are also able to learn to "ask for" particular food types by giving various knocking signals with the bill, in what could be thought of as a simple kind of "Morse code". In experiments, they were able to signal for a pistachio nut with one blow, for a cricket (Orthoptera) with two blows, and for a mealworm with three blows. Moreover, they could instantaneously understand that the presentation of a picture of a pistachio meant that a corresponding box containing that reward was now available as an item of food. This demonstrates an ability that clearly approaches the cognitive feats of which parrots are known to be capable. Indeed, the forebrain of a Great Spotted Woodpecker is almost as highly developed as that of a Common Raven (*Corvus corax*).

Compared with non-storers, food-storing birds, such as certain tit species and corvids, possess a relatively large hippocampus, that part of the brain which is involved in the extensive use by birds of spatial memory. These species are able to memorize thousands of food locations. Among the Picidae, however, storers and non-storers do not exhibit such clear differences in the development of the hippocampus. Hairy and Downy Woodpeckers are as well endowed in this respect as is the food-storing Red-headed Woodpecker. The latter stores its food in centralized larders and has a relatively smaller hippocampus than the Red-bellied Woodpecker, which is a "scatter-hoarder" in the same way as are tits and jays. The high values of the two *Picoides* species may, indeed, indicate that spatial skills are needed not only for scatter-hoarding, but also for other spatially difficult challenges that are frequently encountered by woodpeckers.

Woodpeckers are generally good fliers, some species being regular migrants which cover large distances between their breed-

On a tall, dead tree trunk in East Africa, a male Bearded Woodpecker vigorously pecks at a hole, flicking shards of wood to the ground and swallowing a grub. The bill is ideal for chiselling and excavating, tearing off bark and wood fibres, as well as for grabbing and carrying food. The second photograph captures the split-second semi-closure of the eyelid, to protect the sensitive membranes from flying wood chips. Whereas some species remain in one place for just a few seconds, Bearded Woodpeckers spend a long time at each hole, consume all that they can reach, and then fly to the next potential food source some distance away.

In common with other large *Dryocopus* and *Campephilus* species, Black Woodpeckers often excavate huge pits in their search for the nests of tree-living ants. Large chunks of bark are removed before the bird chisels deep, long rectangular holes into the tree trunk, following the texture of the wood fibres. Although Black Woodpeckers can sometimes be hard to locate, the large gouges in softwood trees are a tell-tale sign of their presence; even so, the large foraging area exploited by this species means that the birds are not necessarily close at hand.

[*Dryocopus martius* martius, Oka Game Reserve, near Moscow, Russia. Photo: Roland Seitre/Bios]

ing and non-breeding quarters (see Movements). The normal active flight of the majority of species involves series of rapid wingbeats interspersed with briefer periods of gliding on closed wings, producing an efficient bounding flight that is highly characteristic of this family. Certain species, such as the melanerpiners, have a somewhat straighter, less undulating flight, and the largest picids, including the logcocks and the ivory-bills in the Campephilini tribe, also fly in a more direct manner. Furthermore, the typically undulating fliers, such as the *Dendrocopos* and *Picoides* species, are capable of more sustained flapping flight in a straight line when pursuing rivals, although such chases are usually over relatively short distances. Conversely, even the really big woodpeckers can sometimes show a slightly dipping pattern when, for instance, moving across a clearing.

## Voice

The sounds emitted by woodpeckers are single short calls, variably protracted series of call notes, often with a rattling quality, and screams. In addition, a variety of instrumental signals is produced. No woodpecker species has the capacity for vocal utterances that attain the musical quality of the songs of passerine birds or waders (Scolopacidae). Moreover, the vocalizations of the Picidae are not learned. The instrumental signals, notably the drumming, are quite unique in the avian world.

Analyses of the vocalizations of the widespread pied woodpeckers in the genera *Dendrocopos* and *Picoides* have yielded a repertoire of about 13 calls, which fall into seven categories. In most other cases, the vocal repertoires of woodpeckers are poorly documented, but all members of the Picidae certainly appear to have a wide range of calls. These constitute important signals in various social situations, and they carry specific messages. Although the following commentary is based mainly on studies of pied woodpeckers, it is more than likely that other picids also possess a similarly rich vocal repertoire. Indeed, further research will probably show that the calls of woodpeckers provide an excellent model for avian acoustic communication, adding an extra dimension to the knowledge that has been gained from the extensively studied songs and other vocalizations of the oscines.

All pied woodpeckers, with the possible exception of the Arabian Woodpecker, utter single notes at varying levels of excitement, from low to intense, which reveal the location of an individual. They are given at high rates by excited birds, particularly during alarm at the nest. In the case of some species, of which the Great Spotted Woodpecker is an example, these calls can be heard over a considerable distance. The single-note calls of the majority of picids comprise short clicks, generally referred to as "Kick-calls". Those of the Hairy Woodpecker and its relative Strickland's Woodpecker are rather long, and those of the Red-Cockaded Woodpecker consist of protracted "churr" calls. Churrs of similar physical structure are widespread among species of the genus *Melanerpes*.

Most pied woodpeckers and other woodpecker species, however, use rattle-like or trill-like calls, sometimes preceded by an introductory call note, as a means of maintaining contact over long distances. This can apply to the communication between the members of a pair and also to that between territorial neighbours. Pair-members may respond immediately with this call when they receive the partner's signal. Shorter versions of these signals are given also by fledged young, probably to indicate their whereabouts to the parent. Among the large species, as well as some small ones such as the Lesser Spotted Woodpecker, these signals are not so rapid as to be described as trills, but, rather, they are made up of long and, in some cases, loud series of notes. Detailed relevant studies have not yet been carried out, but it is likely that these signals are adapted to the environment. Initial analyses have already revealed that call notes are roughly within the frequency window of 1-2.5 kHz for good sound transmission in forest.

One of the larger species, the Black Woodpecker in the genus *Dryocopus*, is known to possess two very distinct types of call that are delivered in specific contexts. The one most often heard is the loud flight call, given in short series, and with a grating quality. It can be transcribed as "krükrükrükrü". The other is uttered by an individual when not moving, and is often given upon landing. It is a far-carrying "kleea", not so conspicuous as the preceding call type.

Pied woodpeckers, and probably most, if not all, other picids, possess calls the use of which is restricted to the breeding season. These calls are usually produced in more or less regular, sometimes protracted series, and they are loud and, often, squeaky

and long. These vocal signals may be associated with other forms of advertisement, such as drumming and the "Flutter-aerial-display" (see Breeding). They are most similar in function to the songs of other birds, and they become very important and conspicuous among those woodpecker species which perform only little or no drumming. These vocalizations, as well as the long-distance call type mentioned above, are frequently delivered from the upper tiers of the habitat, and it seems that they are given mainly by males. The strange call of the Middle Spotted Woodpecker belongs in this category. It consists of a far-carrying slow series of nasal "gwäh" notes, and it is unlike any sound that is produced by other, sympatric woodpeckers. In an interesting analysis of 326 songs of this species which he heard in spring in three different parts of France, over a period of several years, M. Cuisin reported a rather surprising level of variation. For example, the number of syllables in the song varied from just a single "gwäh" to as many as 33, and the speed of delivery from fairly rapid to slow and laboured, while the vocal quality was sometimes clear and sometimes hoarse. In addition, he recorded a wide variation in the frequency with which songs were uttered. The vocal activity of the Middle Spotted Woodpecker is known to be reduced in situations where its population density is low, but it seems likely that, within any particular area, there is also a comparatively wide variation from year to year in the frequency of acoustic advertisement, as has been recorded for several other woodpeckers. When a species' song is so highly variable, the question arises of how easily it is recognized by potential mates and rivals of the same species. With a sedentary picid such as the Middle Spotted Woodpecker, however, it is quite probable that individuals are very familiar with the finer details of the voice of all of their congeners living in the same area.

The song of the Eurasian Wryneck may also be mentioned here. Delivered in spring, it is this species' most characteristic call. It consists of a series of up to 15 or so whistled notes, at times somewhat harsh in quality, that rise slightly in pitch; the sequence is not unlike the call of a Eurasian Hobby (*Falco subbuteo*), which is sympatric with the wryneck in most of the latter's breeding range. This advertisement is uttered incessantly, even during bright daylight, in the early part of the breeding

season, and becomes less frequent, often ceasing altogether, once pair formation has taken place. This species' sole congener, the Afrotropical Rufous-necked Wryneck (*Jynx ruficollis*), has a comparable song which is used for territorial advertisement.

A wide range of vocalizations is given by woodpeckers in a variety of social, mostly more or less aggressive situations. These calls may be associated with the swinging and bowing displays demonstrated by woodpeckers in agonistic situations (see Breeding), and they are normally referred to collectively as "Wickacalls" as an approximation of the character of the sound. Among the *Celeus* species, for instance, they have a rather nasal quality, while those of the pied and the melanerpine species are whipping sounds. The Acorn Woodpecker's most common call can be rendered as repeated "whaaka-whaaka" or "wa-ka" notes. This utterance is given when a group-member lands, flies past or takes off, and it attains high rates during territorial disputes. At full intensity, when it is sometimes accompanied by wing-spreading, it ends with a rasping "trtrtr". Similar grating or rolling sounds are delivered in synchrony with bowing displays. Other variants of this call type have a twittering quality, and are frequently given by, for example, the social Red-cockaded Woodpecker. Generally, all of these calls vary in intensity, emphasis and overall structure in apparent accordance with the motivation of the individual signaller. Prior to or during copulation, and at change-overs at the nest, woodpeckers emit low intimate calls, rich in harmonics, which are audible to a human being only at very close range.

Among the three or more different types of calls that are produced by nestling woodpeckers, the more or less constant twittering, buzzing or rasping sound is the most conspicuous one. This call reaches the peak of intensity when a food-bearing adult approaches and enters the nest-hole. There appears to be some interspecific variation with regard to the frequency of occurrence and the intensity of these begging calls during the periods between feeds. The two other types of call uttered specifically by nestlings, and which have not been recorded for adults, are soft notes emitted after relief from a stressful situation, or during such a situation, a typical example of which would be a fight with siblings. These calls probably represent short-distance signals directed at the nestmates or parents. The nestlings of wrynecks

Little is known about the diets of most piculets, especially those in South America, so that this sequence of a feeding Ochre-collared Piculet is quite remarkable.

These tiny birds, less than 10 cm long, are found among tall growth, including introduced bamboo, in a relatively small region south of the Tropic of Capricorn.

The photographer has captured this male as it hammers a small hole in a bamboo stem, inserts its bill, and pulls out a larva that was concealed inside.

The grub is swallowed whole, the entire episode being completed in just a few seconds.

The prominent ochre-coloured collar that separates this species from the closely related White-barred Piculet (*Picumnus cirratus*) is shown to advantage in these photographs.

[*Picumnus temminckii*,  
Juréia, São Paulo, Brazil.  
Photos: Edson Endrigo]

produce similar begging sounds; older chicks, however, when threatened in the nest, hiss in the same way as do adult wrynecks when they encounter a threat.

Woodpeckers scream or shriek when captured by a predator or handled by a human. They also emit screaming calls when in peril of "losing the battle" during fights with conspecifics. As was demonstrated by a study of the Acorn Woodpecker, however, not all individuals of a population scream in such situations.

The complexity of certain call categories and the readiness of a species to vocalize, but not the repertoire size, seem to be related to the degree of sociability. Thus, the melanerpine woodpeckers, which include the most social members of the family, are among the most vocal of all the Picidae. In contrast, solitary species such as the White-backed Woodpecker are relatively rarely heard and are very difficult to locate by their vocalizations alone. Even the conspicuously coloured and large ivory-bills in the genus *Campephilus* are likely to be detected more because of the noise which they produce while foraging than by their vocalizations. The tonal quality of long-distance signals, and the frequency with which the members of a pair exchange them, may be related to habitat structure and other ecological factors. In either case, corresponding comparative studies are, unfortunately, not available.

Most species of the subfamilies Picinae and Picumninae produce loud, rhythmic series of sounds by hammering against a resonant object, a practice known as drumming. The two wrynecks, however, do not drum. Despite popular belief among many laypersons, these instrumental signals made by the true woodpeckers and the piculets are not produced while the individual bird performs its woodwork in the context of feeding or nest-excavation. They are, therefore, true means of communication. The mechanics of drumming differ from those involved in the excavating of wood for cavities or while foraging in that the main movements are carried out by the head-and-neck system. The rapid rhythm and the time course of the individual strokes that make up a single burst of drumming are difficult to describe. In a comprehensive empirical and theoretical study that considered the mass of the head, the length of the neck muscles and their distance from the centre of the spine, and the length of the neck, M. Kaiser modelled the basic features of drumming. The

predicted duration of the downstroke amounts to about 100-60% of the upstroke. Moreover, the details of the drumming signal seem to correlate with the ecology of a species. For instance, in the case of typical wood-pecking species, the rhythm or cadence accelerates as the amplitude falls; with species which obtain their food by gleaning, on the other hand, the signal slows down towards the end, or it remains uniform in rhythm and amplitude throughout the roll. Just a few of many examples to illustrate this difference are the Greater Flameback and the Acorn, Fire-bellied, Great Spotted, Nuttall's, Black-backed and Pileated Woodpeckers (*Dryocopus pileatus*), all of which forage by pecking and hammering and all of which have drumrolls that accelerate; whereas, among the gleaners, the Northern Flicker's rolls remain steady in rhythm, and those of the Downy and Ladder-backed Woodpeckers and the Buff-rumped and Buff-necked Woodpeckers decelerate. The cadence within rolls ranges from about ten to 25 beats per second. The number of drumrolls delivered per minute varies, depending on the species; it ranges from 0.3 in the case of the Rufous Woodpecker to 19 in the more widespread Lesser Spotted Woodpecker.

Both sexes drum, although the males perform this action more frequently. Some species appear to exhibit no difference between the sexes in the quality of these instrumental signals, while the females of other species give rolls that are less strongly developed than are those of the males. For instance, the drumrolls of the female Black Woodpecker are generally shorter than her mate's, and they vary more in rhythm, which is also somewhat slower. The extent of seasonal fluctuation in the frequency of drumming suggests that this activity has a close link with territorial behaviour. Signalling posts are often rather exposed and in the upper parts of trees. As a point of interest, woodpeckers often combine comfort behaviour with drumming, and they will preen during the regular pauses between individual rolls.

Drumming, when analysed quantitatively, is fairly species-specific, at least where sympatric picids are concerned, and in many cases the differences between species are perfectly detectable even to the human ear. The woodpeckers themselves, however, will not uncommonly react in a rather indiscriminate manner to drumming signals. Hence, they may react to playbacks of the tape-recorded drumming of other species, and they engage in

In general, woodpecker species which undertake substantial wood-working when foraging are rather poorly equipped to reach along a trunk or branch for surface-dwelling food. By contrast, species such as the Greater Yellow-nape are expert gleaners, picking ants, termites and beetles from the bark while in a perched position. Gleaners move on quickly to another feeding site after exhausting a food supply, although, since the renewal time of surface prey is short, the individual can return to the same spot regularly. Greater Yellownapes, a female of which is shown here, rarely peck or excavate, but they do prey on the young of other hole-nesting birds.

[*Picus flavinucha wrayi*, Fraser's Hill, Peninsular Malaysia. Photo: Morten Strange/VIREO]

The largest of the Picidae known to survive in the New World, the Pileated Woodpecker favours dead or dying wood, pecking and hammering at one spot for long periods, particularly in winter, for its preferred prey of large carpenter ants (*Camponotus*). These photographs of a male show clearly the combination of bill and tongue in action. About half of the bill is pushed into the tree, the mandibles slightly apart to allow the tongue to extend into the hole. When the prey item is located and speared, the bill is retracted from the hole and the morsel consumed. In this instance, the tongue is first manipulating the prey against the upper mandible to facilitate the swallowing of the food.

interspecific drumming "duels". Of course, this is not always the case. D. J. Dodenhoff and colleagues carried out a useful investigation to determine the extent to which woodpeckers exchanged drumming interspecifically, and examined the variables within drumming by which one species might recognize another. Using playback of four North American *Picoides* species, Nuttall's, White-headed, Hairy and Downy Woodpeckers, they found that individuals responded far less intensely to drumrolls of other, sympatric picids when the latter's drum cadences were dissimilar to their own; on the other hand, there was no significant difference between the behavioural reactions to drumrolls of conspecifics and the reactions to those of other species that are not sympatric when the cadences of the drumrolls were similar. The results, published in 2001, suggest that the drum's cadence encodes information for species recognition, and that, if an individual drums at a similar cadence to that of a sympatric heterospecific, then the signal may elicit the same response as that to a conspecific.

More species-specific vocal long-distance signals may be closely associated with or interspersed with drumming, as demonstrated by, for example, the Lesser Spotted Woodpecker in Eurasia and the Yellow-bellied Sapsucker in North America. In some cases, such vocalizations may partly replace drumming as a territorial advertisement, the Northern Flicker being a typical example of this, or they may even almost fully replace it, as occurs with the Middle Spotted Woodpecker. These digressions from what might be considered the norm for the respective genera are perhaps a reaction, or an adaptation, to the possible interference from other drumming species living in the same habitats.

Woodpeckers show a distinct preference for dead wood as a substrate for drumming. Thus, drumming could advertise habitat quality, since dead wood is, for most picid species, an important constituent of high-quality habitats. The evidence gathered so far, however, does not support this hypothesis. Rather, woodpeckers appear to choose particular drumming sites mainly because they produce loud and far-carrying sounds. These sites can also be artificial structures, such as metal poles, television aerials and buildings. Indeed, metal parts of buildings and such structures as sirens are not infrequently used for drumming, and

the result is a remarkably loud and startling signal. One observer in southern England who watched a Great Spotted Woodpecker hammering on a public-address system at a racecourse noted that, of the three large, conical speaker horns, the bird had selected to hammer on the metal base of the one that was pointing directly towards a rival woodpecker about 100 m away on a tree; the latter's drumming response to the exceptionally loud signal was described as sounding "pathetic" in comparison.

This drumming signal may have originated from the regular habit of carrying out woodwork on dead trees, an activity that inadvertently discloses the location of the bird and reveals the quality of the substrate on which it is working. It has probably evolved from the rather regular strokes that are produced when the woodpecker excavates a nesting or roosting hole. Taps at the hole are often given in encounters between the members of a breeding pair, and for several species of picid these constitute another, simpler instrumental signal.

Various species have developed more complex or irregular types of drumming than the simple rolls that are produced by most members of the family. Variation is especially pronounced among the melanerpine woodpeckers. The infrequent drumming of Lewis's Woodpecker consists of a weak roll followed by three or four individual taps, while the drumroll of the Red-bellied Woodpecker may be preceded by a single, discrete strike of the bill. The sapsuckers drum in a very distinctive manner. The Yellow-bellied Sapsucker produces rolls with clearly separated taps at the end and, sometimes, also at the beginning, giving a signal which sounds like "toc-toc-trrrrrrrrrr-ta-ta-toc-toc---toc". The Red-naped Sapsucker's drum is structured similarly. Likewise, the signal of Williamson's Sapsucker comprises a regular roll with several beats appended, although these terminal strikes are more widely spaced than those of the other sapsucker species. This pattern is not, however, confined to the sapsuckers. The Bearded Woodpecker in the Afrotropics also produces a drumroll with an ensuing series of four regular taps. Furthermore, the distinctive drumming of the Rufous Woodpecker in Asia has been likened to the sound emitted by a stalling engine, and is often transcribed as "bddd-d-d--d---dt". A reversed pattern is shown by the Lineated Woodpecker, which commences with a couple

In the dense, gloomy understorey of South-east Asian evergreen forests, the strikingly bright yellow bill of the Maroon Woodpecker is often the first thing that draws the alert observer's attention to this picid's presence among the shadows. Seldom ascending more than a few metres above ground level, this species spends most of its life among the lush, tangled undergrowth, where the long pale bill, with its chisel-shaped tip, is perfectly suited to this woodpecker's foraging technique. It hammers a hole into live wood, quickly excavating a pit 2-3 cm deep and twice as long along the stem. From this pit, the bird catches beetles and other insect larvae with its sticky tongue. Maroon Woodpeckers also frequently attack rotten wood and decaying fallen logs, which they quickly break into pieces by hammering with the bill, thereby exposing larvae which can be easily snapped up. This woodpecker, incidentally, plays a prominent role in the augury practised by the Iban people of Borneo; of seven augural bird species, two are members of the Picidae, the other being the Rufous Piculet (*Sasia abnormis*).

[*Blythipicus rubiginosus*, Mount Kinabalu, Borneo. Photos: Roland Seitre/ Bios]

Many woodpeckers obtain their food from dead or decaying wood, a typical example being the Pale-billed Woodpecker of Central America. A variety of methods is employed to remove bark from trees.

The technique used by this and many other of the large species starts with a few bill blows that leave characteristic horizontal marks on the exposed wood; the bark is then levered off, and disposed of with a swift flick of the bill. Some picids, however, such as the Red-cockaded and Strickland's Woodpeckers (*Picoides borealis* and *P. stricklandi*) of North America, will use their feet to dislodge loose bark.

[*Campephilus guatemalensis*,  
*guatemalensis*,  
Guanacaste, Costa Rica.  
Photo: Rob Curtis/VIREO]

of slow taps which are then followed by the roll. Some species produce only short double raps. One such example is the Chestnut Woodpecker, the drumming of which is a simple "dop, dop". This type of instrumental signal, however, is most typical of the ivory-bills. Thus, in the rainforests of South America, the Red-necked and the Robust Woodpeckers (*Campephilus robustus*) betray their presence by their distinctive "tok tok". In the case of another ivory-bill, the often syntopic Crimson-crested Woodpecker, the second blow is extended into a brief burst, so that the drumroll sounds like "da-drrr".

Mutual tapping, with one bird inside the hole and the other at the entrance, is typical of the Red-headed Woodpecker, as well as of some other melanerpine species such as the Jamaican Woodpecker (*Melanerpes radiolatus*), the Red-crowned and Red-bellied Woodpeckers and the Yellow-bellied Sapsucker. Double raps at the hole are also known to be part of the instrumental signals of the Pileated Woodpecker. That species' Eurasian congener, the Black Woodpecker, produces single strikes at the hole on various occasions, as when advertising a cavity and, especially, at change-overs during the periods of hole-excavation and incubation. These taps may lead to rhythmic series of blows with a delivery rate of about 80 blows per minute, even running to frantic and long series of blows at a rate of 140 per minute, and some brief fragments of drumming may be evident as well. This close relationship of the instrumental signals becomes apparent in the Guadeloupe Woodpecker, too. This species delivers short rolls and mutual tapping at the hole.

Besides drumming and tapping, other non-vocal sounds are produced by the Picidae. Most notable among these are the noises produced by the wings. The wingbeats of most woodpeckers can be heard in the flapping phase of the bounding flight. More conspicuous, and possibly of some relevance for communication, are the audible wingbeats of an excited woodpecker when searching for the location of an opponent, as has been demonstrated in playback experiments, or the wing noise of an agitated picid when it flies to its opponent or mate. The wings also produce sound during the fluttering aerial display (see Breeding). Even the tongue can produce a vibrating sound on tree surfaces, as had been noted by J. Jackson for the Red-cockaded Woodpecker, but it is not certain whether this has any functional significance.

## Food and Feeding

Woodpeckers feed primarily on insects and their larvae, and other arthropods, and many of the members of this family rely to a greater or lesser extent on plant products such as nuts, fruits and tree sap. Many also take the nestlings of other hole-nesting species, but open-nesting birds are not exempt from woodpecker predation, either. The diet of nestling woodpeckers consists mainly of insects, represented chiefly by hymenopterans, beetles, hemipterans, homopterans, caterpillars, and dipteran flies. Some picids, including the Acorn, Lewis's and Jamaican Woodpeckers, the sapsuckers, and the Syrian and other pied woodpeckers, feed acorns and fruits to older broods.

Access to the larvae of wood-boring insects and to the nests and mounds of ants and termites is made possible as a result of the morphological adaptations of the Picidae (see Morphological Aspects), and this ability is also one of the reasons for the great success of the family in so many climatic regions of the world. In addition, many woodpeckers are rather omnivorous and opportunistic feeders. The American melanerpines belong in this category, but so, too, does the Great Spotted Woodpecker of Eurasia. Insular species, such as the Jamaican Woodpecker and the West Indian Woodpecker (*Melanerpes superciliaris*), are particularly flexible in their choice of food. Very frequently, there are marked seasonal differences in the diet, a good example of which is provided by the northern populations of the Great Spotted Woodpecker. This species, in the boreal part of its vast range, changes from a predominantly insect diet in the summer to one of pine or spruce (*Picea*) seeds in the winter, and in spring it supplements its diet with tree sap. Similar radical seasonal changes are observed among the sapsuckers, which for much of the time rely on the sap of trees, and among other melanerpines, including, for example, Lewis's Woodpecker, the Acorn Woodpecker and the Red-bellied Woodpecker.

The picid bill is the ideal tool for excavating food. At the same time, even the bill that is most specialized for chiselling is still suited for other tasks, such as grabbing and carrying large objects, tearing off bark and wood fibres, and pulling apart pieces of meat. Only those woodpeckers which do not undertake much excavating work possess a bill that is optimized for grasping objects or for digging; in the first case the bill is slightly curved

Fallen branches and trees are an important component of the forest ecosystem, although one that is scarce in managed modern temperate plantations. Fallen, rotten timber is visited and exploited by many woodpecker species. An excavated pit is already apparent on the side of this log, and the male Pileated Woodpecker is opening up a second, in search of the ants that comprise the bulk of its diet. Rotting wood is a transitory habitat, home to a wide variety of invertebrates, and is exploited by many bird families, none more so than the Picidae.

Windrush]

and has a pointed tip, while, in the second, the digging bill is long. The action of the bill is greatly augmented by the long, barbed tongue (see Morphological Aspects) with which ants and termites can be licked up, and with which a wood-boring larva, once its tunnel has been chiselled open, can be finally speared. A further way in which the bill's range of operation is evident is in the use of cracks and other structures as anvils, a highly interesting aspect that is discussed in greater detail below.

Woodpeckers, then, are primarily insectivores, with a diet that reveals a special emphasis on wood-boring larvae and on those that hide in crevices in and under the bark of dead limbs or trunks of trees, or in the ground. The large larvae of long-horned beetles (Cerambycidae), the round-headed borers, are typical woodpecker prey. So also are the flat-headed borers, larvae of the metallic wood-boring beetles of the family Buprestidae, the larvae of the bark beetles (Scolytidae), and wood-boring caterpillars of carpenter moths (Cossidae), as well as hymenopterans, especially horntails (Siricidae). The ivory-billed woodpeckers in the genus *Campephilus* are renowned for their habit of taking very large beetle larvae, and both they and other woodpeckers also readily take adult beetles. Among the smaller picids, the White-backed Woodpecker of Eurasia is a prominent example of a specialist predator of wood-boring larvae, in this case those of long-horned beetles and carpenter moths. Not surprisingly, woodpeckers also capture and consume other insects, and spiders, which they may happen to find under or on the bark. During the warm seasons of the year, and especially when feeding young, they commonly exploit the flush of leaf-chewing caterpillars and plant-lice. Generally, the nestling's diet differs from that of the adult, and particularly from the latter's diet outside the breeding season, in being more diverse and in containing less plant material and more soft-bodied insects and insect larvae.

There is a degree of uncertainty over the way in which woodpeckers find their food when it is concealed in timber. It is probable that they detect it initially by some optical give-away signs; with some probing taps they are able to locate a hole. Field experiments have demonstrated that they readily learn to find food, such as sunflower seeds, in holes covered with tape, and many other observations indicate that woodpeckers possess an excellent knowledge of the locations of potential prey. One observer

placed mealworms in holes in a log and then plugged the holes with cork stoppers, an operation designed to prevent other birds from obtaining the food, which was intended for the local Great Spotted Woodpeckers. The plan worked: while the House Sparrows (*Passer domesticus*), Common Starlings (*Sturnus vulgaris*) and others were unable to locate the worms, the woodpeckers immediately knocked out the plugs to obtain the food. There is some speculation that a prey item may be located by the sound that it makes, but hard experimental evidence for this appears not to exist. Field experiments have also shown that woodpeckers react to smell, although, once again, there are no decisive data that would indicate that olfaction plays a role in the detecting of prey.

Ants (Formicidae) are a common food of the Picidae. The two wrynecks are ant specialists. The adults feed both themselves and their nestlings chiefly on ants, and their pupae and eggs, which they obtain from the terrestrial nests of these insects by gleaning, probing and tongue action. In fact, at least 60% of all woodpecker species are known to include ants in the diet. Perhaps surprisingly, termites (Isoptera), on the other hand, are eaten by only a few species, among them the Ground Woodpecker of South Africa. The many picids which feed on ants range from the smaller species to the largest, and the habit is particularly marked among the members of the genera *Picus*, *Dinopium*, *Gecinulus*, *Campethera*, *Geocolaptes*, *Piculus*, *Colaptes*, *Celeus*, *Dryocopus*, *Meiglyptes*, *Hemicircus* and *Mulleripicus*. Indeed, ants are the most important food for the Eurasian Green Woodpecker; and even in the diet of its less specialized relative, the Grey-faced Woodpecker, ants of the genera *Myrmica* and *Lasius*, along with termites and their brood, still prevail and can often comprise more than 90% of the stomach contents of individuals. The food taken by the threatened Red-cockaded Woodpecker includes up to 95% ants by biomass, with a clear peak in spring, when the diet of males contains on average 85% ants. The males of that species consume more ants than do the females, and ants also form an important portion of the nestling diet. That ants and termites represent an important food source for the large *Dryocopus* logcocks has been demonstrated by studies of the Pileated Woodpecker and the Black Woodpecker, but at least two other of their congeners, the Lineated and the White-bellied Woodpeckers, are also known to take many ants. The diet of the

Probing is a technique used to obtain prey that may be concealed in a crevice or hole little wider than the diameter of the bill. It is a method frequently employed by the delicately marked Fine-spotted Woodpecker when foraging in epiphytes and vine tangles, at the base of trees and oil palms (*Elaeis guineensis*), or on the ground. Having inserted its bill, the bird flicks out its sticky tongue, gluing small insects, especially ants, to the tip. The elongated tongue of woodpeckers means that the depth to which these birds can probe is increased substantially beyond the mandible tips.

[*Campethera punctuligera punctuligera*,  
Fajara golf course,  
Gambia.

Photo: Gordon Langsbury]

Black Woodpecker has been found to contain 54% ants in winter and up to 97% in the milder seasons, and these insects comprise about 80-99% of the diet of nestlings of this species. These large *Dryocopus* woodpeckers target the nests of large ants living within trees. Thus, they prey on *Camponotus* ants that live and nest in the core of living pines and spruces, while the Neotropical species, such as the Lineated Woodpecker, seek out the well-armed ants of the genus *Azteca* in hollow parts of trumpet trees (*Cecropia*). Other large ant-eating and termite-eating woodpeckers are the Ashy Woodpecker (*Mulleripicus fulvus*), which is confined to the Indonesian island of Sulawesi, and the related Great Slaty Woodpecker, the biggest of all the Old World's picids, which occurs from north-west India across to south-west China and southwards to the Greater Sundas. In Central America and north-west South America, the smaller Cinnamon Woodpecker (*Celeus loricatus*) also locates ants that live symbiotically in plants, and exploits these.

Woodpeckers seem not to shy away even from rather aggressive ants. The overlapping tarsal scutes and the feathers that cover the nostrils of many species would seem to comprise the corresponding adaptations to counter the armoury of these insects. At least one species, the White Woodpecker of the Neotropics, is known to open the nests of wasps and wild bees to take the broods and the honey of these hymenopterans.

Very little is known about the diets of the piculets. For the few species for which food items have been recorded, ants appear to be by far the most important source of nutrition, although termites are also sometimes eaten and, in several cases, small beetles, spiders and other arthropods. A notable exception is the African Piculet. This species, the only picumnine present in the African continent, appears to avoid ants altogether, preferring instead to sustain itself on wood-boring beetle larvae supplemented with adult beetles and some other insects. It is also worthy of note that the largest member of this subfamily, the Antillean Piculet, feeds principally on arthropods, including ants, but also takes a reasonable quantity of fruit.

Practically all members of the Picidae for which adequate information is available ingest some plant material, and some species rely at least partly on plant products. In fact, frugivory is widespread among the woodpeckers, and fruits and berries are taken by many species. Although they rely heavily on ants

and other insects, the wrynecks have been observed to feed on the berries of elder (*Sambucus*), and even the ivory-bills occasionally consume fruit, as also do two of the logcocks, the Pileated and White-bellied Woodpeckers. Nuts and the stones of fleshy fruits are frequently eaten by the pied woodpeckers, and the northern populations of the Great Spotted Woodpecker are heavily dependent on the seeds of pines and spruces. The most frugivorous group, the American genus *Melanerpes*, not only takes much fruit but also, in the case of many of its species, eats nuts and, above all, acorns, while the related sapsuckers have been observed to eat buds in spring. Although some species appear to take certain fruits merely to get at the seeds which they contain, as with the Syrian Woodpecker when it attacks apricots and prunes (see also Relationship with Man), the seeds are not the primary goal for the truly frugivorous woodpeckers. Hence, woodpeckers may be important seed-dispersers in some ecosystems.

Frugivory is apparently least common among African woodpeckers and is most common among the melanerpines and the South American *Celeus*. Woodpeckers of these last two groups may be among the most frequent visitors to Neotropical fruiting trees. They act as dispersers of seeds only when they swallow the fruits, and whether they do that depends very much on the type of fruit involved. For example, the Black-cheeked Woodpecker (*Melanerpes pucherani*) has been observed to swallow the seeds of the flacourtiaceous tree *Caesaria corymbosa*, but to strip the arils of the burseraceous *Protium* and drop the seeds under the mother tree, thus in the latter case acting as a seed thief from the plant's perspective. The Red-crowned and Golden-fronted Woodpeckers and the Campo Flicker eat fruits of cacti on a sufficiently regular basis to act as seed-dispersers for those plants. Gila Woodpeckers feed on the berries of mistletoes (*Phoradendron*) during November and December, but because they spend little time in the host plant they contribute little to the dispersal of the hemi-parasite. The Golden-naped Woodpecker is a typical example of a melanerpine woodpecker that takes much fruit. It feeds on the fruits of the bird- and bat-dispersed *Cecropia* trumpet trees, on figs, on various arillate seeds, and on bananas, oranges and palm fruits, and it also accepts these fruits at artificial feeders. *Cecropia* fruits, figs and various other plant foods make up about half of

The Yellow-crowned Woodpecker, a small species inhabiting dry, open woodland across most of the Indian Subcontinent, takes much of its food by gleaning. Moving over the bark of a tree, it plucks insects from the surface and from crevices. It also excavates bark and dead wood for subsurface larvae. This is one of a number of Old World picids that also feed on nectar, although this is a more common component in the diet of New World woodpeckers. Several of the latter take sugar water from feeders specially set up in gardens to attract hummingbirds (Trochilidae).

[*Dendrocopos mahrattensis mahrattensis*, Keoladeo Ghana (Bharatpur) National Park, India. Photo: Manfred Pfefferle]

the diet of the Jamaican Woodpecker and of the West Indian Woodpecker. A predilection for fruits results in some melanerpines being attracted in rather large numbers to commercial orchards of oranges, papayas, bananas and apples, where they may cause some damage (see Relationship with Man).

Many of the smaller and medium-sized Picidae feed on nectar. This behaviour has been recorded for a number of *Dendrocopos* species, among them the Brown-capped Wood-

pecker, the Yellow-crowned Woodpecker (*Dendrocopos mahrattensis*), the Crimson-breasted Woodpecker (*Dendrocopos cathpharius*) and the Great Spotted Woodpecker, and several other Asian or Eurasian species, including the Lesser Yellow-nape, the Streak-throated Woodpecker (*Picus xanthopygaeus*), the Grey-faced Woodpecker, and the Black-rumped and Greater Flamebacks. The sipping of nectar is also not uncommon in the New World among melanerpine and *Celex*

These photographs of Lineated Woodpeckers illustrate the capability of one species of employing very different feeding techniques. Hammering and pecking, and probing into excavations, are common foraging methods used by this woodpecker. In broad terms, males prefer larger branches than those utilized by females. In this instance, however, the female has hammered several holes in a trunk and is probing one of these for invertebrates, whereas the male, on the right, has pecked the bark from a smaller overhanging branch and is plucking insects from the exposed wood.

While some woodpeckers depend on the same type of prey throughout the year, others switch between seasons, reflecting the availability of different foods. In autumn, the Red-bellied Woodpecker takes advantage of the season's crop of soft-cased fruits, of both cultivated and wild species, especially in the northern half of its United States range. It switches in winter to seeds and nuts, which it will hoard for use when the supplies are exhausted in late winter. During the summer, this species' diet is dominated by insects, especially ants, although it also licks sap from scarred trees or from wells created by sapsuckers (*Sphyrapicus*).

[*Melanerpes carolinus*,

woodpeckers, and a number of species will readily take sugar water from feeders, too.

Because of their ability to excavate, woodpeckers can tap another rich source of plant fluids. This is the sap that is available in the sap-transporting cells of the phloem of trees. After the dormant season, rich sap flow becomes established in the early spring, at a time when other food sources may still be poor or depleted, and thus provides vital sustenance at a critical time immediately prior to the nesting season. Many species of woodpecker cover the bark of living trees with series of regularly spaced holes from which they obtain the sugary sap. Typically, the holes, known as "sap wells", are arranged in horizontal rows, and these rows, together with those made in previous years, can extend over rather distinctly large parts of a tree. The holes are just deep enough to reach the tree's sap-transporting vessels, and secretions may appear within seconds after the woodpecker has penetrated the bark. Once sap has begun to flow, the woodpecker licks up the sugary and protein-rich fluid. Other bird species, including other woodpeckers, as well as mammals such as squirrels (*Sciuridae*), mice (*Muridae*), dormice (*Gliridae*) and deer (*Cervidae*), and various insects, also take advantage of this food source. As an added bonus, the woodpeckers readily snap up ants that are attracted to these pits to collect a share of the nutritious fluid.

For the North American Yellow-bellied Sapsucker, tree sap constitutes an important part of the nutrition. This woodpecker taps numerous deciduous and coniferous species, very commonly poplar (*Populus*), willow (*Salix*), birch (*Betula*), maple (*Acer*), hickory (*Carya*) and alder (*Alnus*), as well as pines, spruces and firs (*Abies*). Sap is tapped at all parts of a tree, on the trunk as well as in the crown. Upon its return from the wintering grounds, the sapsucker uses old sap wells or other sources of sap on bruised parts of a tree. During late summer and autumn sap and phloem form the species' staple food, and many fresh wells are made. If insect food becomes scarce for any reason, the utilization of sap may start earlier in the summer. The Red-naped Sapsucker uses sap holes throughout the year, exploiting various conifers and deciduous trees and bushes on the breeding grounds. Williamson's Sapsucker, like the other species of its genus, drinks sap from various tree species, among them the lodgepole pine (*Pinus contorta*), the alpine hemlock (*Tsuga mertensiana*), both red and white firs (*Abies magnifica*, *A. concolor*), the Jeffrey pine (*Pinus jeffreyi*) and the quaking aspen (*Populus tremuloides*).

Sap-sucking is also important for various other melanerpine species, including the Acorn, Gila, Red-bellied, White-fronted (*Melanerpes cactorum*) and Hispaniolan Woodpeckers. Acorn Woodpeckers, in order to acquire a supply of sap, drill holes 3-19 mm deep and 5-15 mm wide into live oaks; for Californian populations of this species, sap is especially important in the months of June and July. For the White-fronted Woodpecker, it figures most prominently in the diet during the dry season in the austral winter, in semi-desert conditions, when sap-feeding accounts for between 16% and 83% of the species' foraging efforts.

Contrary to the earlier beliefs of many ornithologists, amateur and professional alike, sap-sucking is by no means restricted to the New World. At least four of the pied woodpeckers, at least in some parts of their respective ranges in the Old World, all rely on sap in spring. These are the Arabian, the Rufous-bellied, the Great Spotted and the Eurasian Three-toed Woodpeckers. The importance of the nutritious sap for these species, and the exact role that it may play in their survival in the period preceding the breeding season, have not, however, been properly quantified. Its contribution to the daily energy intake and as a protein source is probably substantial. Tree sap may even be, for short periods, the key resource for survival in harsh environments, such as boreal and mountain forests, and arid habitats.

Frugivory and pecking, especially when coupled with a largely sedentary lifestyle, lead naturally to the exploitation of another rich food source, namely seeds. Indeed, it is the species of woodpecker which frequently engage in those activities that also habitually exploit seeds and nuts. The significance of this food varies geographically. Generally, it is most important in more seasonal environments, and the degree to which it is exploited varies within a species' range. The Acorn Woodpecker's staple diet consists of dried acorns, but green acorns are taken as well. Acorns make up about half of the nutriment of northern populations, for which they are the basic energy source in winter; South American populations of the species, however, are less dependent on acorns, and rarely store them. Other seeds, such as those of pines, are also taken by this woodpecker, which, furthermore, occasionally feeds older broods of nestlings with acorns. Acorns contain tannins, a fact which generally renders them less profitable for birds. Compared with jays, however, Acorn Woodpeckers fare much better with a diet that consists of acorns alone, and they are able to cope with the physiological effects of tannins. Two of the species congeners, the Red-bellied

The most frugivorous group of all the Picidae is the New World genus *Melanerpes*. A typical example is the Red-crowned Woodpecker of northern South America. This female is feeding on the sweet fleshy fruits of a mango tree, but the species is equally fond of papayas, bananas and various other fruits and berries. Indeed, its liking for fruit is such that it often brings it into conflict with owners of commercial fruit plantations, and even gardeners may consider this bird a nuisance because of its fruit-eating habits. When feeding on fruit, the woodpecker sometimes pierces the skin and then pecks small pieces in situ. Alternatively, it will tear off a larger chunk of the growing fruit and fly with it to a nearby tree, where a crevice or crack in the bark may be used as an anvil to enable the bird to pick more manageable pieces at its leisure. As well as consuming fruit, many woodpeckers eat nuts and seeds, and some species probably play an important role in seed dispersal.

[*Melanerpes rubricapillus rubricapillus*, in llanos of Venezuela. Photo: Jean-Louis le Moigne/NHPA]

and Red-headed Woodpeckers, also regularly eat acorns and various other seeds and nuts.

The harvesting and consumption of acorns and other nuts is a practice that is restricted seasonally, and in the case of another *Melanerpes* species, Lewis's Woodpecker, it is associated with a corresponding habitat shift and migration-like movements. In Eurasia, the northern populations of the Great Spotted Woodpecker are the ones most dependent on the availability of pine or spruce seeds, or beech mast. This may also be correlated with some local movements and habitat shifts, and poor seed yields can lead to eruptive dismigration by this species (see Movements). Various studies have shown that Great Spotted Woodpeckers strip about ten pine cones of their seeds per day, and they consume a daily total of about 700-1450 seeds, weighing 11-14 g.

With the exception of the wrynecks and the piculets, most members of the Picidae are rather omnivorous, and many different types of food have been recorded in their diets. A number of species will occasionally snatch a lizard or a frog. This has been documented for the Eurasian Green Woodpecker, the Great Spotted and Pygmy Woodpeckers, the Greater Yellownape (*Picus flavinucha*), the Okinawa Woodpecker and the Afrotropical Bearded Woodpecker in the Old World, and for the Acorn, Jamaican, Red-bellied and West Indian Woodpeckers in America. In some cases, the parent may even feed these items to the young, and it is particularly noteworthy that tree-frogs of the species *Eleutherodactylus martinicensis* constitute about 10% of the prey items fed to nestlings by the Guadeloupe Woodpecker. In the Neotropics, the White Woodpecker has been observed feeding on raw meat hung up to dry, an example of the kind of opportunism that is rather widespread among the Picidae. Among the more unusual arthropod prey, scorpions (Scorpiones) are known to be taken now and then by Great Spotted and Fulvous-breasted Woodpeckers, centipedes (Chilopoda) are an occasional prey of Greater Yellownapes, and millipedes (Diplopoda) are sometimes eaten by Golden-tailed Woodpeckers. Molluscs also feature in the diets of the Picidae: for example, Great Spotted Woodpeckers have been observed to open mussels, and snails are taken by the Jamaican Woodpecker. An interesting observation concerns the collecting of small bones from raptor pellets by the Red-cockaded Woodpecker prior to egg-laying, presumably as a source of calcium. Bone fragments have also been found in the nestling food of Eurasian Three-toed Woodpeckers.

In most parts of the world in which they occur, woodpeckers are rather frequent visitors to gardens, where they will freely visit birdtables and other artificial feeders. Besides accepting a wide variety of natural foods, often placed out specially to attract these birds, they will also feed avidly on such highly nutritious items as suet. Indeed, in the more severe winter conditions in the northern parts of the world, the survival prospects of several picids can be enhanced by the provision of such food in gardens.

Woodpeckers utilize many distinct foraging techniques. The most typical are wood-excavating in its various forms, the flaking-off of bark, probing, and gleaning. With the exception of some melanerpine species, flycatching is only rarely used to obtain prey. Usually, there are clear seasonal differences in the frequency with which the various feeding techniques are employed. Costly subsurface techniques occur during the harsher conditions of the non-breeding season, when the range of foraging methods used is also at its least diverse, while gleaning and opportunistic foraging are typical of the breeding season. A further general trend is that the mobility of a woodpecker decreases with increasing body size, the result being that larger species tend to stay longer on a foraging site, and to move less frequently and more slowly.

There are many styles adopted by woodpeckers when excavating for food. In most cases, shallow pits are created, and the action consists of a combination of hammering and tearing away wood. The tiny piculets hammer small holes to gain access to the ants which burrow into thin twigs and stems. By contrast, the Black Woodpecker and other *Dryocopus* species excavate huge pits in their search for the nests of tree-living ants. Some of the distinctly chisel-billed species, such as the White-backed and Maroon Woodpeckers, prefer soft wood for their work, literally

gouging into the substrate. The Yellow-bellied Sapsucker drills shallow holes in many tree species in order to obtain sap and phloem; these holes may be arranged in vertical columns, as horizontal bands or, when on smaller branches, in spiralling bands. Among the more terrestrial picids, the well-studied Eurasian Green Woodpecker pecks funnel-shaped holes up to 12 cm deep in the ground, having first swept away moss, dead leaves, debris or snow with the bill, and it then procures its ant prey with the action of its very long tongue. Such holes, which are often exploited in lengthy and repeated visits, expose the tunnel systems of the ants, which appear en masse when disturbed by the woodpecker. When snow cover is heavy, it may dig tunnels almost 1 m long in order to reach its favoured food.

Foraging woodpeckers employ a variety of techniques to remove bark from trees. They may begin with a few tangential blows of the bill, which they then use as a lever to pry off a piece of bark. These bill blows leave characteristic horizontal marks arranged in regularly spaced rows on the exposed wood. Loose bark is simply torn off with the bill and disposed of with a swift flick of the bill. Some woodpeckers, including, among others, the Red-cockaded and Strickland's Woodpeckers of America, have been recorded as dislodging bark with their feet.

Access to concealed prey is very frequently achieved through the action of probing. The woodpecker inserts its bill into a crevice or hole in bark or exposed wood, or in epiphytes and vine tangles, or in the ground or in mud, as, for example, in mangrove stands; the same method is employed for probing in fruits and in flowers. Having inserted its bill in this way, the woodpecker then

The Celeus woodpeckers subsist mainly on ants and termites, but most are known to feed regularly on fruit, too. This behaviour is particularly marked among the South American members of the genus. They frequently roost in fruit trees, and will ignore invertebrates completely for short periods when a fruit crop is abundant. As the photograph of a male Chestnut Woodpecker shows, the bird has no difficulty in clinging to a slender twig in order to get at the fruit, and it will remove all of the flesh down to the stone. A woodpecker will return to the same individual fruit, or to the same tree, for several days to take advantage of such easily obtainable food. Although frugivory is most common among the *Melanerpes* and *Celeus* species living in the Neotropics, it is also practised by many other members of the family. These range in size from the small Antillean Piculet (*Nesocittes micromegas*) to two of the largest of all woodpeckers, the Pileated and White-bellied Woodpeckers (*Dryocopus pileatus* and *D. javensis*).

The Yellow-fronted Woodpecker is one of the *Melanerpes* genus that is almost entirely dependent on plant material for food. It stores seeds for use in leaner times, a habit more usually associated with omnivorous woodpeckers living in seasonal climates. Some woodpeckers disperse the seeds of tropical plants, although their usefulness in this respect is variable. This species' relative, the Black-cheeked Woodpecker (*Melanerpes pucherani*), for example, swallows the seeds of the flacourtiaceous tree *Caesaria corymbosa* and voids them later, thus aiding their dispersal; in the case of the burseraceous *Protium*, however, it simply drops the seeds beneath the tree, thus acting as a seed thief from the plant's perspective.

[*Melanerpes flavifrons*, Iguazú National Park, Misiones, Argentina. Photo: Julián Alonso]

flicks out its sticky tongue so as to glue small insects, especially ants, and to spear grubs and other prey hidden deep in the substrate by means of the tongue's barbed tip. The use of the sticky and barbed tongue, which increases the range of action of the bill far beyond the mandible tips, is highly characteristic of the gleaning and probing behaviour of foraging woodpeckers. An additional point of interest is that, should a woodpecker accidentally drop an item of food, it may very occasionally open a wing slightly to prevent the food from falling to the ground; although there are few observations of this behaviour, it has been recorded for about half a dozen picid species.

Gleaning is the most common surface manoeuvre carried out by all members of the family. It is a relatively simple action in which the woodpecker, while clinging to or sitting on the substrate or perch, grabs a nearby food item. The picid anatomy allows these birds to reach a long distance with little effort. This is a great aid to frugivorous species, some of which, such as the melanerpines, are particularly skilled in reaching beneath a perch. There are, however, specific differences in just how far a woodpecker will reach sideways when on a trunk. It seems that, generally, those species which undertake a lot of woodwork are poor reachers. The Chestnut Woodpecker, for example, is very good at reaching, but does not excavate very frequently. Many members of the Picidae, particularly the smaller ones, hang upside-down to get at certain food items. During the process of foraging in this manner, a woodpecker may run along the underside of a branch, as do Middle Spotted and Arabian Woodpeckers, among others, or it may cling crosswise in a more tit-like fashion, as demonstrated by the Great Spotted, Lesser Spotted and Buff-rumped Woodpeckers.

When a tree harbours many caterpillars, this abundant source of food is eagerly exploited by some picids. In Europe, this situation coincides more or less with the period when Great Spotted Woodpeckers have just completed their breeding cycle, and from June to August both adults and juveniles of this species often take advantage of the glut of caterpillars. Moving around rather clumsily among the foliage of such trees, they hop about, and hang upside-down with wings flapping, while gleaning prey.

Woodpeckers are generally good fliers, and most are capable of covering large distances between feeding sites. In normal

circumstances, they exhibit an efficient bounding flight (see General Habits). A different mode of flight is needed, however, for aerial flycatching. This is a foraging tactic practised by several of the picids, being most pronounced among the melanerpines. Acorn Woodpeckers are expert fly-catchers, and are most active in utilizing this foraging strategy in the late hours towards dusk. They sally from a snag or fence post and catch a single insect on each flight. In spring this foraging mode is most important, often involving the whole social unit, and aerial prey is also a significant part of the diet of the nestlings. In South America, the White Woodpecker occasionally catches insects on the wing. Probably the woodpecker most specialized in flycatching, however, is another *Melanerpes* species, Lewis's Woodpecker. Both its foraging activities and its migratory behaviour (see Movements) are reflected in its overall style of flight, typified by longer phases of flapping flight and by relatively low air speed. Individuals of this species frequently sit on prominent perches, from where they spend much time in scanning the surroundings for potential prey. From these perches they sally into the air, approaching insects in a crow-like flight, with elaborate manoeuvres leading to the final capture; having successfully caught the prey, they frequently use gliding flight to return to the perch. Lewis's Woodpeckers do not take aerial prey only in single excursions; over 10% of their flycatching involves continuous flights lasting several minutes, and in which several insects may be seized. The Yellow-bellied Sapsucker, too, frequently takes prey on the wing. It sallies occasionally from an exposed perch, returning to the same post or to a different one.

Yet another skill possessed by woodpeckers, and again associated with pecking and the ability to work on hard wood, is the use of what are termed "anvils". Practically all woodpeckers which take prey that they cannot mandibulate sufficiently for ingestion carry such items to a fork, crevice or similar place in which the unwieldy item can be fixed. With the help of such an anvil, they can smash hard-cased beetles, open galls, remove the stones of fruits or prepare them for consumption, and so forth.

The use of anvils is not unique among birds, since, for instance, thrushes (*Turdidae*) and probably also kingfishers (*Alcedinidae*) smash snails on stones, but it is certainly most highly developed among the woodpeckers. Picids which rely almost to-

Fallen fruit is an easily accessible source of food for many birds and other animals. Although not a terrestrial woodpecker in the true sense, the Green-barred Woodpecker spends at least some time foraging on the ground. This is especially the case with the races inhabiting the Chaco woodland, pampas and scrub and in the southern parts of the range, which are partly terrestrial. Ants constitute by far the greater part of the diet of this Neotropical species, but it is opportunistic and will feed on berries and fruits. This male, having come across some fallen citrus fruit in the Argentine pampas, proceeds to attack it with vigour. The northern subspecies of the Green-barred Woodpecker are more arboreal in their habits, but they, too, will take advantage of fruit, whether still on trees or on the ground.

[*Colaptes melanochloros leucofrenatus*, Salado's Depression, Buenos Aires, Argentina. Photos: Yves Bilal]

A great many woodpeckers include nuts in their diet, one of them being the Great Spotted Woodpecker. Insects and larvae are its dominant food items in summer, while in autumn the birds switch to plant material, such as walnuts and hazelnuts.

This species, the most numerous picid in much of its Eurasian range, is an opportunistic omnivore. It has also been recorded as taking nectar, sap, scorpions, frogs and even mussels, as well as nestlings of hole-dwelling birds. Experiments show that woodpeckers readily learn to find food. Great Spotted Woodpeckers quickly removed cork stoppers from holes in a log to obtain mealworms that had been placed inside.

Right: *Dendrocopos major pinetorum*, The Netherlands. Photo: Jan van de Kam/ Bruce Coleman]

tally on anvils for obtaining pine and spruce seeds are the most specialized, and the best-studied species in this regard is therefore the Great Spotted Woodpecker. The most primitive types of anvil, those described above, are used by most species. In many cases, a particular anvil is utilized only once, although some woodpeckers may use one site repeatedly. A more advanced form of this behaviour is represented by the use of a number of anvils of varying sizes, with selection being made according to the object that has to be manipulated at any given time. In the most highly developed form of anvil use, the anvil is created by the woodpecker itself for that specific purpose. Great Spotted Woodpeckers concentrate their activity at one anvil which can accommodate cones of different sizes; they utilize ancillary anvils much less frequently, and mainly to open cones of a specific shape. In order to use the same anvil repeatedly, the woodpecker has to empty it before reuse. To do this, the Great Spotted Woodpecker has devised a neat method: it places the new object between its breast and the substrate, it then removes the old one, a pine cone for instance, and finally, with a few blows of the bill, it fixes the new object in the anvil for processing. Hundreds of stripped cones may lie under a heavily used anvil. This behaviour, involving the clearing-out of a site for reuse, occurs apparently only among very advanced species. So far, the Great Spotted Woodpecker is the only one which seems to carry out these actions as a regular part of anvil use; such behaviour has not been observed for related species.

During anvil use, the woodpecker wedges food or some other object into a crack in the bark, mandibulates it, leaves, visits the site again later, and sometimes then transports the item to another place. The moving of objects among different anvils is a rather common component of anvil use.

Anvils allow woodpeckers to take advantage of highly nutritional food sources that would otherwise be inaccessible to them. In its most highly evolved form, the use of anvils has all the characteristics of genuine tool-using. In this context, another kind of tool use has been observed in which a Gila Woodpecker dipped pieces of bark or seeds into a honey syrup provided at a feeder, and then fed the nutritious liquid to its fledglings.

Especially if anvils are primitive, as is the case with cracks and other suitable sites that are used opportunistically, it can often be difficult to draw a line between caching and anvil use if fragments of food are left behind. The storing of food is sometimes, therefore, not clearly separable from the use of anvils. When an anvil has not been cleaned out for reuse, the intended food, or some of it, then remains in its position, and the new item has to be placed into another crevice. Syrian Woodpeckers, for example, may fill long cracks with the opened stones of plums or with apricots. Thus, it may sometimes not be clear whether a species really caches food.

Notwithstanding these possible problems in defining caching behaviour, there are many perfectly obvious cases of food-storing among the melanerpine woodpeckers. Two types of food-storing can be recognized, known respectively as scatter-hoarding and larder-hoarding. The Red-bellied Woodpecker provides an example of the former. These woodpeckers begin to collect and store acorns, hickory nuts, hazel (*Corylus*) nuts, corn, pine seeds and various other seeds in autumn, and continue to do so into early winter; they store single food items usually in crevices, and occasionally also cache insects and fruit. Every item is placed in a different location, a food-storing strategy that is reminiscent of the caching behaviour of crows (*Corvidae*) and tits.

The larder-hoarding species, on the other hand, focus their storing activity on just a few sites. Red-headed Woodpeckers place larger insects in crevices or cavities as interim stores. They store many acorns, beech mast and other nuts and corn in single cracks and bark crevices during years with good mast crops, and they defend their one or few larder trees against all intruders, both of their own and of other species. Harvesting of the crop occupies most of the woodpeckers' active time in the early autumn. Items are stored in any kind of natural or man-made crevice, and holes are not excavated by the woodpecker itself; if a nut does not fit into the intended storage site, the nut is broken into pieces rather than the crevice being prepared to fit the food. Some stores are sealed with wood chips. Lewis's Woodpeckers also shell the acorns and nuts which they harvest in autumn, using several anvils for

When snow covers their foraging areas and insects are scarce, woodpeckers living in the higher latitudes of the Northern Hemisphere are often forced to change their dietary habits.

Many become more dependent on cached food, or turn to the most readily available plant matter. In most cases, this means pine (*Pinus*) or spruce (*Picea*) seeds, which offer a highly nutritious source of food.

This male White-backed Woodpecker demonstrates the manner in which this species uses its bill as a pair of tweezers, reaching between the scales of the cone to remove the seeds.

Plant matter, including seeds, nuts and fruits, makes up only a small proportion of the diet of this woodpecker. Even in the harsh conditions of a Siberian winter, when temperatures remain below zero throughout the day for several months on end, it is more likely to obtain its food by hammering deeply into the lower trunks of small trees in search of the large wood-boring larvae of cerambycid beetles.

Almost all woodpeckers which take large or hard items of food also make use of what are termed "anvils". These are crevices or forks in trees, or similar sites, which are readily utilized for securing nuts, fruits and large hard-cased insects, and preparing them for consumption. Most such anvils are used only once, and in some cases the woodpecker itself creates the anvil. Anvils are particularly important for certain picids which eat conifer seeds, and one species in particular, the Great Spotted Woodpecker (*Dendrocopos major*), has developed the behaviour further. This woodpecker repeatedly uses the same anvil, which is designed so that it can accommodate cones of different sizes. Before each use, the woodpecker has to clear out the anvil, and for this it has devised an interesting method which reveals just how advanced this species is: while holding the new cone firmly in place between its breast and the substrate, it removes and discards the old one and then, with a few bill blows, fixes the new cone in position. A single Great Spotted Woodpecker is capable of stripping up to 50 cones per day, the number depending on the species of conifer. As a result, thousands of broken cones can be found beneath a heavily used main anvil. In addition, a small number of secondary anvils may be used infrequently, primarily to process cones of a specific shape. It has been estimated that, in winter, an individual Great Spotted Woodpecker can, on a daily basis, consume up to 1700 pine seeds, or 8000 larch (*Larix*) seeds, or as many as 10,000 spruce (*Picea*) seeds.

[Anvil and pine cones, northern Finland.  
Photo: David Tipling/  
Windrush]

Some woodpeckers are so dependent on a particular food source that they cache food to ensure a sufficient supply to see them through the winter.

One of the most remarkable phenomena is the storing behaviour of the fittingly named Acorn Woodpecker. In North America, where acorns make up half or more of this species' diet, and are the staple food in the non-breeding season, the woodpeckers set up special "larders", or "granaries". Small groups of this social picid drill numerous funnel-shaped holes in a tree trunk, into each of which they push an acorn collected from nearby. These granaries can contain up to 50,000 holes, excavated over many years, and are defended by all group-members.

[*Melanerpes formicivorus*, central California, USA. Photo: Dave Maslowski]

this processing work, and they store the food in natural crevices. They may widen natural cracks for this purpose, but they do not drill individual holes for each acorn. These woodpeckers tend their stores by moving the acorns around, which inhibits fungal growth. If superabundant, insects, such as swarming carpenter ants (*Camponotus*), are also stored in cracks near the nest, from where they are later retrieved and fed to the young. Although Lewis's Woodpeckers do not defend any feeding territories, they do defend individual food caches vigorously. Competition over the mast accumulated in the stores is most intense with the Acorn Woodpecker. Only when a crop is in ample supply, as for example in almond plantations or, rather exceptionally, near corn silos, will they sometimes do without stored mast.

There is no doubt that the thousands of funnel-shaped holes produced by Acorn Woodpeckers are there for the purpose of storing acorns, and indeed this woodpecker is certainly the best-known storing species among the Picidae. Prior to storage, the acorns are collected in the trees or on the ground. Acorn Woodpecker stores are seldom very far away from oak trees. These larder-hoarding woodpeckers store acorns whole or piecemeal in crevices in bark or wood, in anthropogenic structures or amid epiphytes, but most acorns are cached in specially made holes. These densely spaced holes, with nearest-neighbour distances of about 28 mm, cover large areas of the outer surface of such trees as oaks, pines and others. Stores of this kind, which are also referred to as larders or granaries, may contain up to 40,000-50,000 holes, and it takes years for the woodpeckers to excavate all of these. The larders are tended constantly and are carefully looked after. The food-storing behaviour of this group-living species varies geographically, however, and not all Acorn Woodpecker groups possess granaries. Storing appears to be least common in the southern parts of the species' range.

Many species of woodpecker regularly prey on the nests of other birds. The picids for which this behaviour is well documented include the Greater Yellowthroat, the Grey-faced Woodpecker, the flickers, the *Melanerpes* species, and the *Picoides* and *Dendrocopos* pied woodpeckers. The Great Spotted Woodpecker is particularly notorious for its habit of taking the eggs and nestlings not only of hole-nesters, but also of Eurasian Penduline Tits (*Remiz pendulinus*) and of species which rear their young in open nests. Even Acorn Woodpeckers will occasion-

ally steal eggs, while its close relative the Red-headed Woodpecker, one of the most omnivorous of all the Picidae, obtains the young of hole-nesting birds by widening the hole entrance. This latter species has a really wide range of prey that includes, in addition to the eggs and nestlings of both hole-nesting and open-nesting birds, a wide variety of insects such as grasshoppers, crickets, beetles and their larvae, moths, butterflies and caterpillars, and wasps, as well as earthworms, lizards and mice.

An interesting and unusual observation of predatory behaviour concerned a Cuban Green Woodpecker which was watched as it visited a heronry. The dense colony held many Snowy Egrets (*Egretta thula*) and Cattle Egrets (*Bubulcus ibis*), with scattered pairs of Tricolored Herons (*Egretta tricolor*). Although it seemed initially that the woodpecker might have been seeking insects, its main food, among the small mangrove bushes, it was eventually confirmed that it was, in fact, puncturing the egrets' eggs to reach the contents inside.

There are many overt and subtle differences in the way in which woodpeckers move while foraging. The style of locomotion may be an important means of niche separation among species, and even between the sexes (see Habitat). Generally, the most economic method would be for a woodpecker to hop upwards and to fly downwards, but many deviations from this general pattern exist. Gleaning species are agile, often moving sideways and back again on large trunks, and frequently moving downwards, while smaller species, such as the Middle Spotted and Arabian Woodpeckers, move deftly along the undersides of limbs. Clinging to terminal twigs demands a strong grip, and is therefore a feature mainly of small picids or rather powerful ones.

Similarly, there are many different ways in which a single patch of foraging habitat is used. For example, a woodpecker may spend a long time at one spot to excavate, or it may hardly stop at all while gleaning, or it may pause just briefly to work on a single site. There appear also to be differences in the likelihood that a woodpecker will return to the same site. For gleaners, renewal times of the prey are short, so that reuse of the same site poses little problem. For species that feed on solitary burrow-dwelling creatures, however, it usually pays them not to return once they have exploited the site. This foraging strategy, known as trap-lining, requires a knowledge of all or most of the sites where prey are likely to be found, as well as a good memory

of when such sites have been visited. Downy Woodpeckers can be categorized as trap-liners; they have been found to return to the same spot in only two out of more than 1200 cases. The regular rounds of their home ranges made by the Ground Woodpeckers in South Africa no doubt serve a similar purpose.

Many of the Picidae forage solitarily, and this is to be expected in the case of those which seek prey that are unpredictable in occurrence. In the tropics, however, many of the gleaners not uncommonly forage in mixed flocks with other bird species, including, at times, other woodpeckers (see General Habits).

Like most other bird species, woodpeckers drink by inserting the bill into water and then raising the head and bill to allow the liquid to flow down into the gullet. Small puddles in tree forks and similar hollows constitute important arboreal sources of water, as also do many bromeliads in which water collects. In addition, woodpeckers frequently leave the trees and descend to the ground in order to drink from rainwater puddles and other freshwater sources, whether temporary or more permanent.

## Breeding

Woodpeckers breed in holes carved into wood or, in the case of a few species, dug into the ground. The nest-chamber is not lined with any additional soft material other than the few wood chips and "sawdust" that may remain at the bottom of the mainly pear-shaped hole, and the eggs are white. Monogamy is the predominant breeding system among the Picidae. It is associated with a relatively high contribution by the males to nest-hole construction, nest-guarding and brood care. As a rule, the male remains in the hole with the eggs or young during the night. During the daytime, both parents are needed to incubate the eggs and raise the young. The fact that the male undertakes most of the excavating work, and also takes a large share of the parental duties, is the key for understanding the breeding and social systems of the members of this family.

Although little information is available on the territoriality of tropical species, the territorial behaviour of woodpeckers living in the temperate zones is well documented. Woodpeckers in general are territorial birds. Furthermore, they defend their territories not only during the breeding season, but throughout the rest of the year. In particular, those Northern Hemisphere species which store food (see General Habits, Food and Feeding) maintain and defend winter territories. The territories occupied and defended during the non-breeding season often differ from those maintained during the breeding period, the former frequently being associated with special resources. Red-headed Woodpeckers, for example, leave their breeding territories in autumn and migrate to areas that offer a good supply of beech mast or of oak trees (see Movements). Such shifts of habitat, with the associated territorial shifts, can occur on almost any spatial scale.

Woodpeckers advertise their presence with drumming and vocal signals. Conflicts take place close to prospective nest-sites, at roosts, or at localized resources such as food stores. Aggressive encounters are frequent at the beginning of the breeding season, and reach a peak around the time of egg-laying. These aggressive clashes involve several types of vocalization, together with wing-flicking and swinging movements of the head and body. In close combat, the bill and the feet are the main weapons, and in such circumstances the opponents may both fall to the ground in the heat of the action. Fights can involve only two individuals, more often than not of the same gender, or two pairs.

The displays of woodpeckers consist of variations of a common repertoire of movements. The courtship displays and aggressive displays of the picids have much in common, and it is not always easy to distinguish between the two types of behaviour. The basic pattern of behaviour in close encounters is exhibited by both the wrynecks and the piculets, as well as by the true woodpeckers in the subfamily Picinae. In such situations, the feathers of the crown and nape are erected, the head is extended, and the bill is directed forwards at the opponent; invariably, the display includes the spreading of the tail. At higher intensity, the displaying woodpecker often droops its wings and engages in variable kinds of swinging movements of the head and body.

*For the Gila Woodpecker of North America's southern deserts, life revolves around cacti. As well as providing nesting holes, these plants are a source of invertebrates, fruit and nectar. The sipping of nectar is by no means uncommon among the melanerpine and Celeus woodpeckers, and nectar is taken at least occasionally by a number of other picids. The Gila Woodpecker is, however, the only member of the family to have been observed using a tool to obtain food. One was watched dipping pieces of bark and seeds into honey syrup at a garden feeder, and then provisioning its fledglings with the nutritious liquid.*

[*Melanerpes uropygialis uropygialis*, Arizona Desert, USA. Photo: John Cancalosi/BBC]

Some species do no more than swing the head laterally, with the bill held more or less upright. Most, however, perform rhythmic movements of both the head and the body. In the majority of species these involve lateral swaying, with the bill pointing directly forwards or slightly upwards and describing circles or figures-of-eight, but the display movements of the melanerpine woodpeckers are more in the vertical plane. In the case of the latter group, characteristic bowing movements are performed, and these are typically accompanied by loud calls. In contrast, the accompanying vocalizations of other picid species, which swing horizontally from side to side, are not necessarily very far-carrying.

These types of behaviour are exhibited when partners meet and also during aggressive encounters with competitors. In addition, all woodpeckers flick their wings in defence, and some of the species spread the wings widely and hold them extended in courtship, too. Wing-flicking frequently precedes an assault, which often involves an antagonist stabbing at its opponent, and finally making a supplanting attack. Observations of aggressive encounters involving a single intruder, as well as of fights between neighbouring pairs, have often revealed that opponents are attacked sex for sex, and the same results have been obtained in experiments in which dummies have been used as "rivals". Aggression is reduced during the period of brood care, which has the effect of enabling locally high breeding densities to be achieved without too much needless agitation.

Aerial displays by woodpeckers are apparently signals for the mate only. The flutter-aerial-display typically comprises a gliding flight in which the wings are held well above the back, particularly upon landing. During the course of this flight, series of drawn-out, somewhat squeaky calls are uttered. The "circle-flight" of Lewis's Woodpecker is more elaborate. The male of that species circles its nest tree in a smooth glide, with the wings extended and held at a high angle; the flight ends at the nest entrance, where the "churr" call is given. Woodpecker males possibly use aerial displays to show a prospective nest-site to the female.

Mate-feeding forms part of the courtship ritual of wrynecks, and the male sometimes continues to feed his partner even during the incubation period. Otherwise, courtship

Nectar represents an excellent source of sugar-rich protein, and is taken from a wide variety of plant species, as illustrated by the male Gila Woodpecker in this photograph and the preceding one. The agility and suppleness of the woodpecker are well demonstrated here: while clinging crosswise on a thin branch, the bird twists its head and neck through 270 degrees to reach into the hanging bell of the flower. Besides feeding on insects and their larvae, Gila Woodpeckers take both nectar and rising sap in summer, and then forage for seeds and galls in autumn and winter. An observer in Arizona noted small groups of these picids tearing the galls of *Pachypsylla venusta* from the leaves of a tree, before wedging each in a crack in a fence post and chiselling out the contents. Hundreds of gall cases were subsequently found littering the ground beneath the fence post.

feeding is known to be practised by only few of the Picidae species. It has been observed for two of the *Dinopium* flamebacks, the Olive-backed Woodpecker and the Black-rumped Flameback, and for two *Melanerpes* species, the Guadeloupe and Hispaniolan Woodpeckers.

Among many picid species, the pair-bond, or, at least, loose contact by vocal communication and before roosting, appears to be maintained through the non-breeding season. Nevertheless, it

is not unusual for pair-members to split up for the entire period between breeding seasons, particularly when each individual defends a localized resource such as a food store (see Food and Feeding). Many individuals may maintain a cohesive relationship, but often this is not very obvious to the observer, and there is certainly a great deal of variation both within and among species.

Breeding partners not infrequently remain together over several breeding seasons, and the divorce rate is rather low. Instances of an individual mating with a different partner do occur, however, even if the previous partner is still within the same area. The high male investment in the breeding process means that polygamous matings are predisposed more towards polyandry than towards polygyny, and it may lead to a reversal in the courtship roles of the sexes. Egg production is no constraint, since woodpeckers are indeterminate egg-layers; this means that the number of eggs that a female lays is controlled by clutch size, rather than by the number which she has already produced in a given season. In a well-documented case of polyandry by the Great Spotted Woodpecker in Japan, the female laid her eggs in two different nests from which two and three nestlings eventually fledged. Her contribution to the feeding of the nestlings was about 6% and 38% of the total feeding effort at each respective nest. In Japan, males of the Great Spotted Woodpecker that breed with polyandrous females occupy territories that are intermediate in quality between those of unmated males and those of monogamous males; they also produce fewer offspring than do the latter. The success of polyandrous females is only marginally higher than that of monogamous ones. On the other hand, a study of Lesser Spotted Woodpeckers in Sweden showed that the number of young successfully reared to fledging by polyandrous females was about 40% greater than that achieved by those in monogamous pairings. Almost 10% of the females of this smaller species are polyandrously mated, and about 3% of the males exhibit multi-nest polygyny. Females of such polygynous males are, however, likely to fail in their efforts to raise a brood successfully.

One important constraint on the evolution of more diverse mating patterns among the Picidae is the male's role of nocturnal incubation and brooding. A single woodpecker would face great difficulties if attempting to raise a brood from hatching to fledging entirely on its own. Only when the nestlings no longer require brooding can one partner rear them to the flying stage,

Although several woodpecker species catch insects on the wing, the technique is probably more highly developed in the Lewis's Woodpecker of western North America than in any other member of the family. From a prominent perch, the woodpecker scans the surroundings, often for lengthy periods, looking for large insects. On sighting a suitable prey, it approaches at low speed, using a flapping flight resembling that of a crow (*Corvidae*); closing in on the insect, it employs elaborate twisting manoeuvres to catch the prey, before gliding back to a perch. More remarkably, this species frequently performs continuous hunting flights lasting for some minutes, during which several insects are often seized.

[*Melanerpes lewis*, Siskiyou County, California, USA. Photo: William Grenfell]

Nestling woodpeckers are generally fed on soft-bodied insects, mostly the adults and larvae of ants, bees, wasps, beetles, *Lepidoptera* and flies. As the chicks grow, they cope with larger prey, such as the adult moth which this male Golden-fronted Woodpecker has brought to its nest-hole in Central America. Perhaps surprisingly, some picids, including pied woodpeckers of the genera *Dendrocopos* and *Picoides*, and sapsuckers (*Sphyrapicus*), will also feed acorns and fruits to older broods. Fragments of bone have been found in the nestling food of Eurasian Three-toed Woodpeckers (*Picoides tridactylus*), perhaps supplied as a source of calcium for growing chicks.

[*Melanerpes aurifrons*, Guatemala. Photo: Stephan Bonneau/Bios]

The most terrestrial of the Palearctic Region's true woodpeckers, the Eurasian Green Woodpecker relies on grassland ants throughout the year. *Formica* species are favoured in winter, and those of the genus *Lasius* in spring and summer. Using the bill to sweep moss, dead leaves or snow from the surface, the bird pecks funnel-shaped holes up to 12 cm deep; these holes, which are exploited repeatedly, expose the tunnel systems of the ants, which appear en masse when disturbed by the woodpecker. The bird pictured has found an exposed ant nest at the base of a tree, and snow does not prevent it from feeding. This species will dig tunnels up to a metre long through snow in order to reach ants.

although, even then, without being able to compensate fully for the loss of its mate. There may, however, be extremely rare exceptions to this general rule. A highly unusual observation was made in 1999, when a solitary pair of Red-cockaded Woodpeckers, without helpers, was found to have two simultaneous nests in two separate cavity trees within a cluster (see General Habits). The male incubated and brooded and fed the young at one nest, while the female carried out all these duties at the other; a single young fledged from each nest. It is probably significant that the recorded incubation and nestling periods at both nests were several days longer than is usual for this species, in addition to which the two parents combined to feed both nestlings in the days just before the young left their respective cavities.

Genetic analyses also indicate that woodpeckers are generally monogamous. A comprehensive study of very dense populations of the Great Spotted and the Middle Spotted Woodpeckers in Europe could not find any evidence for extra-pair fertilizations. Even among the socially breeding species, the same underlying pattern of monogamy or polyandry is evident.

Ecological constraints are the most likely explanation for the evolution of co-operative breeding by woodpeckers. Together with other benefits for juveniles of staying with the enlarged family, ecological factors contribute to the maintenance of this breeding system. The two best-studied picids in this respect are the Acorn Woodpecker and the threatened Red-cockaded Woodpecker. When individuals would encounter great difficulties in attempting to find a good breeding site, either because vacancies are rare or are hard to find, or because certain risks, such as predation, are high, it may pay those individuals to stay with the family with which they were raised. The fact that the young of some tropical species, such as those of the Great Slaty Woodpecker in Asia, remain with the parents until a new breeding cycle commences is a further indication of possible constraints on dispersal and on the production of holes.

The social system of the Acorn Woodpecker has been extensively studied in recent years. It is characterized by the occur-

rence of a co-operative polygynandry and by the presence of non-breeding helpers recruited from the group's offspring. The system is very variable and is one of the most complex ones to be found in the avian world. Single pairs occur, as well as groups of 15 adults which contain up to ten non-breeding helpers. In all instances, there is only a single active nest at a time in the breeding territory. The whole group takes part in the job of nestling care, and all members defend the territory and the acorn stores. Because conspecific intruders are predominantly females, the breeding females are involved in territorial defence significantly more than are the males. The group-members roost either individually in adjacent holes or as small bands of several birds in one hole, engaging in brief mutual mounting prior to roosting. Within groups, dominance hierarchies are established which probably regulate access to mates and which, at least among immatures, are not sex-related. Temporary breeding pairs, without helpers, are formed by birds that disperse individually in autumn.

Groups of this species usually comprise up to four reproductively active males, which are related to each other, and one breeding female. In about 20% of groups, a second breeding female, usually a sister of the first, is present. The group's offspring of previous years are attached as helpers to those which are actively breeding. Broodmates remain at the breeding territory for up to several years.

Whether or not an individual Acorn Woodpecker stays with its family as a helper is influenced by the variation in quality of the territories available. Those woodpeckers which have hatched in high-quality territories tend to remain with the group rather than to disperse, although the data accumulated so far suggest that the lifetime fitness of these individuals is lower. Studies indicate that females disperse earlier, and two to three times farther, than do males, and that they also make greater attempts to enter another breeding group. Similarly, the chances of finding a new breeding opportunity vary between the sexes, and are better for females than for males. Reproductive vacancies caused by the death of breeders in other groups are often filled by sibling

units, comprising up to two sisters and four brothers, which have dispersed together from the natal group. Many broodmates stay together for their entire lives, and share mates.

Costs can be incurred by staying with the natal group. In such situations, Acorn Woodpeckers, rather than engaging in incestuous relationships, forgo the chance of breeding for some years, thereby reducing the overall reproductive potential of the population by about 10%. Thus, relatedness to other group-members largely determines whether an Acorn Woodpecker breeds within its group. If individuals of opposite sexes are closely related, such as brother and sister, or parent and offspring, they are very unlikely to breed with each other. Incest avoidance is a powerful principle that provides a fundamental explanation of the relationships in this complex breeding system. Helpers, when with a parent or uncle/aunt of the opposite sex which hold breeding status, never breed incestuously with these relatives. On the other hand, if the female is replaced by a new, unrelated one, male helpers may achieve fertilizations. When a vacancy for one or more breeding males arises, some male helpers may on rare occasions produce offspring with their mother.

In the minority of instances in which two breeding females are present in a group, these lay their eggs together in one nest. In such cases, however, competition between the females is intense and the individuals involved partly destroy each other's eggs. They share parentage of the group's offspring equally. Paternity is much more skewed. All male helpers, so long as they are not closely related to the female, may fertilize eggs. One particular male is, however, responsible for most of the offspring, and that male is in this respect almost three times as successful as its closest competitor. All other males are able only rarely to contribute genetically to the brood. Unlike other co-operatively breeding species, the reproductively active individuals in Acorn Woodpecker groups engage in matings only with members of their own group.

Young males of the Red-cockaded Woodpecker either disperse to other areas up to 22 km away to search for a breeding

opportunity, or delay their attempts at reproduction and wait for a breeding vacancy in their own group. In the case of the second strategy, they remain within the natal territory and become helpers to their parents in the next breeding cycle. These two strategies are roughly equivalent in terms of relative fitness. Most Red-cockaded Woodpecker helpers are males, which outnumber female helpers by a factor ranging variously from 10:1 to 27:1. The oldest of these males inherits the territory if the breeding male disappears, while others may become breeders in an adjacent territory. The males which disperse often remain unmated territory-holders, or establish themselves as helpers in a non-natal group, or become floaters. Females stay with the natal group in only very few cases, and they disperse farther than do males, moving up to 32 km. The risk of incest seems to be low for the Red-cockaded Woodpecker. Helpers do not fertilize the eggs that produce the brood which they help to raise. Otherwise, the rare extra-pair fertilizations that occur stem from males which do not belong to the group.

For these two co-operatively breeding, group-living woodpeckers, the benefits gained by an individual through staying with the group include the availability of suitable breeding sites, specialized food sources, such as fruiting trees, mast and anthills, and large food stores. These resources can often be difficult to find; or they may, prior to exploitation, require great investment on the part of the woodpecker, involving the establishment of a food store, hole-construction, and learning the whereabouts of feeding sites; or they are, in many cases, already occupied by other woodpeckers. In such circumstances, successful establishment by the individual after dispersal becomes exceedingly difficult. Although single woodpeckers can, of course, produce their own holes, this is by no means an activity without costs and without constraints. Appropriate nest-sites may be limited because suitable dead wood cannot be found, or hole-building may take a very long time if the wood is hard and the species' requirements are very specific. This is particularly the case for Red-cockaded Woodpeckers, which have great difficulty in

Given that ants form a major component of the diet of so many picids, it is surprising that relatively few woodpeckers regularly feed on termites. For species such as the Streak-throated Woodpecker of the Indian subcontinent and mainland South-east Asia, however, termites figure prominently in the diet. As this male demonstrates, this species attacks termite nests on the ground. Several other picids exploit the nests of terrestrial termites, the Campo Flicker (*Colaptes campestris*) of South America being a good example, whereas others open up the nests of arboreal termites and use them as roost-sites or nest-sites.

Photo: Otto Pfister]

A number of woodpecker species regularly prey on the nests of other birds, taking both the eggs and the nestlings of hole-nesters. The Great Spotted Woodpecker has, in fact, gained a somewhat notorious reputation for this kind of predatory behaviour. This male in south-east England preyed on nests of both Blue Tits and Great Tits (*Parus caeruleus* and *P. major*) and, as the photograph shows, fed the chicks to its own brood. Great Spotted Woodpeckers also depredate open nests, in addition to which they are, at least locally, key predators of Eurasian Penduline-tits (*Remiz pendulinus*). The suspended pouch-like nests of the latter are easily opened up by the powerful bill of this picid.

establishing new roost-sites and nest-sites. Analyses of extensive demographic data reveal that, for this species, the strategy of remaining with the group and acting as a helper is as successful as is that of dispersing and finding new breeding opportunities. The Red-cockaded Woodpecker, along with other co-operatively breeding picids, exhibits some morphological and behavioural features which have probably evolved as responses to group-living. Red-cockaded Woodpeckers are much more vocal than are any of their congeners, and the plumage badges which may elicit aggression (see Morphological Aspects) are tiny and can easily be concealed. Such features, and probably some others, reduce the costs of staying with the parents. For the Acorn Woodpecker, the localized resource provided by the granaries, which are the work of many individuals of this species carried out over many years (see Food and Feeding), may have been an important driving force in reducing post-natal dispersal and, consequently, promoting the strategy of group-living.

Comparative studies of the evolution of group-living and co-operative breeding among some members of the Picidae have not yet evaluated the possible role of fruits and other plant material in this process. These sources of food may foster the strategy of living in social groups by the fact that, rather than being scattered over wide areas, they occur in localized clusters. This means that joint effort is required on the part of the birds to locate fruiting trees on the one hand and, on the other, to provide sufficient food for a large number of birds. Indeed, the way in which chattering groups of White Woodpeckers reportedly drop into a fruiting tree is reminiscent more of the behaviour of parrots than of that of typical picids. The contrasting situation is presented with resources that are elusive and hard to procure, as is the case with the large larvae of wood-boring beetles; these circumstances certainly preclude any behaviour similar to that appropriate for the exploitation of localized fruiting trees.

The critical resource that drove the evolution of group-living among ground-dwelling woodpeckers seems to be that of suitable nest-sites. The Andean Flicker and, to a lesser extent, the Campo Flicker form loose colonies, with pairs concentrated in areas where there is an adequate supply of sites suitable for the excavation of burrows.

Co-operative breeding is probably an ancestral trait. The forming of loose colonies, as described for flickers, and the occurrence of occasional helpers among solitary and monogamous species is, therefore, not surprising. Co-operative breeding is widespread also among African barbets, and it is a strategy adopted by at least three species of the Neotropical barbet-toucan clade. In these instances, the basic mechanism is similar to the one found in the Picidae: the young of one brood help to raise those of the next brood, and males contribute a great deal, particularly to the task of incubation.

Rare instances of woodpecker pairs being helped by another, closely related species have been documented. In North America, for example, there are cases of Hairy Woodpeckers feeding Downy Woodpecker chicks and of American Three-toed Woodpeckers feeding nestlings of the Black-backed Woodpecker. In a recent observation in Oregon, a male Williamson's Sapsucker was watched as it fed the nestlings of a pair of Red-breasted Sapsuckers; interestingly, the male true parent provided fewer feeds than did the other two adults. It has been suggested that these instances of helping involve individuals that are responding to a strong feeding stimulus, a theory which is widely acknowledged as a probable explanation for the more frequent cases of passerine young being fed by non-conspecifics.

Irrespective of whether a woodpecker species breeds as single pairs or in co-operative groups, the typical picid nest is carved into dead wood, or into living branches and trunks which contain soft or rotten wood at the core. Trees, bushes and palms that provide corresponding resources are therefore essential for many picids, but these birds are able also to use a wide variety of other substrates in which to dig their nest-holes. For example, utility poles and fence posts are frequently used, the latter particularly by small species such as the Red-crowned, Heart-spotted, Ladder-backed, Smoky-brown (*Veniliornis fumigatus*) and Spot-breasted Woodpeckers. Root systems projecting from a riverbank may suf-

Although invertebrates comprise the bulk of the diet of most woodpeckers, many individuals are opportunistic, especially when close to human habitation. Such opportunism is, in fact, rather typical of the White Woodpecker of the Neotropics. This female is pecking chunks from raw meat that has been hung up to dry in south Brazil. The species also opens the nests of wasps and wild bees to take both the grubs and the honey, as well as indulging in aerial flycatching. It also forages quite frequently in fruit trees, including commercial plantations, a habit which can make it an unpopular bird among local growers.

Tree sap constitutes an important source of nutrition and energy for many woodpeckers, but the four sapsucker species are the most specialized in their systematic exploitation of this resource. Sapsuckers drill neat rows of holes on mature trees, these sometimes covering a wide area of the trunk. The bird takes an occasional sip from the holes, but spends more time alert to potential competitors, and vigorously defending its wells. Even within the limited North American Pacific coastal range of the Red-breasted Sapsucker, here seen visiting its sap wells on a mountain ash (*Sorbus*) tree, several other species will take advantage of open wells.
